Sandfly Any of various small biting two-winged flies of the families Psychodidae, Simuliidae, and Ceratopogonidae.
Transovarial transmission Vertical transmission of a virus from mother to offspring.
Zoonosis A disease of animals that can be transmitted to humans.

Introduction

The genus *Phlebovirus* is one of the five genera of the family *Bunyaviridae*, in which are included more than 300 virus species. The five genera (*Orthobunyavirus, Hantavirus, Nairovirus, Phlebovirus, Tospovirus*) are grouped in one family, primarily because they share structural characteristics,

all bear a tripartite RNA genome of negative polarity, and all have a roughly similar protein-coding pattern within each genome segment. It has been demonstrated that Uukuniemi virus, the prototype virus of a group of tick-borne viruses, and its relatives have the same ambisense coding strategy as do phleboviruses. In addition, a high degree of similarity occurs in proteins of Uukuniemi virus and in those of some phleboviruses. As a consequence, all viruses previously included in the genus *Uukuvirus* are now classified in the genus *Phlebovirus*. Therefore, in the genus *Phlebovirus*, viruses previously known as phlebotomus fever viruses and uukuviruses are now placed.

The first description of what was most likely phlebotomus fever occurred at the time of the Napoleonic wars, when a similar disease was reported as 'Mediterranean fever'. The disease was first described with considerable accuracy by Pick in 1886, who termed it 'dog fever' (*hundsfieber*), probably due to the marked signs and symptoms of conjunctivitis, which resembled the eyes of a bloodhound. At the same time in Italy, the disease was already known as pappataci fever, suggesting a possible link with sand flies. In Yugoslavia, epidemics of the disease occurred each summer among newly arrived Austrian troops stationed along the Adriatic coast.

Rift Valley fever virus (RVFV) was first isolated in 1930 during investigation of an epidemic with high mortality rates among sheep on a farm in the Rift Valley in East Africa. In retrospect, epizootics due to this virus had been identified as early as 1912. Epizootics were reported to have occurred in many sub-Saharan countries after 1940 and the vector-borne origin of the disease was definitively proved in 1948.

RVFV is one of the most important viral zoonoses in Africa. Transmission of the virus to humans occurs via arthropod vectors, aerosols of blood or amniotic fluid of infected livestock, or by direct contact with infected animals. RVFV in humans is manifested by a broad spectrum of infections, from asymptomatic infection to a benign febrile illness, to a severe illness (approximately 1–3% of cases) that can include retinitis, encephalitis, and hemorrhagic fever. In addition to the human illness, disability, and suffering, RVFV outbreaks can result in devastating economic losses when livestock in an agricultural society are affected.

RVFV was first confirmed outside Africa in September 2000. An outbreak occurred in southwestern coastal Saudi Arabia and neighboring coastal areas of Yemen. RVFV isolated from the floodwater mosquito *Aedes vexans arabiensis* during the outbreak was closely related to strains from Madagascar (1991) and Kenya (1997), suggesting that the virus was imported through infected mosquitoes or livestock from East Africa.

From blood samples taken during an epidemic occurring in Italy among Allied troops during World War II, Sabin isolated two serologically distinct agents, sandfly fever Sicilian virus and sandfly fever Naples virus. Since then, many distinct viruses have been isolated from sandflies or humans in both the Old World and the New World and, on the basis of serological relationships, classified in the phlebotomus fever group (**Table 1**).

In 1971, in Italy, Toscana virus (TOSV) was isolated from the sandfly, *Phlebotomus perniciosus*. The virus was shown to be antigenically related to sandfly fever Naples virus, and antibody to TOSV was shown to occur at a relatively high prevalence of antibodies in healthy humans. TOSV has since been shown to cause human disease and has been associated with acute neurologic disease.

Morphology, Structure, and Strategy of Replication

The prototype phlebovirus is RVFV. Similar to other bunyaviruses, the virion is spherical or pleiomorphic, depending on the method used for fixation, with a diameter of 90–100 nm. The virion consists of a core containing the genome and its associated proteins, which are in turn surrounded by an envelope composed of a lipid bilayer containing equivalent numbers of two glycoproteins.

The genome consists of three single-stranded RNA segments: large (L, 6.5–8.5 kbp), medium (M, 3.2–4.3 kbp), and small (S, 1.7–1.9 kbp). Sequence studies demonstrate that the three segments are identical on the 3′-end (UGUGUUUC) and a complementary 5′-end. The S RNA produces many copies of the nucleocapsid protein (20–30 kDa) and the L RNA produces a few copies of the large (L) protein (150–250 kDa), which is a transcriptase.

Table 1 Viruses of the genus *Phlebovirus*

Virus species	*Viruses*
Bujaru virus	Bujaru, Munguba
Candiru virus	Candiru, Alenquer, Itaituba, Nique, Oriximina, Turuna
Chilibre virus	Chilibre, Cacao
Frijoles virus	Frijoles, Joa
Punta Toro virus	Punta Toro, Buenaventura
Rift Valley fever virus	Rift Valley fever, Belterra, Icoaraci
Salehebad virus	Salehebad, Arbia
Sandfly fever Naples virus	Sandfly fever Naples, Karimabad, Tehran, Toscana
Uukuniemi virus	Uukuniemi, EgAN 1825–61, Fin V 707, Grand Arbaud, Manawa, Murre, Oceanside, Ponteves, Precarious Point, RML 105355, St. Abbs Head, Tunis, Zaliv Terpeniya
Unassigned	Aguacate, Anhanga, Arboledas, Arumowot, Caimito, Chagres, Corfou, Gabek Forest, Gordil, Itaporanga, Odrenisrou, Pacui, Rio Grande, sandfly fever Sicilian, Saint-Floris, Urucuri

The glycoproteins, together with a nonstructural protein (NS_M), are translated from an mRNA complementary to the M segment as a precursor which is post-translational to G_N and G_C proteins. The S segment codes for two proteins. The N protein is read from a subgenomic mRNA complementary to the 3′-end segment of the viral RNA; the second, a nonstructural protein (NS_S, 29–37 kDa), is read from a subgenomic virus-sense mRNA species corresponding to the 5′-half of the viral RNA (**Figure 1**). This strategy of replication is called 'ambisense', and it is utilized also by members of the genus *Tospovirus* as well, and of viruses of the family *Arenaviridae*.

The maturation of phleboviruses occurs in intracellular smooth membranes, principally in the Golgi complex. Exceptionally, RVFV matures on the cell surface of infected rat hepatocytes. The glycoproteins accumulate in the Golgi complex, causing vacuolization, but the Golgi complex remains functional. Virions bud into Golgi vesicles, which are then transported to the cell surface where the particles are released by exocytosis.

The Agents

Rift Valley Fever

RVF was first recognized as a viral zoonosis in Kenya in 1930. Since then, several massive epizootics affecting domestic livestock have been reported in widely separated parts of Africa. In 1977–78, RVFV appeared for the first time in Egypt in an epizootic epidemic of unprecedented size. It was estimated that in some areas along the Nile, 25–50% of sheep and cattle were infected, and that there were as many as 200 000 human cases and at least 600 deaths. Several types of severe and sometimes fatal illnesses were observed in humans, including hepatitis with hemorrhagic manifestations, meningoencephalitis, and retinitis. During this epidemic, RVFV was isolated from *Culex pipiens* mosquitoes; however, arthropods of many species have also been shown to be potential vectors.

During epizootics of RVFV, disease occurs first in animals, then in humans. RVFV produces severe disease in domestic animals, sheep being more susceptible than cattle, goats least susceptible. A greater than 90% rate of mortality is observed among infected lambs, and 20–60% among adult sheep. Pregnant ewes (90–100%) abort within a few days after infection.

RVFV can be transmitted to humans by contact with tissues or blood of infected animals during slaughter, autopsy, or disposal of infected animals. The possibility of transmission of the virus via such an airborne route among abattoir or laboratory workers has been recognized. Vector-borne transmission, particularly at the beginning of epizootic phase, is important.

The most common form of illness associated with RVFV infection in humans is the acute febrile disease (see **Table 2**). The febrile period lasts 4–7 days; patients then recover completely within 2 weeks. During the epidemic of RVFV in 1977–78 in Egypt, 5–10% of patients experienced a typical febrile illness, followed by decreased visual acuity after 7–20 days. Hemorrhagic RVFV, which occurs in about 1% of cases, was not documented until a 1975 epizootic in South Africa. Patients infected during this epidemic experienced the sudden onset of a febrile illness, which was followed 2–4 days later by jaundice and hemorrhagic manifestations. Hematemesis, melena, gingival bleeding, and petechial and purpuric skin lesions were common. In fatal cases, death occurred within a week of the onset of jaundice. Shock and hepatic insufficiency represented the most probable cause of death. Mortality rates range from 0.2% to 14%. The exact incidence of each of the severe clinical syndromes complicating RVFV during the epidemics has not been established. These rates could be

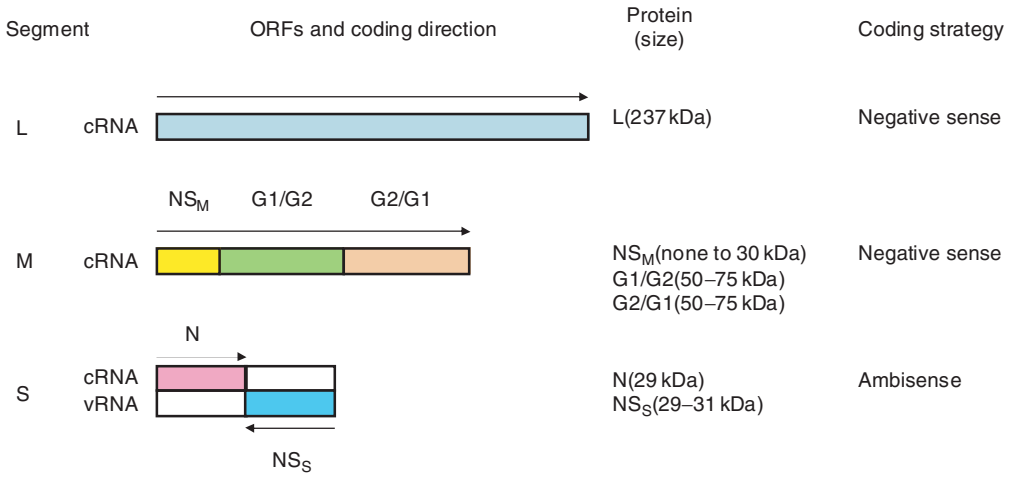

Figure 1 Genome organization and coding strategy of phleboviruses.

Table 2 Phleboviruses infecting humans

Virus	*Evidence of infection*	*Isolation from humans*	*Geographic distribution*	*Arthropod association*
Alenquer	Febrile illness	Blood	Brazil	Unknown
Arboledas	Antibody		Colombia	*Lutzomyia* spp.
Arumowot	Antibody		Africa	*Culex antennatus, Culex rubinotus, Mansonia uniformis*
Bujaru	Antibody		Brazil	Unknown
Cacao	Antibody		Panama	*Lutzomyia trapidoi*
Candiru	Febrile illness	Blood	Brazil	Unknown
Chagres	Febrile illness	Blood	Panama, Colombia	*Lutzomyia trapidoi, Lutzomyia ylephiletor*
Corfou	Antibody		Greece	*Phlebotomus major*
Gabek Forest	Antibody		Africa	Unknown
Gordil	Antibody		Africa	Unknown
Karimabad	Antibody		Iran	*Phlebotomus* spp.
Punta Toro	Febrile illness	Blood	Panama	*Lutzomyia trapidoi, L. ylephiletor*
Rift Valley fever	Febrile illness Hemorrhagic fever	Blood, CSF	Africa, Arabian peninsula	*Aedes caballus, Aedes circumluteolus, Aedes lineatopennis, Aedes vexans arabiensis, Culex theileri, Culicoides* spp., *Eretmapodites chrysogaster, Mansonia africana*
Saint-Floris	Antibody		Africa	Unknown
Salehabad	Antibody		Iran	*Phlebotomus* spp.
Sandfly fever Sicilian	Febrile illness	Blood	North Africa, South Europe, Central Asia	*Phlebotomus* spp.
Sandfly fever Naples	Febrile illness	Blood	North Africa, South Europe, Central Asia	*P. papatasi, P. perfiliewi*
Toscana	Febrile illness Meningitis	CSF	Italy, Spain, Portugal, Cyprus, France, Greece	*P. perniciosus, P. perfiliewi*

influenced by susceptibility of the human population, the virulence of various RVFV strains, and population dynamics of the vector.

Sandfly Fever Viruses

Classical phlebotomus fevers caused by sandfly fever Naples and sandfly fever Sicilian viruses are mild, self-resolving, flu-like illnesses characterized by sudden onset, fever, frontal headache, low back pain, generalized myalgia, retro-orbital pain, conjunctival injection, photophobia and malaise, and, in some cases, nausea, vomiting, dizziness, and neck stiffness (see **Table 2**). Fever is always present, ranging from 38 to 41 °C. The incubation period is 2–6 days, and the duration of disease varies from a few hours to four days (phlebotomus fever is also known as 'a 3-day fever'). Patients completely recover within 1–2 weeks. No deaths associated with phlebotomus fever have been reported but the large numbers of cases that can occur during epidemics, particularly during wars, make these illnesses potentially incapacitating to entire populations, and therefore are important.

Toscana Virus

TOSV was initially isolated from *P. perniciosus* in central Italy in 1971. The virus was subsequently isolated from *Phlebotomus perfiliewi* (but never from *Phlebotomus papatasi*) in other areas of Italy and from the brains of Kuhl's Pipistrelle bats (*Pipistrellus kuhlii*) captured in areas where the insect vectors were present. The virus also has been isolated from humans. Transovarial transmission has been demonstrated experimentally by viral isolation from male *Phlebotomus* spp. Venereal transmission from infected males to uninfected females has also been demonstrated. For many years, the known distribution of TOSV was limited to Italy and Portugal. More recently, the geographic distribution of the virus has been extended to France, Spain, Slovenia, Greece, Cyprus, and Turkey, according to results from viral isolation and serologic surveys.

TOSV is neurovirulent, a characteristic it shares with RVFV. Clinical cases with signs and symptoms ranging from aseptic meningitis to meningoencephalitis caused by TOSV are observed annually during the summers (see **Table 2**). All studies reported that the highest risk of acquiring TOSV is in August, which corresponds with peak sandfly activity.

Seroprevalence studies suggest that a substantial proportion of infections likely result in asymptomatic infections or cause only mild illnesses. Only severe cases, those involving CNS disease, require hospitalization.

After an incubation period ranging from a few days to 2 weeks, disease onset is intense, with headache, fever, nausea, vomiting, and myalgias. Physical examination may show neck rigidity Kernig signs, poor levels of consciousness, tremors, paresis, and nystagmus.

In most cases, cerebrospinal fluid (CSF) contains more than 5–10 cells with normal content of sugar and protein in it, or leukopenia. The mean duration of the disease is 7 days, and the outcome is usually favorable. However, a small number of severe cases with unusual symptoms have been reported. No sequelae have been described.

A study including subjects of a high-risk, professionally exposed population reported a seroprevalence of 70%, but without neurological symptoms. These data confirmed that TOSV infection can occur with either mild or no symptoms and suggest the frequent presence of TOSV infection in regions where the vector occurs.

Diagnostic Procedures

Diagnosis of phlebovirus infections has been classically attempted by isolating the agent or demonstrating seroconversion in paired acute- and convalescent-phase serum samples. Several molecular techniques have been developed and used to demonstrate the presence of the virus or viral RNA in patient samples.

Virus Recovery and Detection

The recovery of phleboviruses from acutely ill phlebotomus fever patients is rare, given that viremias associated with disease are transient (24–36 h) and most patients do not seek medical care within this period.

The most common method of phlebovirus isolation is intracranial inoculation of suckling mice. However, several studies have demonstrated that Vero cells (from kidney tissue of an African green monkey) are more sensitive than are newborn mice for isolation of phleboviruses from wild-caught sandflies. Similar results have been obtained with RVFV.

Identification of isolates can be made with serological methods, such as immunofluorescence, neutralization in mice, or by plaque reduction (PRNT) using hyperimmune sera. Identification can also be performed by complement fixation (CF) or hemagglutination-inhibition (HI); however, care should be taken in areas where more than one phlebovirus circulates, as these latter tests do not discriminate between certain antigenically related viruses. For example, sandfly fever Naples, Toscana, and Tehran viruses are indistinguishable by CF, yet easily identified by PRNT.

Notable diagnostic success in TOSV infections was achieved through molecular reverse transcription-polymerase chain reaction (RT-PCR) techniques. This approach has shown the occurrence of different TOSV variants.

Serologic Tests

Serologic diagnosis can be performed with many different methods. Most of the work in the past has been done with HI. PRNT provides more clear-cut results, but this test is time consuming, and is not more useful for diagnosis than are other tests when a single serum sample is available. However, the PRNT is the most common assay for assessing antibody titer.

Enzyme-linked immunosorbent assays for IgG and IgM antibodies have been established in the case of many phleboviruses; diagnosis is obtained in most cases by detection of specific IgM antibody. The use of immunoenzymatic techniques has been very useful in the developing tests in which the recombinant nucleoprotein expressed in *Escherichia coli* is used as the specific antigen.

Epidemiology

Epizootics of RVFV have been reported in many African countries. Prior to 1977, it was believed that the infection was confined to sub-Saharan Africa. However, the epizootic/epidemic in Egypt in 1977–78 occurred in areas outside the recognized range of the virus. Retrospective studies indicated that RVFV had not been endemic in Egypt prior to the epidemic. The epidemic occurred after the progressive implementation of the Aswan dam project, which regulated the irrigation of the Nile delta. The dam resulted in an increase in the number of breeding places of mosquitoes and also facilitated the transport of animals from Sudan to northern Egypt. From 1973 to 1976, an epizootic outbreak of RVFV occurred in Sudan, which extended from south to north and possibly reached Egypt in 1977.

RVFV was firstly detected outside Africa in September 2000. In southwestern coastal Saudi Arabia and neighboring coastal areas of Yemen, an epizootic occurred with >120 human deaths and major losses in livestock populations from disease and required slaughter. Most RVF activity was associated with flooded wadi agricultural systems; no cases were reported in the mountains or in dry sandy regions, where surface water does not accumulate long enough to sustain mosquito breeding.

Representative phleboviruses have been isolated in Southern Europe, Africa, Central Asia, and the Americas.

Many phleboviruses occur in tropical and subtropical regions, but some important ones are active in temperate areas (e.g., sandfly fever Naples virus, sandfly fever Sicilian virus, and TOSV in Southern Europe and in the Middle East). Most phleboviruses (66%) have been isolated in Central and Southern America and are associated with sandflies of the genus *Lutzomyia*. On the contrary, the majority of sandfly fever viruses isolated in the Old World always are associated with *Phlebotomus* spp. sandflies.

In general, each serotype has a unique distribution, with limited geographical overlap. However, there are indications of simultaneous circulation of different phleboviruses in the same sandfly population. Sandfly fever Naples and sandfly fever Sicilian viruses have the largest geographical distributions, paralleling that of their vector *P. papatasi*. Reported isolations as well as results of serologic studies indicate that sandfly fever Naples and sandfly fever Sicilian viruses are present in the Mediterranean coastal regions of Europe and North Africa, the Nile valley, most of southwest Asia, areas adjacent to the Black and Caspian Seas, and Central Asia as far as Bangladesh.

Despite the preponderance of phleboviruses in the New World, the incidence of phlebotomus fever, and in general of human infections, in the Americas is relatively low. On the contrary, the Old World phleboviruses, such as sandfly fever Naples virus, sandfly fever Sicilian virus, and TOSV, are relatively widely distributed and are well-known causes of epidemics of human infections. In some rural human communities in endemic areas of the Old World, the prevalence of phlebovirus infection is quite high among the indigenous population. For example, results of serosurveys aimed at defining the extent and prevalence of infection with different serotypes among indigenous human populations indicated prevalences as high as 62% for Karimabad virus in some provinces of Iran and 59% for sandfly fever Sicilian and 56% for sandfly fever Naples viruses in Egypt.

A similar serosurvey for the presence of antibodies to sandfly fever Sicilian virus, sandfly fever Naples virus, and TOSV was done in 1977 in Italy. These seroepidemiological studies indicated that both sandfly fever Sicilian and sandfly fever Naples viral infections decreased after the 1940s, probably as the result of insecticide spraying during malaria eradication campaigns. On the contrary, age-specific antibody rates suggested that TOSV, which is transmitted by *P. perniciosus* and *P. perfiliewi*, is endemic in Italy. A high infection rate (24.8%) was observed among residents of the region where the virus was first isolated. Similar results have been found in other Mediterranean countries (Spain, France, Greece, Cyprus).

Because illnesses due to phlebotomus fevers have been of considerable military and historical interest, much of the early research on phlebotomus fevers was performed by military physicians and epidemiologists. In 1984, cases of sandfly fever Sicilian virus infections were documented in Cyprus among Swedish United Nations soldiers. A follow-up study revealed that 11 of 298 soldiers seroconverted to sandfly fever viruses (mostly Sicilian) during a 6 month stay in Cyprus in the summer of 1985. Infection due to sandfly fever viruses (mostly sandfly fever Sicilian virus) was diagnosed in Swedish tourists contracting a febrile illness associated with their travel during 1986–88 to the Mediterranean region. In contrast, a serological survey among Cypriots revealed a higher antibody prevalence to the sandfly fever Naples virus than to sandfly fever Sicilian virus and TOSV.

Clinical cases with signs and symptoms ranging from aseptic meningitis to meningoencephalitis caused by TOSV are observed annually in central Italy during the summer. The incidence of cases of meningitis due to TOSV is directly related to yearly differences in the density of the vector sandflies, which is greatly influenced by variations of climatic conditions. Most cases have been reported in residents or travellers in central Italy or Spain, and sporadically from other Mediterranean countries, such as Portugal, Cyprus, France, and Greece.

In Spain, TOSV is one of the three leading causes of meningitis. A large study conducted in different regions of Spain showed the presence of IgG antibodies to TOSV (26.2%), sandfly fever Naples virus (2.2%), and sandfly fever Sicilian virus (11.9%).

Studies of people living on the Ionian Islands and on the western mainland of Greece showed a seroprevalence for TOSV of 60% and 35%, respectively. It is also reported that in Cyprus 20% of the healthy population had IgG antibody to TOSV.

Therapy

The mild nature of phlebotomus fevers has not encouraged studies on the possibility of treating the disease with specific antiviral compounds. Rather, treatment of phlebotomus fever patients is symptomatic. Due to the severity of the disease, several studies have been done both *in vitro* and *in vivo* in an effort to devise possible treatments of RVFV infections. Two different approaches have been evaluated: the use of an antiviral compound such as ribavirin or its derivatives, or the use of interferon or interferon inducers.

High doses of ribavirin have been used successfully to treat experimental infections with RVFV in several strains of mice. However, at low drug doses, treatment failures occur, resulting in death due to either hepatitis or subsequent encephalitis. Better results have been obtained when animals were treated with liposome-encapsulated ribavirin.

Experimental data and epidemiological experience suggest that the major utility of interferon in RVFV infections could most likely be in early postexposure prophylaxis (e.g., laboratory accidents, high-risk exposures). The success of interferon treatment initiated after

the appearance of clinical symptoms has not been assessed. However, if maximal levels of circulating interferon in humans are obtained before early viremia, as is seen in rhesus monkeys, it is possible that interferon treatment begun at the first appearance of symptoms could affect the course of illness by limiting the incidence of future complications, particularly hemorrhagic fever. In addition, laboratory data and anecdotal information suggest that ribavirin and convalescent plasma may be beneficial in treating hemorrhagic fevers due to RVFV.

Prevention and Control

Vaccines

To date, there are no vaccines available against phlebotomus fever viruses. Given the large number of serotypes that can infect humans, and the lack of cross-immunity between them, to be practical a phlebotomus fever vaccine would have to be polyvalent. Moreover, in view of the relatively benign nature of the disease, vaccination against phlebotomus fever is not cost-effective or advisable as a general public health policy.

As RVFV is primarily of veterinary importance and human epidemics follow livestock epizootics, the immunization of susceptible animals is the most effective means of controlling RVFV infection.

Formalin-inactivated RVFV vaccines have been used for many years in South Africa, Egypt, and Israel to immunize sheep and cattle but they require multiple inoculations to ensure lasting protection. This type of vaccine is recommended for nonendemic areas as well as for livestock to be exported from enzootic areas.

An inactivated RVFV vaccine, developed for human use, is recommended for use to immunize at-risk laboratory and field researchers, or other people at high risk of infection. No clinical cases have been reported after vaccination; however, a few subclinical infections have been detected.

Two live RVFV vaccine candidates have been developed. One is a minute plaque variant and the other is an extensively mutagenized strain, MP-12, passaged in the diploid human lung cell line, MRC-5. Experimental studies in animals have demonstrated that a single dose of MP-12 RVFV vaccine is immunogenic and nonabortogenic in pregnant ewes. It can, therefore, be used safely to protect pregnant ewes and newborn lambs during an RVFV outbreak without increasing mortality due to vaccination.

RVFV MP12 vaccine was developed in cells certified for human vaccine production, and this vaccine may be employed for protecting both humans and livestock against epizootic RVFV infection. Because it is attenuated, this vaccine may be used to prevent an impending RVFV outbreak in an area where the virus is nonendemic, without the risk of spread to the environment.

Prevention of Transmission

During the Egyptian epidemic of RVFV in 1977–78, insecticides were used both inside and outside human and animal shelters to reduce the adult populations of mosquito vectors. However, it was not demonstrated that the use of these chemicals actually decreased the incidence of the disease. In sub-Saharan Africa, where RVFV outbreaks are thought to occur following flooding of vector mosquito breeding habitats, the possibility of using encapsulated formulations of insecticides to control the larval stages has been considered.

Measurements of green leaf vegetation dynamics recorded by advanced very high resolution radiometer instruments on polar-orbiting, meteorological satellites were used to derive ground moisture and rainfall patterns in Kenya and monitor resulting flooding of mosquito larval habitats likely to support RVFV vector mosquitoes (*Aedes* spp. and *Culex* spp.). These data could be used by local authorities for implementations of specific mosquito control measures to prevent transmission of RVFV to susceptible vertebrate hosts.

At present, the only method effective in controlling phlebotomus fevers is to reduce human contact with the vectors that carry their etiologic agents. Insecticides are extremely effective in the control of peridomestic sandfly species, but are of little value for sylvan species. Mechanical means (e.g., protective clothing, bed nets and screening of windows) and use of repellents, such as diethyltoluamide, can also be used to prevent human–vector contact.

Rinderpest and Distemper Viruses

T Barrett, Institute for Animal Health, Pirbright, UK

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Cytopathic effect Alterations in the microscopic appearance of cultured cells following virus infection.
Enzootic A disease constantly present in an animal community in a defined geographic region.
Epizootiology The study of disease epidemics in animal populations.
Hemagglutinin Any substance that causes red blood cells to agglutinate; many viruses possess a hemagglutinin protein in the outer envelope.

History

Rinderpest and its related viruses form a distinct group of paramyxoviruses, the genus *Morbillivirus*. In addition to measles virus (MV), the type virus of the genus, they include important animal pathogens: rinderpest virus (RPV), which infects many species of large ruminant; peste des petits ruminants virus (PPRV), a similar disease of small ruminants; canine distemper virus (CDV), found mainly in carnivores; phocid distemper virus (PDV), in seals; and the cetacean morbillivirus (CeMV), which is found in whales, dolphins, and porpoises. Of the animal viruses, rinderpest is the most important economically. It was also known as cattle plague in the past because of the high mortality associated with infections and the speed with which it spreads in naive cattle populations, which made it an easily recognizable disease. It is one of the oldest documented plagues of domestic livestock. Aristotle (384–322 BC) described a disease in cattle, *struma*, that had all the characteristics of rinderpest and other descriptions date to the fourth century when invasion by Huns into Europe resulted in outbreak of highly contagious disease which had all the characteristics of rinderpest. Steppe cattle of Central Asia are thought to be the original source of rinderpest and 'steepe murrain' was the old English name for the disease. Panzootics of rinderpest were also brought to western Europe with the Mongol invasions in the thirteenth century. In 1709, the disease again entered Europe through Venetian trade with the east and by 1714 had spread as far west as Britain. The economic and social consequences which followed in the wake of these plagues led to the establishment of the first veterinary schools – the first at Lyon, France, in 1762. Other European countries followed France's example and set up their own veterinary schools. Subsequent brief reintroductions into Europe in the early twentieth century, and into South America and Australia through the import of infected cattle led to the establishment of the Office Internationale des Epizooties (OIE), a body that functions as the World Organisation for Animal Health, to deal specifically with animal diseases in relation to international trade.

Rinderpest was introduced into Africa with disastrous consequences in the late 1880s with cattle imported from India to feed Italian troops in fighting a colonial war in Abyssinia (now Ethiopia). The subsequent panzootic spread to nearly all parts of the African continent within a period of 10 years, reaching South Africa by 1897. The devastation that followed its path as it swept across the African continent wiped out 90% of the domestic cattle and wild buffalo (*Syncerus caffer*). A number of other large wild ruminant species were also highly susceptible to the virus and died in large numbers during this so-called 'Great African Pandemic'.

A similar plague of small ruminants, peste des petits ruminants (PPR), was first scientifically documented in West Africa in the early 1940s and is also known as *kata* in that region. At first, it was thought that PPRV was a variant of RPV adapted to small ruminants but it was subsequently shown to be a genetically distinct virus with an independent epizootiology in areas where both viruses co-circulated.

Canine distemper, which infects many terrestrial carnivore species, is also a disease with a long history. In the eighteenth century, Edward Jenner studied its neurological effects following infection in dogs. In 1988, a distinct but closely related virus, phocine distemper virus (PDV), was isolated from seals found dying in large numbers along the beaches of Northern Europe and which showed clinical signs similar to distemper in dogs. Both harbor (*Phoca vitulina*) and gray (*Halichoerus grypus*) seals were affected and the epizootic resulted in the deaths of more than 20 000 seals. In 1990, large numbers of striped dolphins (*Stenella coeruleoalba*) in the Mediterranean Sea were found dying from a similar infection and a virus was isolated from sick animals. This virus has since been associated with mass die-offs among whales, porpoises, and dolphins (order *Cetacea*) and a fatal epizootic in bottlenose dolphins (*Tursiops truncatus*) from the northwestern Atlantic Ocean in the 1980s. A morbillivirus was also isolated from diseased porpoises (*Phocoena phocoena*) found along the coasts of Ireland and the Netherlands between 1988 and 1990 during the epizootic of PDV in seals. This virus was later found to be very closely related to the dolphin virus and genetically quite distinct from all other morbilliviruses. The dolphin and porpoise virus isolates are now commonly referred to as CeMV, and these virus infections have the potential to cause severe disease and threaten the ecology of many marine mammal species.

Taxonomy and Classification

As indicated above, these antigenically closely related viruses are classified in the genus *Morbillivirus* within order *Mononegavirales*, family *Paramyxoviridae*, subfamily *Paramyxovirinae*. The name is derived from the diminutive (*morbilli*) of the Latin word *morbus* meaning 'little plague', to distinguish measles from deadlier diseases such as smallpox. The paramyxoviruses are large enveloped pleimorphic particles which bud from the surface of infected cells and the different species are indistinguishable in the electron microscope. They vary in diameter from 300 to 500 nm. The lipid envelope is derived from the host cell membrane as the virions bud from the cell and it encloses a ribonucleoprotein (RNP) core which contains the genome encapsidated by the nucleocapsid protein giving it a characteristic 'herring bone' appearance. Unlike other paramyxoviruses, the morbilliviruses generally lack neuraminidase but a highly substrate-specific neuraminidase activity has been reported for PPRV and RPV. Only MV and PPRV viruses can hemagglutinate red blood cells reproducibly.

Geographic Distribution

Until the mid-1980s, rinderpest was found in much of tropical Africa and in western and southern Asia. Control and eradication program were established in the mid-1980s and this effort, based on mass vaccination campaigns in the endemic regions, has succeeded in eliminating the disease from Asia and the Middle East; the virus is now almost certainly confined to a defined region of eastern Africa known as the southern Somali ecosystem, a region in eastern Africa comprising southeast Ethiopia, southern Somalia, and northeast Kenya.

PPR is enzootic in West Africa and on the Indian subcontinent and is now spreading from Afghanistan into Central Asia (**Figure 1**). It first appeared as a recognized disease in India in 1988 and has subsequently been found as far east as Bangladesh and north as far as Nepal. Epizootics regularly occur in the Middle East and Turkey through import of infected animals. Turkey's proximity to Southern Europe poses a threat to small ruminants in that region. The widespread distribution of PPRV in southwest Asia suggests that the virus had been present on the continent for some considerable time before it was identified in India. Its presence was most likely masked by rinderpest since all morbillivirus-like diseases in small ruminants in India before 1988 were considered to be caused by rinderpest infections. With the subsequent elimination of rinderpest from Asia and the development of more accurate diagnostic techniques it has now become easier to chart the spread of PPRV in the region.

CDV is found in all but the hottest and most arid regions of the globe. The development of attenuated live vaccines in the late 1950s greatly reduced the incidence of the disease in domestic dogs in developed countries. However, many wildlife species are susceptible to CDV infection and can act as reservoirs for the virus. CDV has also been found in Lake Baikal seals (*Phoca sibirica*) and Caspian Sea seals (*Phoca caspica*) and it poses a threat to the survival of the latter species which is highly endangered. There is also serological evidence for infection in Antarctic seals and, as there are no native carnivores on that continent, unvaccinated sledge dogs are blamed for introducing the virus.

The geographic distribution of PDV is not fully defined but, based on serological evidence, it appears to be an endemic infection in some species of seal in the northern Atlantic and Arctic oceans. These are considered to be the most likely source of PDV for the European

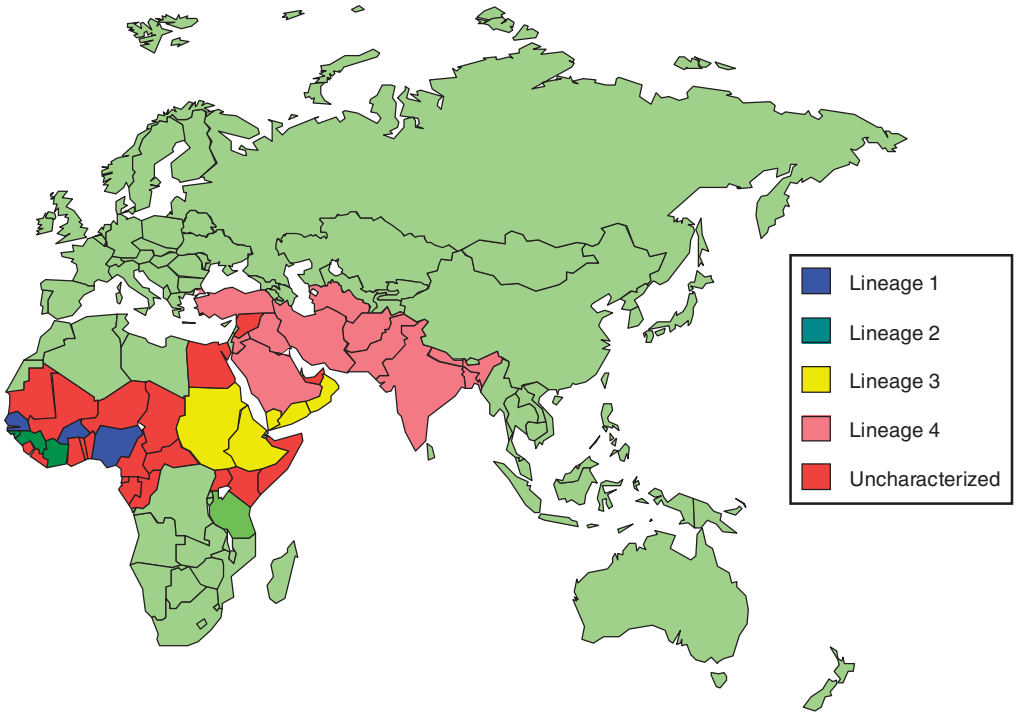

Figure 1 The distribution of PPRV. Where known, the different lineages are color-coded. There are only serological or capture enzyme-linked immunosorbent assay (ELISA) data available for countries shown in red.

seal epizootics. The CeMV appears to have a worldwide distribution and there is serological evidence for the presence of this virus in diverse species from all of the world's major oceans.

Host Range Virus

Each morbillivirus is generally able to cause serious disease only in one order of mammals, the exception being CDV. All cloven-hoofed animals (Artiodactyla) are thought to be susceptible to infection with RPV but the disease is not manifest in all. In the case of cattle, Indian and African breeds (*Bos indicus*, zebu) are more resistant than European (*Bos taurus*). The virus can also infect a range of wild ungulates but disease progression depends on the innate resistance of the species concerned. Some, such as kudu (*Tragelaphus imberbis*), eland (*Taurotragus* spp.), giraffe (*Giraffa* spp.), and wildebeest (*Connochaetes* spp.), are highly susceptible to the virus and died in large numbers during the first African pandemic. Others, mainly small antelope species, proved to be more resistant (**Table 1**).

The full host range of PPRV is unknown but, in addition to sheep and goats, several species of antelope have been fatally infected by contact with infected sheep. Outbreaks of PPRV have been reported in game reserves and zoos where the mortality was 100% in some species.

Table 1 Susceptibility of wildlife to rinderpest

Very high	Buffalo, eland, kudu, wart hog
High	Giraffe, bushbuck, bush pig, sitatunga, Uganda cob, bongo, wildebeest
Moderate	Reedbuck, topi, gemsbok, blesbok, bontbok, oribi, impala, springbok
Low	Waterbuck, dukier, orynx, Grant's gazelle, dikdik, hartebeest
Very low	Thomson's gazelle, hippopotamus, gerenuk

Based on data from Plowright W (1982) The effects of rinderpest and rinderpest control on wildlife in Africa. In: Edwards MA and McDonald U (eds.) *Symposia of the Zoological Society of London, No. 50: Animal Diseases in Relation to Animal Conservation*, p. 1. London: Academic Press.

Goats are generally considered to be more sensitive to PPRV infection than sheep. Indian buffaloes (*Bulbalus bulbalis*) have also been reported to have died from PPRV infections. Cattle have been found in West Africa which were seropositive for PPRV, with up to 80% prevalence in some herds, but there is no evidence that it can cause disease in cattle.

CDV can infect most carnivores but in some it may result in only a mild or subclinical infection, for example, in domestic cats. It causes severe disease in all members of the Canidae (dog, wolf, fox), Mustelidae (ferret, weasel, mink), Procyonidae (raccoon, panda), as well as in collared peccaries (*Tayassu tajacu*, order Artiodactyla). More recently, CDV has been shown to be responsible

for high mortalities in both wild and captive big cats and in hyenas (*Crocuta crocuta*). Failure to recognise the disease earlier in these species may have been due to a lack of awareness of a possible viral etiology and/or the availability of diagnostic tools to detect the virus. Outbreaks of CDV in Siberian and Caspian seals have extended its host range to include these species. PDV is known to infect many species of seal in the North Atlantic and Arctic oceans but its full host range is unknown. There is also serological evidence that terrestrial carnivores in Canada, including polar bear (*Ursus maritimus*), lynx (*Fellis lynx*), and wolves (*Canis lupus*), have been infected with the virus and also with CeMV. CeMV infections have been described in a variety of cetaceans and there are serological data indicating infection in many more.

Virus Propagation

All known morbilliviruses can be propagated on Vero cells, which lack the ability to produce interferon, but it generally requires several blind passages to adapt the virus to these cells. This adaptation can alter the receptor-binding characteristics of the virus and often attenuates it for the natural host. Clinical isolates of rinderpest that retain their pathogenicity can best be grown on primary bovine kidney cells or transformed lymphoid cell lines such as B95a cells. PPRV is normally grown on lamb kidney cells and primary mitogen-stimulated dog or ferret macrophages are the most suitable cells for the isolation of CDV. Alternatively, Madin–Darby canine kidney (MDCK) cells have been shown to be useful for CDV isolation from infected tissues. Primary seal kidney cells were initially used to isolate PDV. Virus is most readily obtained from tissues such as mucosal lesions, lymph nodes, or by co-cultivation of washed buffy coat from infected animals with suitable tissue culture cells. Lung tissue is also a good source of virus for PPRV, CDV, and PDV isolation. Typical cytopathic effects such as cell elongation, cell rounding, the formation of stellate cells, and syncytia can be observed 3–12 days post infection of the cell cultures although several blind passages may sometimes be necessary before cytopathic changes are observed.

Host range is to some extent, but not completely, determined by the expression of a suitable receptor on the host cell. The CD150 molecule, also known as signal lymphocyte activating molecule or SLAM, is thought to be the main cellular receptor for wild-type RPV, CDV, and MV isolates. SLAMs specific to their respective host species may be general morbillivirus receptors. CDV replicates better and causes extensive cell fusion in Vero cells expressing dog SLAM (Vero DST) compared to normal Vero cells and these are a better cell line for propagation and titration of CDV isolates. The expression of SLAM on cells of lymphoid origin, activated lymphocytes, immature thymocytes, macrophages, and mature dendritic cells explains the strong lymphotropism of these viruses. Tissue culture-adapted viruses can use other receptors such as CD46. Alterations in receptor recognition could possibly be a means whereby these viruses could widen their host range in future.

Properties of the Genome

The morbillivirus genomes consist of a single strand of negative-sense RNA just under 16 kbp in length. They are organized into six contiguous, nonoverlapping, transcription units which encode the six structural proteins, namely the nucleocapsid (N), the phospho (P), the matrix (M), the fusion (F), the hemagglutinin (H), and the large (L) proteins, the latter being the viral RNA-dependent RNA polymerase. They have highly conserved sequences at their 3′ (leader) and 5′ (trailer) terminal extremities that act as promoters for transcription and replication (**Figure 2**). The complete promoter elements include sequences that extend into the untranslated region at the start of the N gene open reading frame (ORF) and the untranslated region at the end of the L gene ORF. These regions contain all the *cis*-acting signals necessary for primary transcription as well as for the production of a full-length positive-sense RNA genome copy required for the production of new genome RNA. There are semi-conserved start–stop sequence motifs at the start and end

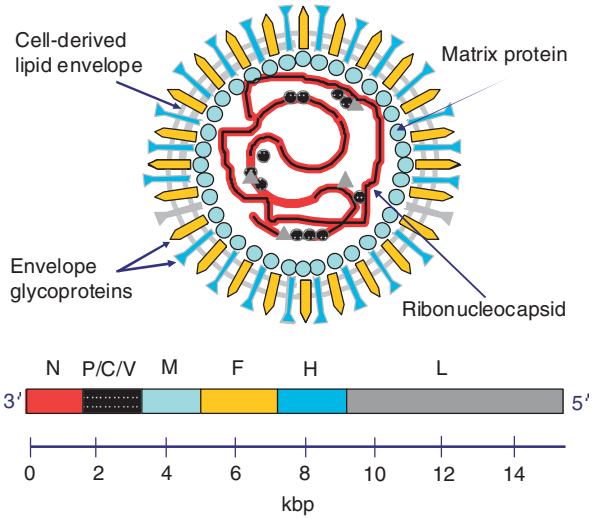

Figure 2 Cartoon showing the structure of morbillivirus virions. The outer envelope is shown with two projecting glycoproteins (H and F) and the inner helical nucleocapsid containing the genome RNA encapsidated with the N protein and the P and L proteins associated with it. The matrix protein is shown as a ring of circles underneath the virus envelope. The linear order of genes in the genome RNA from 3′ to 5′ is also shown.

of each mRNA transcription unit: (UCCU/C) at each transcription start; and a sequence rich in U residues, which signals the polyadenylation of the mRNAs, at the end. Between the end of one transcription unit and the start of the next is an intergenic triplet (usually GAA) which is not translated into mRNA. Downstream mRNA synthesis depends on termination of the upstream mRNA. The N, P, and L proteins, along with the genome RNA, constitute the transcription/replication unit of the virus, the RNP core. The F and H glycoproteins are embedded in a lipid envelope which is derived from the host cell during the budding process. The nonglycosylated M interacts with cytoplasmic domains of the membrane-associated F and H proteins and also with the nucleocapsid RNPs formed in the cytoplasm during replication and brings together the two components that make up the budded virion. The M protein is essential for efficient virus budding to occur.

Morbilliviruses also produce two nonstructural proteins (C and V) encoded in the P gene transcription unit. The first of these, the C protein, is translated by ribosomes that scan past the first AUG codon and start at the second which is located about 20 nt downstream. This protein is in a different reading frame to the P protein and bears no antigenic relationship to it. The second nonstructural protein, the V protein, in derived by alternative transcription of an mRNA from the P transcription unit by which a nontemplated G residue added to approximately 50% of the P mRNAs. The extra Gs are inserted at a specific, highly conserved, sequence (5′ UUAAAAAGGG[G]CACAG), known as the editing site, positioned about halfway along the P protein ORF. This so-called editing process is a property of the virus polymerase as it does not occur in artificial transcription systems. Translation of this mRNA produces the V protein which is a chimeric protein consisting of the N-terminus of the P protein with a new, shorter C-terminus rich in cysteine residues derived from template sequence in the third reading frame. The V mRNA is also capable of translating the C protein as its coding region is located before the editing site in P. The nonstructural proteins have functions in controlling transcription and replication and also are involved in virus evasion of the host's innate immune responses.

Morbilliviruses, like some other paramyxoviruses, have a strict genome length requirement in that they should be divisible by 6 (the 'rule of six'). This requirement can be explained by the fact that each N protein monomer associates with exactly 6 nt and that efficient transcription and/or replication can only occur if the RNA genome is encapsidated by the N protein in its entirety. Reverse genetics systems have been established for MV, RPV, and CDV. This enables virus to be 'rescued' from a DNA copy of its genome and this copy can be manipulated to make virus mutants which can then be used to determine the functions of various proteins and sequence motifs and to study the molecular basis of host range and pathogenicity.

Evolution

The close antigenic relationship and sequence similarity of morbilliviruses indicate that they all evolved from a common ancestor; however, the details of their evolutionary history are unclear. The phylogenetic relationship between the different morbilliviruses, based on the sequence of the P proteins, is shown in **Figure 3**. RPV, PPRV, CDV, and CeMV are equidistant from each other. It appears, therefore, that no existing morbillivirus represents the ancestral virus. MV is genetically more closely related to RPV and PDV to CDV, suggesting that they evolved more recently from their respective common ancestors. A factor that must be considered in their evolutionary history is that animals which have recovered from morbillivirus infections are immune for life and so fairly large populations are required to ensure a constant supply of naive hosts needed to maintain these viruses in circulation. The minimum population size that satisfies this requirement has been estimated to be about 300 000 for MV, and so this virus could not have existed before settled human populations became large enough. Herds

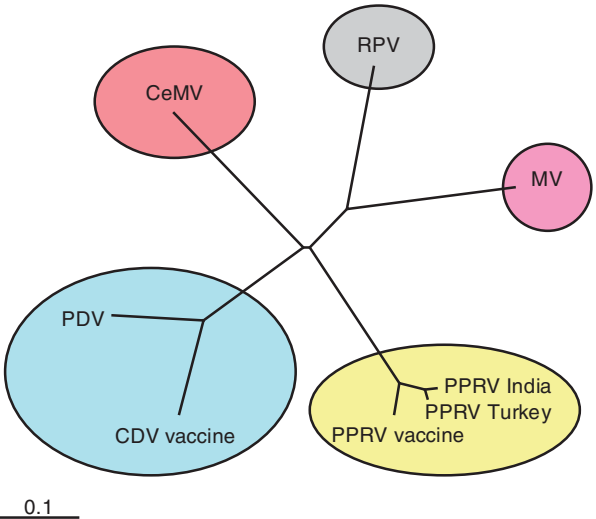

Figure 3 Radial tree showing the morbillivirus phylogenetic relationships based on their P protein sequences. The P proteins were aligned using ClustalW (BLOSUM) matrix program. A neighbor-joining radial tree was then generated from this alignment using ClustalX v1.83 and TreeView v1.6.6. Three different PPRV sequences were included to show the extent of variation within each morbillivirus type. The PPRV vaccine and PPRV Turkey are the most distant viruses in the group. Access numbers: RPV (X98291); PPRV (AY560591, X74443, AJ849636); CDV (AF305419); PDV (D10371); DMV (AJ608288); MV (AB012948).

of ruminants roaming the steppes of Central Asia, the historic source of rinderpest, would, however, have been able to maintain a morbillivirus in circulation. It is probable that when human communities became large enough, rinderpest, or a rinderpest-like infection, was passed to them from their domesticated cattle. RPV and PPRV are equidistant from the putative ancestral virus and so PPRV did not evolve directly from RPV and must have a long independent evolutionary history in small ruminants.

Carnivores preying on infected ruminants may similarly have become infected with the progenitor morbillivirus which subsequently evolved in these species to become CDV. CDV infects a wide variety of carnivores and so there is potentially a large reservoir of virus in susceptible wildlife species. PDV most probably evolved quite recently from CDV. Seals have many opportunities to become infected with CDV by contact with terrestrial carnivores such as wolves, foxes, dogs, and polar bears. Arctic seals populations, unlike European seal populations, are large enough to enable a morbillivirus to be maintained and subsequent evolution would select a virus more adapted to replicate efficiently in seals.

The two CeMVs that have been isolated from dolphins and porpoises are very closely related to each other, as related as different lineages of either RPV or PPRV, and can be considered to constitute one virus species. CeMV is antigenically closest to PPRV but is equidistant for the putative ancestral virus by sequence analysis and so this virus also has had a long independent evolutional history.

Serological Relationships and Variability

All the morbilliviruses are antigenically related, the F, M, and N proteins being the most highly conserved across the group. The two virus-coded glycoproteins, the H and F, are embedded in the virus envelope and neutralizing antibody responses are generated to both of these proteins. The H protein, responsible for attachment of the virions to the host cell surface receptor molecule and is therefore a determinant of host range, is the least cross-reactive of the morbillivirus proteins. While it is possible to differentiate strains of each morbillivirus by monoclonal antibody and sequence analysis, these variations do not result in different serotypes and for vaccination purposes each morbillivirus has only one serotype.

Epizootiology

Rinderpest and PPR are normally introduced into new regions by importation of live animals. Transmission through infected meat and meat products is considered to be a very low risk due to the highly labile nature of the viruses. Historically, rinderpest outbreaks have been associated with wars and civil conflict when there is uncontrolled movement of people and troops, often bringing live animals from enzootic regions as food. Sheep and goats, and possibly other ruminants, may show only mild disease or subclinical infection with RPV but nevertheless they can then pass the infection to in-contact cattle. Trade in live animals is also another factor that has been responsible for long-distance spread of rinderpest.

Epizootics of rinderpest in naive populations are generally very severe and mortality rates can exceed 90% and affect all age groups, the classic characteristics of cattle plague. The last outbreak of this nature occurred in Pakistan in 1994. In endemic areas, disease is less severe and most often affects animals less than 2 years of age as older animals are generally immune due to previous exposure or vaccination. Newborns are protected for up to 9 months by maternal antibody. The rinderpest virus strain in circulation in the last enzootic focus in Africa belongs to African lineage 2 (**Figure 4(a)**) and is unusual in that it causes only mild disease in cattle. It becomes clinically apparent when it spreads to highly susceptible wildlife species such as buffalo, eland, and kudu. These have suffered very high mortalities when infected with this strain of virus during outbreaks in Kenyan national parks and because of this wildlife are considered excellent sentinels for incursions of rinderpest. They are closely monitored for evidence of reintroduction of the virus from its only known enzootic focus in the southern Somali ecosystem.

PPRV shows a similar epizootiology and can also cause very high mortalities in naive populations of sheep and goats. Introductions into disease-free areas are usually traceable to movement of infected animals from enzootic regions. Phylogenetic analysis on PPRV strains reveals that there are four distinct lineages in circulation (**Figure 4(b)**). PPRV infections in wildlife have not been studied in any detail but the severity of disease when it occurs in captive small ruminants infected by contact with domestic livestock makes it unlikely that there is a significant wildlife reservoir of the virus.

CDV causes periodic epizootics in domesticated dogs and wild carnivores and it remains a problem in poor urban areas where there are many stray dogs and vaccination is not carried out rigorously. In enzootic areas, the density of the susceptible population is an important factor in determining the frequency of epizootics and can also affect its maintenance and spread. Again, disease is most often seen in young animals after maternal antibody has waned. A variety of wild carnivore species are highly susceptible to CDV infections and presence of the virus can be a high-risk factor for some endangered species.

The source of PDV in the two epizootics that occurred in European seals is thought to have been either Canadian harp seals (*Phoca groenlandica*) or Arctic ringed seals (*Phoca hispida*). Retrospective analysis of seal sera from Canada

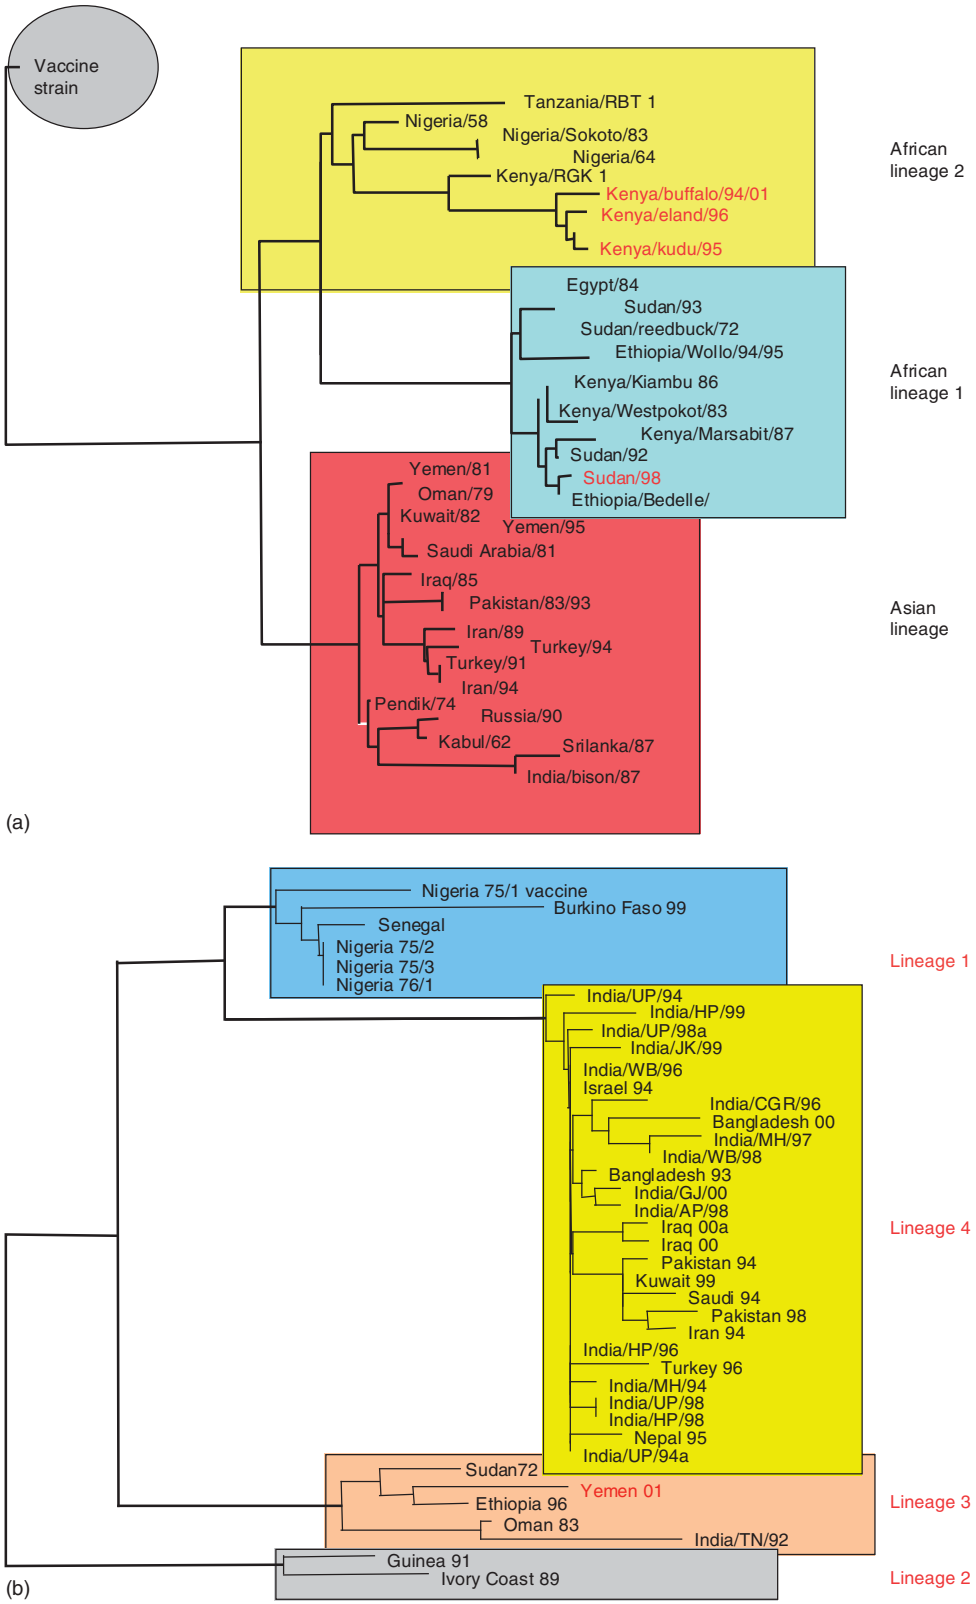

Figure 4 A computer-generated tree showing the relationship between (a) the African and Asian lineages of rinderpest virus and (b) the currently circulating PPRV lineages. The trees were generated using the PHYLIP program using partial sequence data from the F protein gene. Only RPV African lineage 2 remains extant and the outbreaks in Kenya since 1994 are highlighted in red. The vaccine strain of rinderpest dates to the early part of the twentieth century and was used as the outgroup in the rinderpest and PPRV analysis.

dating back to the early 1980s showed that they were positive for virus-specific antibodies. The two European PDV epizootics, in 1988 and 2002, were remarkably similar and this may be explained by the susceptibility, migratory patterns, and/or breeding habits of the seals. The gray seal is the most likely candidate to act as the vector in the transmission of PDV between Arctic and European seals and between colonies of harbor seals as they are known to move much greater distances between haulout sites. Another important factor is the relative resistance of gray seals to the disease, possibly enabling PDV to circulate in that population without necessarily causing high mortality.

The pilot whale (*Globicephala* spp.) is considered to be the most likely endemic source of CeMV and also the vector for its transmission to other species. Pilot whale populations have the characteristics required for both; they move in large groups (pods), have a widespread pelagic distribution, and are known to associate with many different cetacean species. A high proportion of pilot whales sampled in the mid-1990s showed evidence of infection and over 90% of pilot whales that were involved in mass strandings between 1982 and 1993 were seropositive for morbillivirus.

Transmission

All morbilliviruses are extremely labile in the environment and are inactivated by heat, ultraviolet (UV) light, and chemicals that alter pH or destroy their lipid envelopes. Therefore, although highly contagious, they require close contact between infected and susceptible animals for their transmission which normally occurs via infected air droplets. All secretions and excretions potentially harbor virus and, along with fomites, can also be a source of infection. In the case of seals, contact at haulout sites allows the proximity required for aerosol transmission.

Clinical Features of Infection

Morbillivirus infections begin in the upper respiratory tract and, after a variable incubation period spread from the local draining lymph nodes via the lymph and blood to other lymphatic tissues and then to the upper and lower respiratory tracts, gastrointestinal mucosa and in some cases the brain. With virulent strains, there is a marked leucopenia leading to a deficiency in the immune system. The incubation period ranges from 3 to 6 days in natural infections or following experimental parenteral inoculation. With less virulent strains of RPV, the incubation period can extend to 15 days and in many cases there may be no clinical signs but the animals seroconvert. The cell (epithelial and lymphoid) tropisms explain the pathological signs most associated with morbillivirus-induced disease: mucocutaneous lesions, severe infection in the gastrointestinal tract; and destruction of the lymphoid organs and consequent immunosuppression. In some cases, skin lesions can be associated with RPV infection but this is not a common finding. Hyperkeratosis of the cornea leading to blindness is a striking feature seen in kudu. Pneumonia is less marked in RPV than in PPRV and other morbillivirus infections.

In CDV infections, the incubation period can range from 1 to 6 weeks. Animals then show an initial febrile response and develop clinical signs commonly seen in other morbillivirus infections: mucopurulent nasal and ocular discharges, vomiting, diarrhoea, and pneumonia. Neurological signs such as convulsions, tremors, and seizures or behavioral changes are seen and they can develop acutely or weeks or months later or they may follow a subclinical infection. Recovered dogs frequently show persistent nervous tics or involuntary movements of one or more legs. In some cases, a hyperkeratosis (hard pad) develops on the foot pads.

Seals infected with either CDV or PDV also show the usual signs associated with a morbillivirus infection, fever, serous or mucopurulent oculonasal discharge, conjunctivitis, dyspnea, diarrhea, lethargy, and abortion in pregnant females. Bronchopneumonia is the most marked pathological feature in aquatic and marine mammal infections (CDV, PDV, and CeMV) which severely affects the animal's ability to dive and forage for food and quickly results in loss of body condition and a reduced blubber thickness. During the epizootic in the Mediterranean in 1990–91, many striped dolphins (*Stenella coeruleoalba*) were also found to be in poor body condition and loss of fat stores led to decreased buoyancy. Skin lesions, necrosis of the buccal mucosa, lymphodepletion, and hemoconcentration were commonly observed. Neurological signs similar to those found in CDV infections are a feature of both PDV and CeMV infections.

Pathology and Histopathology

The severity of gross pathological lesions observed in RPV and PPRV infections, like the clinical signs observed, is related to the virulence of the virus strain involved. Erosions and ulcerations are found in the upper respiratory, urinogenital, and digestive tracts. In the small intestine there is necrosis and destruction of Peyer's patches. Destruction of the epithelial lining of the gut is responsible for the severe bloody diarrhea seen in acute cases and the packed cell volume can be increased by 40–65%. In the cecum, colon, and rectum of animals infected with RPV and PPRV, so-called 'zebra' or 'tiger' stripes are often found and result from the distension of blood vessels

packed with erythrocytes. Dehydration also causes changes in hematology and blood chemistry. A nonsuppurative encephalitis with central nervous system (CNS) degeneration occurs during infections with CDV, PDV, and CeMV, but no CNS involvement has ever been reported in ruminants infected with either RPV or PPRV. Immunosuppression associated with morbillivirus infections can lead secondary bacterial infections which may complicate both the clinical and pathological findings and latent or concurrent infections can be activated.

Histologically, the morbilliviruses show a strong tropism for epithelial and lymphoid cells and all lymphoid organs are affected with damage to the mesenteric lymph nodes, the gut-associated lymphoid tissue, the lymphoid follicles of tonsils, lymph nodes, spleen, and mucosa-associated lymphoid tissues, where severe destruction of the B- and T-cell areas is seen in infections with virulent strains. Mild strains induce less extensive lymphoid destruction and mucosal lesions and in these animals tissue samples show unremarkable histopathological changes in the gastrointestinal tract and the lymphoid tissues and this may account for the reduced ability for these strains to transmit by contact.

Immune Response

There is a strong cell-mediated component in the response to morbillivirus infection and immunosuppressed individuals are known to be at extreme risk from MV. Neutralizing antibodies are generated only in response to the H and F glycoproteins and vaccines containing purified H or F proteins are effective only if administered with a strong cytotoxic T-cell-stimulating adjuvant, for example, Quil A (ISCOM vaccines). Inactivated whole virus vaccines give only a poor and short-lived protection. Both the H or F proteins can confer immunity to disease as poxvirus recombinant vaccines expressing either of these glycoproteins can confer fairly long-term (up to 3 years) immunity to clinical disease. In addition, RPV recombinants can also confer cross-immunity to PPR disease in the absence of cross-neutralizing antibodies. All morbillivirus infections appear to give lifelong protection against disease but it is not clear if subclinical reinfection can occur.

Prevention and Control

In 1711, during a prolonged epizootic of rinderpest in Italy, the Pope's physician, Giovani Lancisi, promulgated rules to deal with the disease in cattle. He insisted on movement controls on all animals in the areas affected, the slaughter of diseased and in-contact cattle, and their burial in lime. He also introduced the idea of quarantine and his policies were backed by strong legal enforcement with severe punishments for transgressors, principles which are still applied today to control animal diseases. This approach, along with import restrictions on cattle from the East, succeeded in controlling the disease in Europe and by the beginning of the twentieth century western Europe was free of enzootic rinderpest. However, these conditions are not always easy to impose in developing countries.

The existence of only one serotype for each of the morbilliviruses, the absence of persistence of infectious virus, and lifelong immunity after recovery from the initial acute infection suggest that outbreaks of these viruses should be easy to control. In addition, the morbilliviruses need close contact for infection to occur, are labile and do not survive long in the environment, and disinfection of infected premises is fairly straightforward. These characteristics of the virus, and the availability of a safe and effective vaccine, were the main drivers for the decision to try to control rinderpest following its resurgence in the early 1980s. International rinderpest control campaigns were begun in the late 1980s, and in 1992 the United Nations Food and Agriculture Organisation (FAO) recommended the global eradication of rinderpest as an internationally coordinated program. In 1994, this became the Global Rinderpest Eradication Programme (GREP), a time-bound program to eliminate rinderpest from the world by the year 2010.

All this effort has succeeded in eradicating the virus from Asia and has eliminated it from most of Africa. The last outbreak of rinderpest occurred in India in 1995 and in Pakistan in 2000. In Africa, the last confirmed case caused by African lineage 1 virus was in southern Sudan in 1998 and so this has probably been eliminated in the field, while the last confirmed case of African lineage 2 was in buffalo in Meru National Park in 2001. Meru is in northeastern Kenya, within the southern Somalia ecosystem, and the major obstacle to completing the GREP by the projected date of 2010 is the continuation of conflict in Somalia.

It was feared that even if rinderpest were eliminated from the domestic cattle populations wild ruminants might act as a reservoir of infection, but history shows that when the disease is eliminated from cattle it disappears from surrounding wildlife, as evidenced by its disappearance from Tanzania, South Africa, and southern Kenya, areas of the continent with many wildlife species. Nevertheless, during outbreaks, rinderpest-infected wildlife can help spread the disease over large distances.

In contrast, only limited resources have been directed to solving the problem of PPRV although a very effective live-attenuated vaccine is also available. From an economic and social perspective, PPR is now considered to be of great importance as it threatens small-ruminant production, the mainstay of many subsistence farmers in much of the developing world.

CDV vaccines have been very effective in controlling infections in domestic dogs; however, not much can be done to prevent infections in wild carnivores, seals, dolphins, and whales. Even if good vaccines were available, vaccination of wild animal populations is logistically very difficult. There are also ethical issues to take into account, such as the potential for uncontrolled spread of vaccine, which may not be attenuated for all species, and the disturbance caused to the animals which may also be harmful.

Diagnosis

Rapid and accurate diagnosis is the key to success in controlling morbillivirus outbreaks in domestic livestock. Clinical signs, however, are not always clear enough to make a confirmatory diagnosis, even when severe clinical signs are evident, as other viruses can mimic those commonly seen in morbillivirus infections. For example, rinderpest and bovine viral diarrhea viruses are often confused and PPRV can be mistaken for pasteurellosis or other microbial pneumonias. Confirmatory laboratory diagnosis is therefore essential.

Simple and rapid diagnostic tests such as capture enzyme-linked immunosorbent assay (ELISA) and reverse-transcriptase polymerase chain reaction (RT-PCR) have been developed for RPV and PPRV in recent years, and, since these are easy to use for analyzing large numbers of samples, these are now favored for virus detection. With RT-PCR, the DNA product can be sequenced and used for phylogenetic analysis that can be used to identify the strain of virus involved and the potential source of virus entering a new region.

For serological detection of morbillivirus antibodies, the ELISA format is favored and the success of the rinderpest eradication campaign depended to a large extent on the ability to seromonitor large herds following vaccination. The test is based on the use of a highly specific monoclonal antibody directed against the H protein of RPV in a competitive ELISA format. A companion test for the detection of PPRV antibodies is also available.

Vaccination

The first attenuated rinderpest vaccines were produced in the 1930s when the virus was adapted to replicate in goats (caprinized) and rabbits (lapinized). In the 1940s, a chick embryo-(avianized) adapted vaccine was produced. These vaccines were widely used but they had drawbacks in that they were not fully attenuated and could cause disease in more susceptible breeds. In the early1960s, a tissue culture-adapted strain of RPV, the 'Plowright vaccine', was developed by multiple passage of the virus in primary bovine kidney cells. The vaccine is relatively easy to produce, safe for use in all cattle breeds, and does not spread by contact. It is highly effective in preventing disease and the immunity induced in vaccinated cattle proved to be lifelong. This vaccine has been used successfully since the early 1960s for the control of rinderpest. A similar vaccine to control PPR was produced in the late 1980s by multiple passages of the virus on Vero cells and this is now being used to control the disease in parts of Africa and Asia.

Egg-adapted (Onderstepoort vaccine) and canine tissue culture-attenuated (Rockborn) vaccines for CDV were produced in the 1950s and are still widely used to vaccinate dogs against distemper. Immunity lasts for several years following vaccination of dogs with either vaccine. The distemper vaccines are not attenuated for all carnivores; for example, some species of ferret are extremely susceptible to CDV and develop disease on vaccination.

All morbillivirus vaccines, like their wild-type progenitors, are extremely fragile and heat-labile and so it is expensive and logistically difficult to store and use them in hot climates. The establishment of an effective cold chain for the delivery of vaccine was an essential feature of the success of the rinderpest eradication campaign as was follow-up seromonitoring studies to determine the level of herd immunity and the effectiveness of vaccination teams.

Future Prospects

Rinderpest is currently on the verge of global eradication and if successful it will be the first veterinary virus disease to have been eradicated globally and the second after smallpox. This goal must not be forgotten and the mild strain of the disease which may still persist in Somalia is of great concern. The worst case scenario is that such a clinically mild strain could move unnoticed into other regions of Africa where, since mass vaccination has ceased, there is a vast naive cattle and wildlife population which could become reinfected. This would provide an excellent opportunity for the virus to evolve to become more pathogenic for cattle. There is a high probability that this could happen as the virus most closely related to this strain was isolated from a giraffe in Kenya in 1962 and is highly pathogenic in cattle.

There is also a major gap in our understanding of the ecology of morbillivirus disease in wild animals, especially in marine and aquatic mammals, and this is an area of research which should be encouraged.

Many questions also remain concerning the host range determinants, biology, molecular biology, and pathogenesis of the morbilliviruses which hopefully can be addressed using reverse genetics.

Glossary

Antigenemia Presence of viral antigen in blood.
CFTR Cystic fibrosis transmembrane conductance regulator, a chloride channel localized in the apical membrane of epithelial cells implicated in secretory diarrhea.
Genotype Specific genetic makeup of one or more viral genes determined by sequence comparison.
Intussusception Pathological event in which the intestine acutely invaginates upon itself and becomes obstructed, followed by local necrosis of gut tissue.
Serotype Significant differences in the antigenic composition of the neutralizing antigens, VP4 and VP7 in the case of rotavirus.
Transcytosis Active transport by which polymeric IgA and IgM antibodies are transported from the basolateral to the lumen of the intestine by the polymeric Ig receptor.

Introduction

Using electron microscopy, rotaviruses were discovered as the etiological agents of epizootic diarrhea of infant mice (EDIM) in 1963 and of calf scours in 1969. Using this same technique, Ruth Bishop identified a rotavirus (RV) in intestinal biopsies of children with diarrhea in 1973. Since then, rotaviruses have been recognized as the most important cause of severe gastroenteritis in children worldwide and an important pathogen of the young of many animals.

Notwithstanding that the overall global mortality from childhood diarrhea decreased in the last 20 years, recent studies suggest that the proportion of hospitalizations attributable to RV-induced diarrhea may have increased during the same time period. For this reason, the burden of RV-related deaths was recently revised, and it is estimated that RV causes around 611 000 childhood deaths every year. More than 80% of these deaths occur in developing countries of sub-Saharan Africa, and South Asia. Worldwide, it is estimated that nearly every child under 5 years of age will have an episode of RV diarrhea, one in five will require medical attention, one in 65 will be hospitalized, and approximately one in 293 will die from RV disease. Although deaths due to RV are rare in developed countries, the incidence of viral infection is the same as in developing countries and health costs associated with RV disease are considerable. In the United States, for example, it has been estimated that 58 000–70 000 rotavirus-associated hospitalizations occur each year and cost-effectiveness studies clearly justify the use of RV vaccines in that country.

Rotaviruses are very well adapted to their host: they replicate very efficiently, sterilizing immunity is not developed and, despite an important host range restriction, many animal hosts exist (**Table 1**). These characteristics help to explain the high viral prevalence, and suggest that the prevention of severe disease is an appropriate goal for vaccination.

Morphology

Rotaviruses were given their name because, when examined by classical electron microscopy, they appear as wheel (*rota*)-shaped, 70 nm particles. However, by cryoelectron microscopy (a method that permits visualization of the viral spikes), the viral diameter is 100 nm (**Figure 1**). Using this method, the virus particle has been shown to be formed by three concentric layers of proteins: the core comprises viral structural protein 2 (VP2), the RNA-dependent RNA polymerase (VP1), guanyl tranferase (VP3), and the viral genome (**Figure 1**), the intermediate layer is formed by structural protein VP6, the most abundant and most antigenic viral protein, and the external layer comprises 780 copies of glycoprotein VP7 and 60 viral spikes formed by VP4. The surface of the virion has three types of pores that penetrate into the interior of the capsid. These channels seem to be important during viral replication, allowing exchange of compounds in aqueous solution to the inside of the capsid and the export of nascent RNA transcripts.

Several RV structural proteins and nonstructural proteins (NSPs) have been crystallized, permitting the initiation of detailed molecular studies of viral physiology. By this method, the viral spikes have been shown to consist of VP4 trimers, the structure of which rearranges upon trypsin cleavage (a process that enhances viral infection) and probably again on entry into the cell. These changes resemble the conformational transitions of membrane

Table 1 Virus-associated factors that contribute to high viral prevalence and reinfections

Characteristic	*Comments*
Natural infection does not generate sterilizing immunity	Goals of vaccination are to decrease severe disease but not to prevent infection
Multiple animal hosts exist	Eradication does not seem feasible
Short incubation period (1–2 days)	Does not allow time for the recall of high levels of immune effector mechanisms
The entry cell is the same as the cell used for viral replication	Does not allow time for the recall of high levels of immune effector mechanisms
Virus is excreted in high quantities (up to 10^{11} pfu g^{-1} of feces)	High levels of viral dissemination in the environment
Up to 30% of children excrete antigen up to 57 days after onset of diarrhea	High level of viral dissemination
High rate of viral mutation and gene reassortment	May permit the virus to evade the immune system. Currently unproven
Over 50% of infections are asymptomatic	RV well adapted to the human host

fusion proteins of enveloped viruses. The crystal structure of the viral hemaglutinin VP8 (VP4 is cleaved by trypsin into VP8 and VP5) that contains several virus-neutralizing epitopes has also been determined. Details of the characteristics and function of the viral proteins are described elsewhere in this encyclopedia.

Classification and Epidemiology

Rotaviruses are classified in the genus *Rotavirus* of the family *Reoviridae* that comprises icosahedral, nonenveloped viruses with segmented, double-stranded RNA (dsRNA) genomes. Based primarily on epitopes in VP6, rotaviruses are classified serologically into seven groups (A–G). These serologically distinct groups are also very distinct genetically and genome segment reassortment does not occur between serogroups. According to current taxonomic classification, serogroups A–E each correspond to a different RV species. Serogroups F and G are currently regarded as tentative species. Most human pathogens fall into groups A, B, and C. The information presented in this chapter is mostly limited to group A rotaviruses which are, by far, the most common cause of severe diarrhea in humans. Among group A rotaviruses, antigenic differences in VP6 have also been identified and used to establish viral subgroups, primarily for epidemiological studies. Serotypes within each serogroup are defined by epitopes in VP7 (glycoprotein, G types) and VP4 (protease, P types) that induce neutralizing antibodies. As the genes encoding these two proteins segregate separately during genome segment reassortment, a binary serotyping system has been developed to identify isolates.

Genotypes, determined by nucleic acid sequence similarity of genes encoding VP7 and VP4, and serotypes, determined by antigenic similarity in VP4 or VP7, as tested by neutralization assays, are generally equivalent for VP7. Currently, 15 G types have been described. G1, G2, G3, G4, and G9 constitute more than 92% of all G serotypes of humans detected globally and appear to be equally virulent. For VP4, there is no direct relationship between genotypes and serotypes and, therefore, a dual system P classification is in use (P genotype numbers are denoted in brackets and P serotypes without brackets). At least 23 P genotypes P[1]–P[23] and 14 serotypes have been described. More than 91% of circulating human RV strains express the P[8] and P[4] genotypes. These genotypes correspond to two subtypes of P1 serotype (P1A and P1B, respectively) that share some cross-reactive epitopes.

Overall, strain variability is less than would be expected from a random association of G and P genotypes since human RV strains belonging to G1, G3, and G4 serotypes are preferentially associated with P[8], while G2 serotype strains are most frequently associated with P[4] genotypes. Importantly, cross-hybridization studies using labeled viral RNA have shown that, in general, viruses that express P[8] form a different genogroup than viruses that express P[4].

In addition to these more prevalent strains, rotaviruses with unusual serotypes currently circulate and can arise sporadically in developed and particularly in developing countries. Several serotypes may coexist within a community, but, in temperate climates especially, each season is usually dominated by a single serotype that may change from season to season. The global distribution of rotaviruses varies over continents: G1P[8] represents over 70% of RV infections in North America, Europe, and Australia, but only about 30% of the infections in South America and Asia, and 23% in Africa. These differences in geographic distribution can probably be explained by variations in sanitary and climatic conditions and/or closer contact of individuals with animal rotaviruses in areas with more RV diversity.

Animal and human group A rotaviruses can undergo genome segment reassortment *in vitro* and *in vivo*. Reassortment originates in cells simultaneously infected with two different rotaviruses and results in progeny viruses that have a combination of genes from each parental strain. In several cases, human rotaviruses have been found that have genes of animal RV origin, adding a further dimension to strain diversity. However, rotaviruses have an important host range restriction in that, in general, humans are infected only with human rotaviruses. This restriction has been exploited for the development of several viral vaccines.

In the temperate zones of the world (mostly developed countries), RV infection occurs primarily during epidemic peaks in the cooler months of the year. A yearly wave of rotaviral illness spreads over the United States; it begins in the southwest in November and terminates in the northeast in March. A similar phenomenon has recently been reported to occur in Europe. This pattern is not seen in countries within 10° of latitude from the Equator (mostly developing countries) where epidemics occur year-round. No clear explanation is available for these temporal patterns of viral prevalence.

Rotaviruses are highly contagious and spread easily but, unlike certain human bacterial infections that occur disproportionately in developing countries, the prevalence of RV infection is the same in developed and developing countries, implying that sanitation and hygiene are not effective measures for disease control.

The Viral Genome and Viral Replication

The RV genome comprises 11 dsRNA segments that code for six structural proteins and five or six nonstructural proteins. The size of segments varies from 0.6 to 3.3 kbp. Each segment contains a single long open reading frame

(ORF), with the exception of segments 9 and 11, each of which may contain two ORFs. The 5′ and 3′ ends of the RNA segments have noncoding regions that differ between rotaviruses from groups A, B, and C. These sequences are important in transcription, replication, and reassortment of the virus genome.

The viral RNA itself is not infectious. For this reason, the engineering of recombinant rotaviruses has been very difficult, and this has impeded functional analysis of the viral RNA noncoding sequences and of the viral proteins. This problem has been partially solved by the development of a cell-free system that supports the synthesis of dsRNA from exogenous mRNA, and by gene silencing using small interfering RNA (siRNA) to specifically inhibit translation of viral proteins. In addition, a reverse genetics system for introduction of site-specific mutations into the dsRNA genome of infectious RV has been recently developed (see *recommend readings*). Evaluation of the utility of this method is eagerly awaited by scientists in the field.

Rotaviruses are highly variable. Three mechanisms for generating genetic diversity have been identified: point mutation, genome segment reassortment, and recombination. Rotaviruses have high rate of mutation and it has been estimated that, on average, at least one mutation occurs during each genome replication. Reassortment of genome segments also occurs at high frequency during mixed infections with two or more rotaviruses, both *in vitro* and *in vivo*. Natural reassortment *in vivo* appears to influence the serotypic diversity in humans, especially in less developed countries (see below). Recombination and related rearrangements of viral RNA segments (e.g., partial gene duplication or deletions) probably play a minor role in generating viral diversity but may be important in longer-term viral evolution.

RV entry into host cells is a multistep process and several molecules have been identified as RV receptors or co-receptors. However , the process has been shown to vary in different viral strains. For example, for several animal RV strains, the first binding step involves the interaction of VP8 with sialic acid, while some human RV strains appear to bind initially to GM1 ganglioside. As a second step, RV binds to the integrin $\alpha 2\beta 1$ in an interaction mediated by the integrin-binding motif DGE in VP5. In addition to these two interactions, integrins $\alpha v\beta 3$ and $\alpha x\beta 2$, and the heat shock protein hsp70, have also been shown to be involved at a later step of rotavirus cell entry. It seems that the association of some of these molecules with rafts is important for viral entry.

Although it was initially proposed that rotaviruses enter by direct penetration, current models favor the hypothesis that virus entry is by endocytosis. Inside the cell, VP5 seems to induce a size-selective membrane permeabilization of the putative viral endosome that facilitates the transit of Ca^{2+} from the vesicle. When Ca^{2+} concentrations in the endosome are lowered, a disassembly of VP4 and VP7 is postulated to occur. This event permeabilizes the membrane of the endosome and the viral transciptase (viral particles without VP4 and VP7) gains access to the cytoplasm and begins to synthesize viral mRNAs. The mRNAs produced by the transcriptase are exact copies of each genome segment, with a 5′-terminal type 1 methylated cap structure and without a 3′-terminal poly(A) sequences.

The viral mRNAs are translated, giving rise to the structural and nonstructural proteins necessary to complete the viral replication cycle. NSP3 is reported to shut off the synthesis of cellular proteins and induces the preferential translation of viral proteins. These proteins accumulate in the cytoplasm in an electron dense region called the viroplasm, where the viral genome is replicated and the assembly of progeny double-layered particles takes place. The mechanism by which one viral particle assembles with each and only one of the 11 RNA segments is unknown. Synthesis of the dsRNAs occurs following the packaging of viral mRNAs into intermediate precursors of double-layered particles.

Assembled double-layered particles interact with NSP4, that has been synthesized by ribosomes associated with the endoplasmic reticulum (ER), and bud into the ER lumen. In this organelle, the double-layered particles acquire a transient lipid membrane. Then, in a very poorly understood mechanism (probably related to the high Ca^{2+} levels of the ER), the viral particles acquire VP7 and lose the transient enveloping membrane, giving rise to the triple-layered particle. Recent experiments suggest that VP4 is acquired by the viral particle in a compartment outside the ER.

The physiological mechanism of exit of the mature triple layer viral particle from the cell is unknown. In polarized Caco-2 cells (intestinal epithelial cells derived from a human colon adenocarcinoma), RV is released before cell death using a vesicle-associated vectorial transport system to the apical pole. However, rotaviruses are lytic viruses, and could also exit the cell after cell lysis. The mechanism of cell death induced by RV is not completely understood. Results in polarized Caco-2 cells and *in vivo* studies in mice suggest that it is by viral induced cell apoptosis.

Pathogenesis

Important viral antigenemia and some level of viremia are observed in the initial phase of RV-induced diarrhea in children and animals. In mice, extraintestinal viral replication occurs commonly during homologous and some

heterologous infections. Also in this model, the level and location of extraintestinal replication varies between RV strains and replication can occur in several leukocytes subsets. However, the clinical relevance of these findings is still unclear and, in children and in animals, the bulk of RV replication most likely occurs in the mature villus tip cells of the small bowel.

RV-induced diarrhea probably occurs by multiple mechanisms that vary, depending on the animal species analyzed (**Table 2**). Pathological findings in the small intestine of children with RV diarrhea include: shortening and atrophy of the intestinal villi, enterocyte vacuolization with distended cisternae of the endoplasmic reticulum, and mononuclear infiltration in the intestinal lamina propia. However, in children a direct relationship between the extent of histopathology and disease has not been demonstrated. This finding suggests that RV diarrhea can occur without important enterocyte death.

In pigs, RV infection induces an intestinal lactase deficiency and increased lactose in feces induces an osmotic diarrhea. Elevated levels of lactose are also observed in the feces of some RV infected children. Lactase deficiency could be due to RV-induced enterocyte destruction or to alteration in the synthesis or metabolism of disaccharidases. In mice, two mechanisms of diarrhea, which do not involve enterocyte destruction, have been identified. NSP4, and a derived peptide of NSP4, induce diarrhea in mouse pups but not adult animals, making it the first viral enterotoxin described. However, its role in RV-induced diarrhea in other species has not been characterized. Also in mice, RV has been shown to activate the intestinal autonomous neural system and increase the secretion of water and electrolytes, as well as the intestinal motility. Racecadotril, an inhibitor of the enteric nervous system, is somewhat efficacious in treating RV-induced diarrhea in children, suggesting that this mechanism plays at least some role in human diarrhea.

It is possible that the three mechanisms (malabsorption, NSP4 enterotoxicity, and enteric neural system stimulation) may play a major or minor role in the pathophysiology of RV-induced diarrhea, depending on the species and the time point after the onset of disease.

Diagnosis, Clinical Characteristics, and Treatment

Initial efforts to isolate wild-type rotaviruses in tissue culture were not very successful. For this reason, early clinical studies characterized rotaviruses by isolating viral RNA from feces and then analyzing the RNA by electrophoresis in polyacrylamide gels. Using this method, rotaviruses were classified depending on the pattern of migration of their RNA segments (electropherotypes). At present, this method seems of limited value because a relationship between electropherotypes and virulence or serotypes is not generally apparent. Currently, diagnosis is commonly conducted using commercial ELISAs that detect viral antigen (mostly VP6) in the feces. Rotavirus is shed in very large amounts making the ELISA a highly effective and accurate diagnostic assay. For epidemiological studies, human RV strains present in feces can be grown in cell culture in MA104 (African green monkey kidney) and Caco-2 cells using trypsin for enhancement of viral growth during the culture. Trypsin cleaves VP4 and increases infectivity in culture. Genotype characterization of RV strains is mainly by reverse transcription-polymerase chain reaction (RT-PCR). RV detection by electron microscopy is only conducted in research laboratories, especially when other viral pathogens are being investigated.

Rotaviruses are highly contagious since approximately 10^{11} particles per gram of feces are excreted, and they are very resistant to ambient conditions. In addition, viral excretion in most children lasts for up to 10 days and, in some children, may extend for 2 months after onset of infection. Rotaviruses are mainly transmitted by an oral–fecal route although, in some cases, a respiratory route has been suggested.

In developing countries, the peak incidence of RV disease occurs in children between 6 and 11 months of

Table 2 Mechanisms of RV-induced diarrhea (may vary according to the animal species studied)

Mechanism	*Comments*
Action of NSP4 as a toxin induces a secretory diarrhea	Only demonstrated in rodents. Non-CFTR mediated. Occurs early in infection prior to cell death
RV stimulates the enteric nervous system (ENS) inducing a secretory diarrhea and increased intestinal motility	Drugs that inhibit the ENS are useful to treat RV diarrhea. Occurs early in infection prior to cell death
Altered metabolism of disaccharidases and other enterocyte membrane proteins induces malabsorptive/osmotic diarrhea	Occurs early in infection prior to cell death
Enterocyte death contributes to malabsorptive/osmotic diarrhea	Late mechanism. In polarized intestinal epithelial cell lines and *in vivo* in murine enterocytes, RV infected cells seem to die by apoptosis

Reprinted from Franco MA, Angel J, and Greenberg HB (2006) Immunity an correlates of protection for rotavirus vaccines. *Vaccine*, 24: 2718–2731, with permission from Elsevier.

age. In contrast, in developed countries, the highest incidence is observed in older children (2 years old). This difference is probably related to differences in sanitation in the different settings. Notwithstanding this variation, RV incidence is similar in both developing and developed countries but mortality is mainly observed in developing countries, presumably due to limited access to appropriate health care. The relative protection of infants younger than 2 months of age, which occurs worldwide, could be related to the presence of protective maternal antibodies. Up to 50% of adults caring for children with RV diarrhea can become infected and, of these, 50% develop disease which is generally mild.

The primary clinical syndrome caused by RV infection is acute gastroenteritis. After a short incubation period of 48 h or less, children frequently present with vomiting that lasts for 1–2 days. The vomiting is often accompanied with fever (37.9 °C or greater). Subsequently, or at the same time, a watery diarrhea appears and, if it is not treated, frequently induces dehydration. It is estimated that up to 50% of RV infections in children are asymptomatic but some of these may represent second or third exposures.

Children attending day care institutions are at high risk of developing RV-induced diarrhea. Although RV infections in neonatal care units have been classically described as asymptomatic, probably due to the presence of maternal antibodies, severe symptomatic outbreaks have also been described. RV strains that induce nosocomial infections in neonatal nurseries are generally different from those circulating in the community. RV infection can cause severe and prolonged disease in children with primary immunodeficiencies, some of whom develop a systemically disseminated infection. Acquired immunodeficiency also predisposes to severe RV disease in bone marrow- and liver-transplanted children. The role of RV-induced disease in immunosuppressed adults with HIV seems, at present, less important.

RV diarrhea is self-limited and treatment is aimed at reducing symptoms until the immune response resolves the infection. Children with mild diarrhea are treated by oral rehydration. Those presenting moderate to severe dehydration may require intravenous rehydration. In cases of severe disease, treatment with probiotics, preparations that contain antibodies against RV, Racecadotril (an inhibitor of the enteric nervous system), and Nitasoxanide (a drug of unknown mechanism of action) have been shown to accelerate resolution of the disease. However, it is not yet clear whether these interventions truly provide significant advantages to ill children.

Immune Response

Immunity to RV is incompletely understood and animal models have been important in the acquisition of our currently available knowledge. Pepsin and gastric acid seem to be important host defense factors against RV infection, since these factors inactivate rotaviruses in adult mice but not in suckling mice. In addition, the innate immune response and interferons, in particular, seem to mediate an antiviral effect, and viral mechanisms for evading this response involving NSP1 have recently been suggested. However, mice lacking T and B cells become chronically infected with RV, suggesting that the adaptive immune system is essential for viral elimination. Also, children lacking T and B cells, or only B cells have been shown to shed virus chronically.

Antibodies seem to be the principal mechanism that mediates protection against viral reinfection. In agreement with the fact that most viral replication occurs in the intestine, the localization of virus specific B cells in the intestine seems important for their capacity to mediate protection. It is postulated that local IgA antibodies can mediate expulsion of rotaviruses inside the enterocytes and exclusion (to avoid *de novo* infection of enterocytes) of rotaviruses in the gut lumen. Neutralizing antibodies to VP4 and/or VP7 can block enterocyte infection directly when present in the gut lumen (exclusion). In mice, anti-VP6 non-neutralizing polymeric IgA may bind virus VP6 during transcytosis from the basolateral membrane of enterocytes to the gut lumen and 'expulse it'. These antibodies may also inhibit RV transcription intracellularly. In addition, antibodies to NSP4 may block diarrhea, but not infection, by blocking the enterotoxic property of the molecule. However, the antiviral effects of antibodies against VP6 and NSP4 have only been shown to be protective in mice. In piglets, a model that is probably closer to humans than mice, the presence of antibodies against VP4 and/or VP7 seems necessary for protection.

Although local antibodies appear to be the principal mechanism that protects against viral infection, T cells also directly mediate antiviral immunity, at least in mice. CD4+ T cells are also essential for the development of more than 90% of the RV-specific intestinal IgA, and thus their presence seems critical for the establishment of protective long-term memory responses. Moreover, murine RV-specific CD8+ T cells are involved in the timely resolution of primary RV infection and can mediate short-term partial protection against reinfection.

In children, primary RV infections are generally the most severe, with severity decreasing as the number of reinfections increases. Complete protection against moderate-to-severe illness is achieved after two natural RV infections, whether symptomatic or asymptomatic. In agreement with the results of animal models mentioned previously, total serum RV IgA, induced by a primary infection, seems to be the best but imperfect correlate of protection against subsequent reinfections. Primary RV

infection induces homotypic neutralizing antibodies to VP7 and VP4 and some level of heterotypic immunity, but the role in protection of these antibodies is still controversial. In this respect, it is noteworthy that an attenuated G1P[8] human RV vaccine has been shown to induce excellent protection against severe diarrhea caused by P[8] rotaviruses, independently of their G type. This vaccine can also induce protection against G2P[4] rotaviruses, but this protection is somewhat lower than against the P[8] viruses. Altogether, these findings suggest a role for neutralizing antibodies directed against VP4 in protection. However, since, as mentioned previously, P[4] viruses belong to a separate genogroup from most P[8] viruses, differences in immunity to other nonneutralizing viral proteins could also be the explanation for the relatively lower protection rate induced by the vaccine against P[4] viruses.

The lack of understanding of RV immunity limits our capacity to develop new RV vaccines. Recent studies have tried to characterize RV-specific lymphocytes in humans to better understand human immunity. Due to the relative inaccessibility for study of the human intestinal immune tissue, cells involved in the RV immune response have been studied in peripheral blood. It is hypothesized that at least a fraction of these lymphocytes are recirculating to and from the intestine, and thus may reflect intestinal immunity. In blood of children with acute RV infection, plasmablasts and plasma cells (secreting mainly RV specific IgM) are found, and these express homing receptors, that allow them to return to the intestine. In the convalescence phase, RV-specific B cells are mainly memory cells, some of which express intestinal homing receptors. In addition, RV-specific CD4+ and CD8+ T cells have been characterized. In children and adults with acute infection, both types of T cells that secrete gamma interferon circulate, but in unexpectedly low frequencies. It is speculated that the limited induction of RV-specific T cells can be related to the occurrence of delayed viral clearance and symptomatic reinfections in a subset of individuals.

Viral Vaccines

The first commercially available RV vaccine was a simian-human reassortant tetravalent vaccine (RotaShield). Although this vaccine was highly effective, it was withdrawn from the market 1 year after its introduction due to its temporal association with low levels of intussusception (1 in 10 000 children). Two new RV vaccines have been recently licensed for use in many countries worldwide. These vaccines appear to be safe and not cause intussusception. The vaccine produced by Merck (RotaTeq^{TM}) contains mono-reassortants of a bovine virus with G1, G2, G3, G4, and P1A[8] human RV genes. The vaccine produced by GlaxoSmithKline (GSK, Rotarix) is a human-attenuated G1P1A[8] virus. In trials that involved over 60 000 infants, both of these vaccines have been shown to be safe and to provide over 70% protection against any RV diarrhea and over 98% protection against severe RV infection. Importantly, both vaccines reduced the rates of all gastroenteritis-related hospitalizations of any cause by over 40%. Despite these encouraging results, it is still undetermined if these vaccines will work in very poor developing countries in Africa and Asia in which children can be malnourished and in which atypical RV strains may circulate frequently. Moreover, the intussusception associated with RotaShield was predominantly seen in children older than 2 months, and the children studied in the safety evaluation of the two new vaccines were mostly 2 months of age. Thus, the safety of the new RV vaccines in children of more than 2 months of age has not been fully established and the development of second-generation vaccines may be desirable. A promising strategy to drastically reduce the risk of intussusception is to administer the vaccine to neonates, in whom intussusception almost never occurs. Current studies in animal models are focused on the development of second generation nonreplicating RV vaccines, such as DNA vaccines, and recombinant RV proteins or virus-like particles.

Glossary

Birth defects Malformations or abnormalities developed during gestation that are apparent at, or soon after, delivery.
Congenital infection Infection of the fetus during gestation as a result of virus passage through the placenta.
Elimination program Vaccination program designed to eliminate 'indigenous' sources of a pathogen from a geographic region and thus restrict sources of the pathogen to imports from other regions.
Enveloped virion Virus particle with a lipid bilayer membrane, or envelope, surrounding the capsid or core. The envelope is usually derived from host cell membranes and contains virus-specified glycoproteins decorating its outer surface.
Icosahedral capsid In the virus particle, the proteinaceous shell surrounding the virus genome – in this case, with symmetry of an icosahedron (appears quasi-spherical or round in electron micrographs).
Live, attenuated vaccine A vaccine formulation using an infectious variant of the virus that has been attenuated or weakened by repeated passage in cell culture or alternate hosts. Such vaccines recapitulate the infection, including induction of a complete adaptive immune response, but do not cause disease.
Persistent infection Infection characterized by continued presence of the virus, often despite the induction of an adaptive immune response.
Plus-strand RNA virus Virus with a single-stranded RNA genome that is of messenger RNA sense and can be directly translated to produce virus-specified proteins.
Serodiagnosis Detection or diagnosis of infection through immune status, usually the presence of IgM antibodies or a rise in IgG antibodies in paired sera collected at the time of symptoms and convalescence (post-recovery).
Systemic infection Infection that spreads from local site entry via the lymphatic system and blood stream to one or more target internal organs or tissues.

Introduction

Rubella virus (RUBV) infection causes a benign disease known as rubella or German measles that can result in profound birth defects if contracted *in utero*. Norman Gregg, an Australian ophthalmologist, first reported the association of congenital cataracts as a consequence of gestational rubella in 1941, establishing RUBV as a major teratogen. The last major epidemic of rubella to impact the United States occurred in 1964–65, resulting in 20 000 congenital rubella syndrome (CRS) cases, and subsequently live, attenuated vaccines were developed and applied in the US, Canada, Japan, and several European countries by 1969. These programs have been successful in greatly reducing the incidence of both rubella and CRS in these countries, particularly the US, in which indigenous rubella was declared eliminated in 2004. Currently, ~50% of countries have national rubella vaccination programs, but the majority of the world's population is not covered and rubella thus remains a worldwide challenge.

Classification

RUBV is a member of the family *Togaviridae* and the only member of the genus *Rubivirus*. The other togavirus genus, *Alphavirus*, contains 26 members, all of which are arthropod-borne. In common with the alphaviruses, the rubella virion consists of a single-stranded, plus-sense genomic RNA contained within a quasi-spherical core or capsid, composed of a single virus-specified protein, C, which is surrounded by a lipid envelope in which are embedded two virus-specified glycoproteins, E1 and E2. Unlike alphaviruses, RUBV has no invertebrate vector and the only known natural reservoir is humans. RUBV also is antigenically distinct from the alphaviruses. Phylogenetic analysis of E1 gene nucleotide sequence of worldwide RUBV isolates has led the World Health Organization to propose a standardized taxonomy for RUBVs which consists of two clades, 1 and 2, and genotypes within each clade. Clade 1 contains seven genotypes and is distributed worldwide. Clade 2 contains three clades and appears to be restricted to Asia.

Host Range and Virus Propagation

RUBV has no known natural host other than humans. No reliable animal model exists for the study of RUBV

pathogenesis. RUBV replicates in a number of laboratory cell culture lines; however, in most of these no cytopathic effects (CPEs) are routinely observed. Continuous cell lines commonly used to propagate RUBV include Vero (African green monkey kidney), RK-13 (rabbit kidney), and BHK-21 (baby hamster kidney). In all cell lines in which RUBV replicates, persistent infections are readily established and maintained, whether or not the cell line exhibits a functional interferon system, and persistent RUBV infection in cell culture cannot be cured by the inclusion of neutralizing antibodies in the culture medium because virus budding occurs at intracytoplasmic locations. Thus, RUBV is highly adapted for persisting infection.

Properties of the Virion

Rubella virions are 60–70 nm spherical particles composed of an electron-dense core separated from the lipid envelope by an electron-lucent zone. Rubella virions exhibit a marked degree of pleomorphism (**Figure 1**). The virion has a density of 1.18–1.19 g ml^{-1}, whereas isolated capsids have a density of 1.44 g ml^{-1}. The C protein (~34 kDa), which comprises the capsid, is present as disulfide-linked homodimers. Although presumed to be icosahedral, the symmetry of the RUBV capsid has not been solved.

The virion spikes are formed by two virion glycoproteins, E1 and E2. E1 has a molecular weight of 59 kDa whereas E2 is a heterogeneous species ranging from 44 to 50 kDa due to differential glycosylation. Both E1 and E2 appear to be primarily in the form of heterodimers which are easily disrupted by routine preparation techniques. The higher-order architecture of the virion spikes is entirely unclear. E1 is more exposed on the virion surface than is E2, contains both the viral hemagglutinin and receptor site, and is also immunodominant in terms of the humoral response.

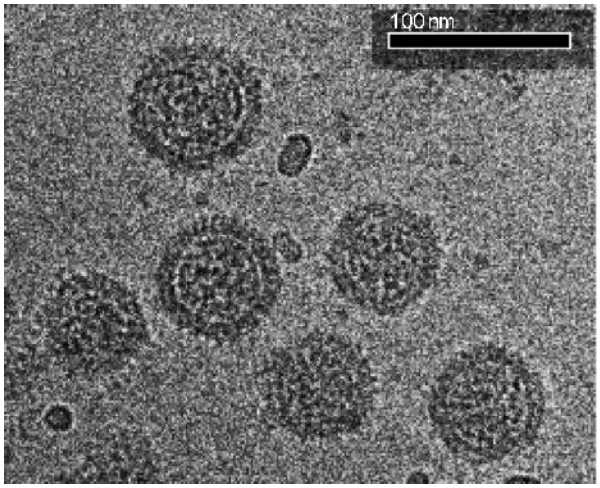

Figure 1 Cryoelectron micrograph of rubella virions. Unlike conventional negative staining, the virions have a uniform structure when visualized by this technique; however, pleomorphism of particle diameter and the gap between the core and envelope remains apparent. Courtesy of Tao Sun, Yumei Zhou, Michael Rossmann, and Teryl Frey (unpublished data).

Rubella virions are stable at physiological pH values and can be frozen at temperatures below –20 °C for years, without loss of infectivity. Live, attenuated vaccine virus is stored in lyophilized form. Rubella virions are susceptible to most commonly used inactivating agents, such as formaldehyde, UV light, and lipid solvents.

Genomic Organization

The RUBV genomic RNA is 9762 nucleotides in length and contains a 5′ terminal cap structure and a 3′ terminal poly(A) tract. A distinctive feature of the genomic RNA is that it contains 30% guanine residues and 39% cytosine residues, the highest G+C content of all RNA viruses. The genome contains two long, nonoverlapping open-reading frames (ORFs) plus untranslated regions (UTRs) at the 5′ and 3′ ends and between the ORF's (**Figure 2**). The 5′ proximal ORF, or nonstructural proteins ORF (NS-ORF), encodes a 2116-amino-acid product that is proteolytically cleaved into two products, 150 kDa (P150) and 90 kDa (P90), which are at the N- and C-termini of the ORF, respectively. The cleavage is mediated by a papain-like cysteine protease located at the C-terminus of P150. P150 and P90 are responsible for virus RNA replication. By computer-assisted comparisons with other viruses, P150 contains a domain predicted to have methyl/guanylyltransferase activity (responsible for forming the cap structure at the 5′ end of the genomic and subgenomic RNAs) in addition to the protease, whereas P90 contains both a helicase domain and an RNA-dependent RNA polymerase (or replicase) domain. The 3′ proximal ORF, or structural protein ORF (S-ORF), encodes a 1063-amino-acid product that is proteolytically processed into the virion proteins by a cell protease, signal endopeptidase. The order of the virion protein genes within the ORF is 5′ C-E2-E1 3′. The S-ORF is translated from a subgenomic RNA synthesized in infected cells and containing the sequences from the start site through the 3′ end of the genome. An infectious clone for RUBV has been developed. An infectious clone is a cDNA copy of the viral RNA contained in a plasmid in which it is placed adjacent to an RNA polymerase promoter. Since RUBV has a plus-sense genome, *in vitro* transcripts from the plasmid will initiate virus replication following transfection into susceptible cells. The infectious clone allows for studies of the effects of site-directed mutagenesis on the RUBV genome.

Intracellular Replication Cycle

The receptor for RUBV on the surface of susceptible cells has not been identified. Following attachment to the receptor, the virus is taken into the cell by receptor-mediated endocytosis. In the reduced pH environment of the endocytic vesicle, fusion between the viral envelope and the vesicular membrane occurs, releasing the capsid and genomic RNA into the cytoplasm of the cell.

The genomic RNA is translated to produce the NS protein precursor which is cleaved into P150 and P90 (**Figure 3**). These proteins then use the genomic RNA

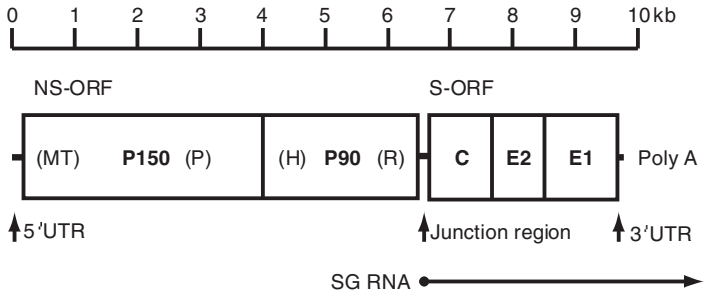

Figure 2 Coding strategy of the RUBV genome. Shown is a schematic representation of the RUBV genomic RNA with untranslated regions (UTRs) drawn as solid black lines and coding regions (ORFs) as open boxes (NS-ORF, nonstructural protein ORF; S-ORF, structural protein ORF). Within each ORF, the coding sequences for the proteins processed from the translation product of the ORF are delineated and, in addition, within the NS-ORF, the locations of motifs associated with the following activities are indicated: methyl/guanylyltransferase (MT), protease (P), helicase (H), and RNA-dependent RNA polymerase (R). The sequences encompassed by the subgenomic RNA (SG RNA) are also shown. The scale at the top of the diagram is in kilobases.

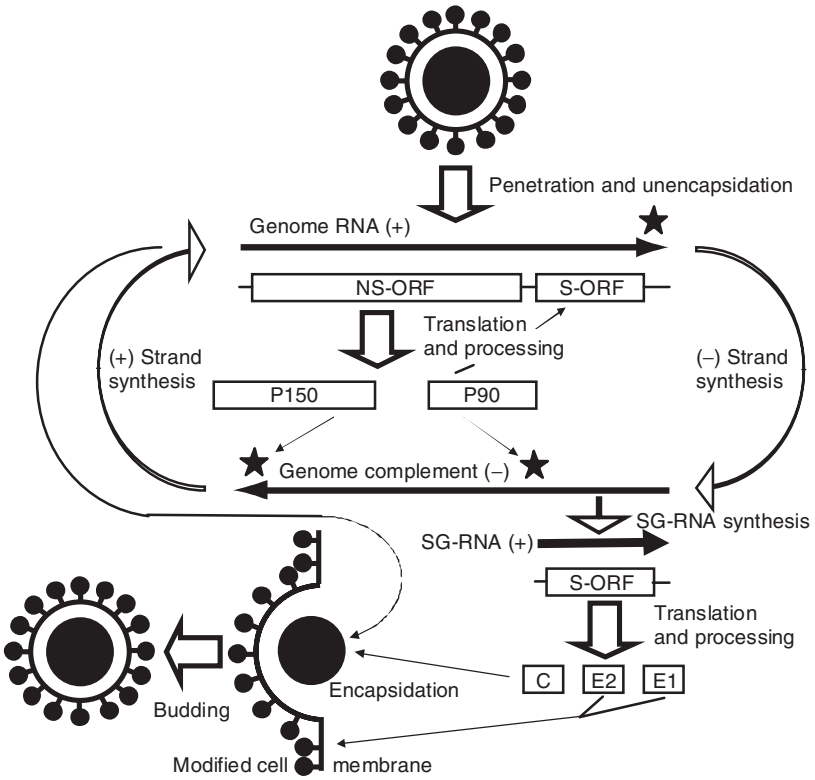

Figure 3 Replication strategy of RUBV. The plus-sense genome and subgenomic RNA are represented by solid black arrows indicating plus polarity; beneath each, the ORFs that they contain are shown as open boxes. The minus-sense genome RNA complement, represented as a dotted arrow, is used solely as a template for the two plus-sense RNA species. Putative *cis*-acting sequences on each RNA, which are recognized by the virus RNA-dependent RNA polymerase to initiate synthesis of complementary RNAs, are marked with stars. The general functions of the virus proteins are indicated by arrows (e.g., P150 and P90 functioning as the RNA-dependent RNA polymerase by interacting with *cis*-acting sequences on the viral RNA species and synthesizing complementary strands).

as a template for synthesis of a genome-length, minus-sense RNA. The genome-length, minus-sense RNA is then used as the template for synthesis of both the genomic RNA and the subgenomic RNA. Synthesis of the subgenomic RNA is initiated by internal recognition of sequences on the genome-length, minus-sense RNA template. Host-cell proteins are likely involved in the replication process and, interestingly, recent evidence indicates that the C protein is as well. RNA synthesis is asymmetric in infected cells in that more of the plus-sense species than the minus-sense RNA is produced. The uncleaved NS protein precursor is active in minus-strand RNA synthesis, while the cleaved P150/P90 complex appears to be active in only plus-strand RNA synthesis. Thus the activity of the NS protease through mediating this cleavage is important in regulating plus- and minus-sense RNA synthesis. RUBV RNA synthesis occurs in cytopathic vacuoles of lysosomal origin, in infected cells.

In the structural protein ORF, E2 and E1 are immediately preceded by hydrophobic signal sequences that function to direct translation of secreted and membrane-associated proteins into the lumen of the endoplasmic reticulum (ER). Therefore, following translation of the C sequences within the ORF, the E2 signal sequence mediates association of the translation complex with the ER. C–E2 cleavage is mediated by signal endopeptidase, or signalase, which functions in the lumen of the ER to remove signal sequences from secreted and membrane-associated proteins; unlike the proteins of the alphaviruses, RUBV C protein does not have autocatalytic protease activity. Following cleavage, the E2 signal sequence remains associated with C. Similarly, the E1 signal sequence maintains the association of the translational complex with the ER, signalase mediates the E2–E1 cleavage, and the E1 signal sequence remains attached to E2. Soon after synthesis, heterodimerization of E2 and E1 occurs in the lumen of the ER. The three-dimesional folding of E1 appears to be a complicated process requiring intramolecular disulfide-bond formation by all 20-Cys residues in the ectodomain of the protein. Both E1 and E2 acquire high-mannose glycans in the ER; E1 contains three potential glycosylation sites and E2 contains four and all appear to be utilized. The sites of O-glycosylation of the E2, which accounts for the size heterogeneity of E2, is not known. E1 contains an ER retention signal that is only overridden once conformational folding is complete, after which the E1–E2 heterodimer migrates to the Golgi. In the Golgi the N-glycans of both E2 and E1 are modified to complex form, although modification is not complete and the extent of modification on both proteins is heterogeneous. Modifications of the O-glycans on E2 also occur and E2 contains a Golgi retention signal, indicating that the Golgi is the preferred site of viral budding in infected cells. However, late in infection E1 and E2 migrate to the cell surface and budding can also occur at this site in some cell lines.

RUBV capsid morphogenesis occurs in association with cell membranes. The association of RUBV capsid protein with membranes is probably mediated by the E2 signal sequence, which is retained at the COOH terminus of C. In fact, C may associate with the E2–E1 heterodimer and migrate as a passenger on the cytoplasmic side of vesicles transporting E2–E1 from the ER to the Golgi and among the Golgi stacks. Unlike the alphaviruses, whose capsids accumulate in infected cells, RUBV capsids only become visible in association with deformed, thickened membranes that appear to be in the early process of budding. A putative encapsidation signal has been localized near the 5′ terminus of the genomic RNA. The C protein is phosphorylated and phosphorylation/dephosphorylation by cell enzymes is proposed as the regulator of the process by which the genome is unencapsidated following entry (phosphorylation) and encapsidated later in infection following replication (dephosphorylation). Interestingly, in cells in which the complete S-ORF is expressed in the absence of genomic RNA, virus-like particles form and are secreted and these have the same morphology and isopycnic density as do virions.

RUBV replicates in the cytoplasm of the infected cell. None of the virus proteins exhibit any involvement with the nucleus during infection and RUBV infection does not appear to inhibit cell macromolecular synthesis in any grossly detectable manner; however, perturbations of specific macromoleclar products and induction of specific genes may occur. Microsopically, RUBV-infected cells appear similar to uninfected cells; however, rearrangements of cellular cytoskeletal elements and organelles such as mitochondria have been reported. RUBV reportedly inhibits growth in primary human cell cultures in part due to an inhibition of mitosis; however, the virus has no reproducible effect on the growth of stable cell lines. In those cell lines which exhibit CPE (Vero and RK-13 cells), cell death is due to apoptosis.

Genetics and Evolution

The RUBV genome is extremely stable. Currently, the genomes of 19 independent strains of RUBV from eight genotypes, five in clade 1 and three in clade 2, have been sequenced in their entirety and all are nearly identical in terms of the size of the genome as well as the coding and noncoding regions within the genome. The only exceptions are 1–2 nucleotide deletions occasionally encountered in the junction region. Maximal observed distance at the nucleotide level is 5% among clade 1 viruses, 7.5% among clade 2 viruses, and 9% between viruses in the two clades. Across the 19 genomic sequences, 78% of the nucleotides are conserved, explaining the low level of variability. A unique feature of RUBV evolution is that

changes to G and C are selected for, indicating an adaptive advantage of the high G+C content of the genome.

Because there are no known close relatives of RUBV, the origin of the virus prior to its introduction into the human population is unknown. Except for short stretches at the 5′ end of the genome and at the subgenomic promoter site, RUBV and the alphaviruses share no nucleotide homology. Thus these two genera are only distantly related. RUBV and the alphaviruses belong to the 'alphavirus-like superfamily' of plus-sense RNA viruses, which includes a large number of plant viruses as well as human hepatitis E virus, the sole member of the genus *Hepevirus*. Within this superfamily, computer-assisted phylogenetic analysis of the NS proteins indicates that RUBV is more closely related to hepatitis E virus than to the alphaviruses and this dissimilarity is borne out by differences in the order of motifs in the NS-ORF. Thus, it is hypothesized that the evolution of the togaviruses may have been more complicated than simple divergence from a common ancestor and probably involved recombination between progenitors of the current alphaviruses, RUBV, hepatitis E virus, and, possibly, certain plant viruses.

Serologic Relationships and Variability

RUBV is monotypic and immunological characterization of diverse strains, including both clade 1 and 2 viruses, has only revealed subtle antigenic differences which map to C or E2. As might be anticipated from the lack of serologic cross-reaction with the alphaviruses, there is no homology at the amino acid level between RUBV and alphaviruses within the virion proteins.

Epidemiology

Historically, RUBV was endemic worldwide. Over the past 35 years, vaccination programs have curtailed this distribution, as discussed below. Before the advent of vaccination programs, rubella was considered a disease of middle childhood in temperate zones, with seasonal peak occurrence in the spring and epidemics at 5–9-year intervals. However, in tropical zones the highest infection rates were in children under 5 years of age. RUBV is not as transmissible as is measles virus and even during epidemics, susceptibles are spared. Thus, infection of adolescents and young adults, the population at risk for CRS, in endemic areas is not uncommon.

Transmission and Tissue Tropism

RUBV is transmitted between individuals by aerosol. The epithelium of the buccal mucosa provides the initial site for virus replication and the mucosa of the upper respiratory tract and nasopharyngeal lymphoid tissue serve as portals of virus entry. The virus is then spread by local lymphatics, which seed regional lymph nodes where further virus replication occurs. After an incubation period of 7–9 days, virus appears in the blood. Viremia ceases with the onset of detectable rubella-specific antibody, shortly after the rash appears 2–3 weeks post infection. Patients are most infectious immediately preceeding and during the rash phase; virus generally disappears from nasopharyngeal secretions within 4 days of appearance of the rash. Congenitally infected infants shed virus for 3–6 months following birth and are a source of transmission during that period. Reinfection with RUBV occurs, usually without clinical illness or virus shedding. There are a small number of cases in which RUBV reinfection of pregnant women with well-documented immunity has resulted in CRS.

During pregnancy, placental tissues are very susceptible to infection. Placental infection results in scattered foci of necrotic syncytiotrophoblast and cytotrophoblast cells and evidence of damage to vascular endothelium. Following placental infection, virus can spread to the fetus but this does not always occur and RUBV is more often recovered from placental tissue than from fetal products of conception. Once fetal infection occurs, virus spreads throughout the fetus and almost any organ may be infected. Severe fetal damage is only associated with infection during the first trimester of pregnancy; the rate of CRS is >50%, 25%, and 10% when infection occurs during the first, second, and third months, respectively. This is due to a combination of an apparent decline in the efficiency of placental transfer after the first trimester and a reduction in the ability of the virus to inflict fetal damage after this time of gestational development.

Clinical Features of Infection

Rubella acquired in childhood or early adulthood is usually mild and it is estimated that up to 50% of rubella infections are clinically inapparent. Symptomatic rubella encompasses combinations of maculopapular rash, lymphadenopathy, low-grade fever, conjunctivitis, sore throat, and arthralgia. The rash is the most prominent feature and appears following an incubation period of 16–20 days. The rash begins as distinct pink maculopapules on the face that then spread over the trunk and distally onto the extremities. The maculopapules coalesce and the rash fades over several days. An associated posterior cervical and suboccipital lymphadenopathy is also characteristic. Infrequent complications include thrombocytopenia and post-infectious encephalitis. Acute polyarthralgia and arthritis following natural RUBV infections of adults are common and occur more frequently and with greater severity in women than in men. Joint involvement is

usually transient; however, chronic arthritis, persisting or recurring over several years, has been reported.

The clinical manifestations of CRS apparent at birth vary widely, most frequently including thrombocytopenic purpura ('blueberry muffin syndrome'), intrauterine growth retardation, congenital heart disease (patent ductus arteriosus or pulmonary artery or valvular stenosis), psychomotor retardation, eye defects (cataract, glaucoma, retinopathy), hearing loss, and hepatomegaly and/or splenomegaly. Nearly 80% of CRS children show some type of neural involvement, particularly neurosensory hearing loss.

Most clinical manifestations of congenital rubella are evident at or shortly following birth and some are transient. However, recognition of retinopathy, hearing loss, and mental retardation may be delayed for several years in some cases. Progressive consequences of congenital rubella have become increasingly appreciated as CRS children from the 1964 epidemic have been followed longitudinally. These predominantly involve endocrine dysfunction (diabetes mellitus, which ultimately affects 40% of CRS patients, and thyroid dysfunction). A rare, fatal neurodegenerative disease, progressive rubella panencephalitis (PRP), described in CRS patients, bears superficial resemblance to subacute sclerosing panencephalitis associated with measles virus. Subsequently, PRP cases have been reported in individuals infected postnatally.

Pathogenesis, Pathology, and Histopathology

There is limited information on the pathogenesis of uncomplicated rubella because of the benign nature of the illness. With respect to the complications that can accompany acute rubella, the postinfectious encephalitis is thought to be autoimmune in nature since RUBV cannot be isolated from cerebrospinal fluid or brain at autopsy. Interestingly, however, extensive inflammation and demyelination are not observed. In a few cases of rubella arthritis, the presence of RUBV in synovial fluid and/or cells has been demonstrated and therefore it is assumed that virus persistence is involved. However, considering the age and sex factors in the incidence of arthritis, it seems likely that immunopathological mechanisms also play a role. In one study, human leukocyte antigen (HLA) class II haplotypes predisposing adult women to arthritis and arthralgia following rubella vaccination were found to also correlate with predisposition to arthritis and arthralgia regardless of vaccination status.

Following fetal infection, virus can be isolated from practically every organ of abortuses or infants who die soon after birth. However, only 1 in 10^3 to 1 in 10^5 cells are infected and it is not known how such a low infection rate leads to the profound birth defects exhibited in CRS. Affected organs are routinely small for gestational age and contain reduced numbers of cells. Considering the inhibitory effect of RUBV on primary cells, it is thought that virus infection early in organogenesis inhibits cell division, leading to both retardation and alteration in organ development. Virus persistence continues after birth, as evidenced by virus shedding, which generally ceases within 6 months of age. Whether virus persistence continues beyond cessation of shedding and plays a role in the delayed and progressive manifestations of CRS is not known.

Histologically, affected organs of CRS patients show a limited number of well-recognized malformations, with noninflammatory histopathology predominating. Particularly apparent are vascular lesions and focal destruction in tissue bordering these lesions. These lesions are likely to be due to virus replication in the vascular endothelium and damage to neighboring tissue may play a role in the pathogenesis of CRS. The neuropathology of CRS is of interest not only because of the defects manifest shortly after birth, but also because some CRS patients develop schizophrenia-like symptoms later in life. CRS brains are generally free of gross morphological malformations, with a common tendency toward microcephaly. Vascular damage, leptomeningitis, decreased number of oligodendroglial cells, and alteration of white matter are observed. Recently, magnetic resonance imaging of a group of CRS adults with schizophrenia-like symptoms revealed specifically reduced cortical gray matter and enlargement of the ventricles, which were not previously observed aspects of CRS-induced neuropathology. Interestingly, the comparative finding that non-CRS schizophrenia patients exhibit a pattern of brain dysmorphosis similar to that found in CRS patients with schizophrenia-like symptoms supports the hypothesis that schizophrenia is developmental in nature (there is some evidence for a viral trigger to schizophrenia).

Immune Response and Serodiagnosis

Following acute infection, anti-RUBV IgM antibodies are detectable at the time of rash onset and for a month or two afterwards, so that serodiagnostic testing for the presence of IgM is the current primary means for diagnosis of acute RUBV infection; in the succeeding weeks anti-RUBV antibodies in all immunoglobulin classes appear. The dominant early and persistent IgG response is in the IgG_1 subclass and antibodies of this class persist indefinitely after natural infection of otherwise healthy individuals. The majority of the antibody response is directed to the E1 glycoprotein, with proportionally lesser amounts of the response directed at E2 or C. Although neutralizing and complement-fixing antibodies are induced as well, the

classical assay for the presence of anti-RUBV antibodies has been hemagglutination inhibition (HAI) and the current standard level of 10 IU ml ^{1} is based on an HAI titer of roughly 8. Because of the importance of serodiagnostic testing for rubella, a worldwide commercial market for rubella tests exists and a number of commercial laboratories offer such kits, most of which are based on latex agglutination or enzyme immunoassay.

RUBV-specific cellular immune responses are measurable within 1–2 weeks of onset of illness. Major histocompatibility complex (MHC)-restricted CD4+ epitopes have been mapped to all three of the virus structural proteins; however, CD8+ epitopes have thus far only been mapped to the C protein. HLA class I and II alleles both positively and negatively associated with antibody and lymphoproliferative responses following rubella vaccination have recently been determined.

Following fetal infection, the fetus produces IgM antibody, detectable at 18–20 weeks of gestation, and maternal IgG antibody crosses the placenta. Both types of antibody exhibit virus-neutralizing activity *in vitro*; however, neither is sufficient to resolve virus infection during gestation. As discussed above, the intracellular maturation of virus probably shields it from antibody. After birth, the presence of IgM or a lack of decline of IgG titer are both considered diagnostic of fetal infection. CRS infants exhibit various degrees of impairment in the cellular immune response to RUBV and it is thus a deficiency in this arm of the immune response that allows the virus to persist. Considering the cellular immune deficiency in CRS infants, it is curious that detectable virus persistence ends relatively shortly after birth. The means by which virus persistence is cleared under these conditions is not understood.

Diagnosis

The common symptoms of acute rubella, lymphadenopathy, erythematous rash, and low-grade fever, are nonspecific and easily confused with illnesses caused by other common pathogens. A definitive diagnosis of rubella requires detection of the presence of IgM antibodies or a rise in IgG antibodies in paired acute-phase and convalescent-phase serum samples. Virus is also readily isolated from saliva or nasopharyngeal washings at the time of rash onset. Reverse transcription-polymerase chain reaction (RT-PCR) assays have been developed to detect virus in saliva, blood, or urine. Generally, virus isolation is only done to collect specimens for molecular epidemiological analysis. Diagnosis of acute rubella is of utmost importance during early pregnancy. There is no intervention for congenital rubella other than abortion; however, as discussed above, maternal infection does not always lead to CRS, resulting in an extremely difficult decision. RT-PCR can be used to detect virus RNA in amniotic fluid or chorionic villi, but is rarely employed. Diagnosis of CRS in a newborn is initially made on the basis of symptoms and confirmed in the laboratory by serological testing for the presence of IgM antibodies, by lack of decrease of IgG antibodies in serum specimens, or by detection of virus or virus RNA. As stated above, CRS infants shed virus and therefore are a source of contagion.

In countries with vaccination programs, the need for detection of acute rubella is rare. However, serodiagnosis for determination of immune status is routine for pre-pregnancy planning, employment in medical facilities and, in some states in the US, to obtain a marriage license. Serodiagnosis can also be used in lieu of proof of vaccination, which is required for school enrollment. Individuals found to be seronegative are subsequently vaccinated, which is done postpartum in the case of a woman who is pregnant at the time of testing.

Prevention and Control of Rubella

As discussed above live, attenuated vaccines were developed and placed in use by 1970. The vaccine used in most countries is the RA 27/3 vaccine. In Japan, five live, attenuated vaccine strains were developed and are currently in use. Additionally, at least one Chinese vaccine strain is currently in use in China.

Attenuated RUBV vaccines cause subclinical infection with transient viremia in susceptible patients. Natural transmission of vaccine virus has not been reported. The RA27/3 vaccine strain produces seroconversion in greater than 95% of recipients. Vaccine-induced titers are lower than those induced by natural infection but appear to last indefinitely. The RUBV vaccine is generally administered to children in trivalent form with the measles- and mumps-attenuated vaccines (MMR) but inclusion of the recently licensed varicella vaccine in a tetravalent vaccine is being strongly considered.

The RUBV vaccines have been among the most successful in terms of induction of immunity with an absence of side effects. However, two issues have arisen concerning rubella vaccination. The first is that the vaccine virus can cross the placenta and infect the fetus. However, US and Israel registries of deliveries to women inadvertently vaccinated during early pregnancy revealed no reported congenital abnormalities. Similar findings were reported in subsequent studies conducted in other countries in conjunction with mass vaccination campaigns. Nevertheless, vaccination during pregnancy is contraindicated and

is deferred until postpartum. Second, is the occurrence of arthralgia and arthritis following vaccination. Joint complications are nonexistent in children with the currently used rubella vaccines; however, transient arthralgia and arthritis is reasonably common among adult female vaccinees. There have also been reports of chronic arthritis and related neurological involvement following vaccination of adult women. Although these complications are consistent with complications that can accompany natural rubella in adult females, recent studies have shown that the incidence of such vaccine-related complications is low and cannot be statistically differentiated from the incidence of similar symptoms in control, unvaccinated populations.

Since the inception of rubella vaccination in 1969, the US has employed a strategy of universal vaccination at 15 months of age augmented with vaccination of seronegative 'at-risk' individuals (women planning pregnancies, healthcare workers) which was successful in bringing the incidence of rubella and CRS to low levels by 1988. A resurgence of rubella and CRS that occurred between 1989 and 1991 among foci of unvaccinated individuals led, in part, to administration of a second dose of MMR vaccine when the recipients were between 5 and 10 years of age. After 2000, the incidence of rubella fell to fewer than 25 cases per year and in 2004 and it was concluded that indigenous rubella had been eliminated from the US. Vaccination programs have also been in place in Europe and Japan since the development of live, attenuated vaccines; however, developing countries were slower to institute rubella vaccination programs. However, efforts among developing countries have accelerated since 2000, particularly in conjunction with ongoing measles elimination efforts, and currently roughly 50% of countries worldwide have national rubella vaccine programs. The World Health Organization Regions of the Americas and Europe have set goals for elimination of rubella and CRS by 2010.

Despite the recent increase in intensity of rubella vaccination efforts worldwide, most of Asia and Africa are not currently included and thus well over half of the world's population is not covered. The cost of the vaccine, the general mildness of the disease, and the nature of national public health infrastructures are deterrents to vaccination programs in developing countries. Moreover, estimates of CRS incidence are difficult to obtain because the three hallmark symptoms of CRS, deafness, blindness, and mental retardation, are not uniformly present and are not readily diagnosable in newborns. Surveys in developing countries show that the rate of CRS in developing countries is the same as that in developed countries prior to vaccination and a recent economic analysis concluded that the cost/benefit ratio for rubella vaccination was similar to that for hepatitis B vaccination, a pathogen that is universally recognized to impart a societal load. Nevertheless, the success of worldwide rubella vaccination appears dependent on piggy-backing on global measles vaccination programs. In addition to its efforts to initiate rubella vaccination programs in developing regions, the WHO established a global Measles–Rubella Surveillance Network in 2003. Interestingly, rubella vaccination and the concomitant reduction in rubella simplifies measles surveillance which requires diagnosis of rubella because of the similarity of symptoms of the two diseases. A major modification in measles/rubella vaccination may be forthcoming in the form of aerosolized vaccines. Aerosol administration mimics the natural route by which these two viruses are contracted and preliminary studies show that aerosolized vaccine uptake and efficacy is as good as or better than the current injection route. Use of aerosolized vaccines would reduce vaccination costs by eliminating needles and the concomitant need for trained personnel for administration. Finally, it is emphasized that rubella reduction in developing countries imparts benefit to developed countries, in which most rubella outbreaks are due to importation, by decreasing such outbreaks and thus easing control efforts. However, discontinuation of rubella vaccination in developed countries would require eradication.

Future

Because of its clinical similarity to any of a diverse group of clinical diseases, RUBV will remain a fascinating pathogen. As an example, the incidence of diabetes in CRS patients is the best statistically direct association between a specific human virus and a specific autoimmune disease. The mechanism of viral involvement, if any, in each of these diseases is not fully understood. Elucidating the mechanism of RUBV-induced birth defects could also provide understanding into teratogenesis by other infectious agents. Unfortunately, our present understanding of disease mechanisms in the RUBV-related syndromes is hindered by the lack of a suitable animal model system that fully mimics the infection seen in humans, making development of an animal model a research priority. RUBV is taxonomically unique and appears to have evolved as a recombinational hybrid of distantly related ancestor viruses. Thus, investigation of the molecular biology of RUBV likely will reveal novel replication strategies and yield insight into virus evolution. The greatest challenge concerning RUBV is the current and forthcoming elimination efforts in most regions of the world.

Glossary

Natsudaidai A popular sour citrus grown in some parts of Japan.
Satsuma A major mandarin-type citrus grown in Japan and some other Asian countries.

Introduction

The genus *Nepovirus* includes viruses which are transmitted by nematodes with polyhedral particles. Typical nepoviruses have a broad host range, a single coat protein, and a bipartite single-stranded RNA genome and are transmissible through seed. Sadwaviruses have been previously considered atypical and tentative members of the genus *Nepovirus*. Like typical nepoviruses, sadwaviruses have polydedral virus particles which contain two species of genomic RNA, but can be distinguished on the basis of the genome organization, sequence homologies, and the number of coat proteins. Some sadwaviruses are transmitted by aphids.

The derivation of the name comes from the virus species, *Satsuma dwarf virus*, the type member of the genus *Sadwavirus*. The major disease caused by satsuma dwarf virus (SDV) is stunting, accompanied by the presence of boat-shaped leaves, in Satsuma mandarin (*Citrus unshiu* Marc.).

Taxonomy and Classification

Satsuma dwarf virus, *Strawberry latent ringspot virus*, and *Strawberry mottle virus* are the definite members of the genus *Sadwavirus*. Lucerne Australian symptomless virus (LASV), Rubus Chinese seed-borne virus (RCSV), and Black raspberry necrosis virus (BRNV) are tentative members (**Table 1**).

Virus species are demarcated on the basis of type of biological vector, if known, host range, absence of serological cross-reaction, absence of cross-protection, and difference in amino acid sequence (less than 75% in the large coat protein and the proteinase-polymerase region).

The genus *Sadwavirus* has not been assigned to any virus family.

Strains and Synonyms

Citrus mosaic virus (CiMV), natsudaidai dwarf virus (NDV), and navel orange infectious mottling virus (NIMV) are distantly related strains of *Satsuma dwarf virus*. Typical symptoms of CiMV-infected Satsuma mandarin are spotting and blotching of the fruit rind. NDV induces vein clearing and mottling on new leaves of nastudaidai (*Citrus natsudaidai*). NIMV produces persistent chlorotic spots on leaves of sweet orange. The strains of *Satsuma dwarf virus* share around 80% sequence homology at the amino acid level.

Strawberry latent ringspot virus has a few synonyms, including rhubarb virus 5. Some isolates from olive, peach, raspberry, and grapevine were serologically distinguishable from the type strain, but sequence diversity among these isolates and strains has not been studied.

Geographic Distribution

SDV occurs mostly in Japan, but has also been found in China and Turkey. Strawberry latent ringspot virus (SLRSV) is distributed throughout Europe and the USA, as well as Australia and New Zealand. Strawberry mottle virus (SMoV) is probably spread worldwide, as well as BRNV. Occurrence of LASV and RCSV is limited to Australasia and China, respectively.

Virion Properties

Particles of sadwaviruses are icosahedral, about 26–30 nm in diameter (**Figure 1**). Some particles are penetrated

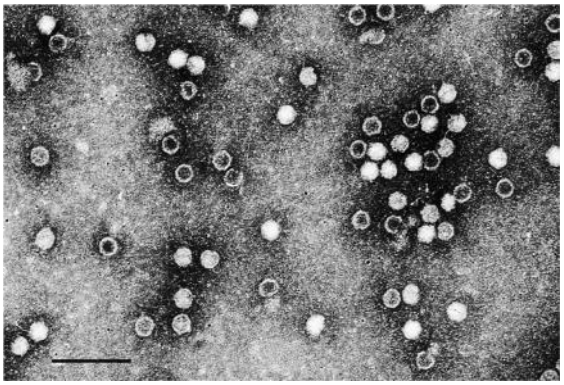

Figure 1 Electron micrograph of negatively stained virus particles of SDV. Scale = 100 nm.

by negative stain in the electron microscope. Typically, particles of sadwaviruses are of three types, named according to the relative rates of sedimentation of purified preparations. Top component (T) particles are empty shells. Middle component (M) and bottom component (B) particles contain genomic RNA. The buoyant densities in CsCl are about 1.43 and 1.46 g cm^{-3}, respectively. SLRSV has only B particles with buoyant density about 1.46 g cm^{-3}. Sadwavirus particles contain two sizes of RNA molecules. SDV has M and B particles that contain either of the different RNAs. In contrast, SLRSV has only B particles. Some particles contain one larger RNA, others contain two molecules of smaller RNA.

Genome Organization

The genome of sadwaviruses consists of two molecules of positive-sense single-stranded RNAs called RNA-1 and RNA-2. The sizes of RNA-1 and RNA-2 are about 7 and 4–5.5 kb, respectively. The 3′ termini of both RNAs are polyadenylated. In the case of SLRSV, both RNAs are linked at the 5′ termini to a small protein (VPg). VPgs of other sadwaviruses are unknown.

Both RNA-1 and RNA-2 have a single large open reading frame (**Figure 2**). The general genome organization is similar to that of como- and nepoviruses. The polyprotein encoded by RNA-1 contains domains for helicase, protease, and RNA-dependent RNA polymerase, whereas the polyprotein encoded by RNA-2 has movement protein and coat proteins. The amino acid sequences of the N-termini of polyproteins encoded by RNA-1 and RNA-2 of SDV are highly conserved. The feature is observed in the polyproteins of tomato ringspot virus in the genus *Nepovirus*. The function of these regions is unknown.

Sequence Comparisons

Comparison among the sequences of sadwaviruses of different species at nucleotide and amino acid levels shows few marked similarities. Some regions show about 20–40% sequence identities, and other parts are less similar.

Phylogeny

Complete genomic nucleotide sequences of SDV, BRNV, SLRSV, and SMoV have been determined. Partial sequences of CiMV, NDV, and NIMV are available (**Table 1**). There is little information on the nucleotide sequences of other sadwaviruses. To reveal relationships, the RNA-dependent RNA polymerase region, which is the most conserved among sadwa-, como-, nepo-, and other plant picorna-like viruses, has been used for phylogenetic comparisons. Alignment of the most conserved regions of the RNA-dependent RNA polymerase region shows that all plant picorna-like viruses are separated to

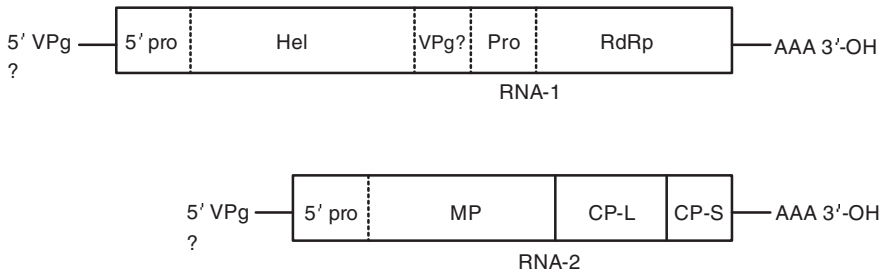

Figure 2 Genome organization of SDV. The boxes represent polyproteins. The vertical solid lines within the box show sites where cleavages occur in the polyprotein and the dashed lines indicate sites where cleavages are presumed to occur. Abbreviations: VPg, genome-linked viral protein; 5′ pro, 5′ protein; Hel, helicase; Pro, protease; RdRp, RNA-dependent RNA polymerase; MP, movement protein; CP-L and CP-S, large and small components of coat protein; AAA, poly(A).

three distinct groups: the first and second groups include comoviruses and nepoviruses, respectively, whereas the third group consists of SDV (and closely related CiMV, NDV, NIMV), SMoV, apple latent spherical virus (ALSV, which is a member of a newly established genus *Cheravirus*), and viruses of the family *Sequiviridae*, which have monopartite RNA geneome.

Satellites

SLRSV has strains that contain satellite RNAs. The SLRSV satellite encodes a polyprotein, which shows little homology with other known proteins. There is no evidence as to the function of the polyprotein. Other sadwaviruses do not contain a satellite RNA.

Host Range and Virus Propagation

Natural host of SDV, CiMV, NDV, and NIMV is limited to woody plants, whereas SMoV, LASV, and RCSV are confined to herbaceous plants. BRNV infects *Rubus* spp. SLRSV has a wide natural host range that includes both woody and herbaceous plants. All sadwaviruses are readily transmitted by mechanical inoculation to herbaceous plants of several families, including Chenopodiaceae, Fabaceae, and Solanaceae. Common experimental hosts used for the propagation of sadwaviruses are *Chenopodium quinoa*, *Cucumis sativus*, and *Physalis floridana*. SMoV propagates very poorly in any of the experimental herbaceous hosts, and purification of virus particles is difficult.

Epidemiology

SLRSV is transmitted by the soil nematode, *Xiphinema diversicaudatum*, and the transmission from plants to plants is slow, reflecting the restricted mobility of the nematode. SDV, CiMV, NDV, and NIMV are disseminated in a similar manner, and soil transmission is suspected, although vectors have not yet been identified. SMoV and BRNV are transmitted by aphids. All sadwaviruses but SMoV are seed-borne, and dissemination in seeds is important for long-distance movement of some sadwaviruses. Indeed, RCSV was first found in the UK from imported seeds from China.

Hosts of SDV, CiMV, NDV, and NIMV (citrus), BRNV (raspberry), SMoV (strawberry), SLRSV (strawberry and fruit trees) are vegetatively propagated, and movement of contaminated budwoods and tubers plays an important role in the long-distance dissemination. For example, occurrence of SDV in China and Turkey is obviously related to unchecked budwoods from Japan.

Cytopathology

Tubules which contain virus particles arranged in a single file are formed in the cytoplasm of infected cells. A file of virus particles is sometimes observed in a plasmodesma between two cells. Virus particles have also been detected in the vacuoles of infected cells in crystalline forms. These structures are also commonly observed in cell infected with comoviruses and nepoviruses.

Prevention and Control

Control measures consist of establishment of healthy stocks, chemical controls of vectors (nematode for SLRSV, aphids for BRNV and SMoV), and introduction of tolerant cultivars when available. Distributions of virus-free materials are important for vegetatively propagated crops (citrus for SDV, strawberry for SMoV and SLRSV, fruit trees for SLRSV). Several diagnostic tools including enzyme-linked immunosorbent assay (ELISA) and reverse transcriptase-polymerase chain reaction (RT-PCR) are available for most of the sadwaviruses. Chemical fumigation of citrus field to prevent soil transmission of SDV is partially effective at best. Many strawberry cultivars are symptomless hosts for either SMoV or SLRSV. Mixed infection with other

strawberry viruses induces apparent foliar symptoms and decline of tubers.

Glossary

Satellite-like RNA A subviral genome dependent upon another virus for replication and encapsidation, but is required for vector transmission of the helper virus.
Satellite RNA or satellite DNA A subviral genome dependent on a helper virus for both replication and encapsidation.
Satellite virus A subviral genome dependent on a helper virus for its replication, but encoding its own capsid protein.
Virus-associated nucleic acid A subviral genome that depends on another virus for encapsidation and transmission, but not for its replication.

Introduction

Satellites of viruses constitute a heterogeneous collection of subviral agents. Satellites can be differentiated from other subviral nucleic acids, such as subgenomic (sg) RNAs, defective (D) or defective interfering (DI) RNAs, and viroids, by their molecular, biological, and genetic nature. Unlike sg RNAs, D RNAs, and DI RNAs, satellites and viroids have little or no sequence similarity to any known virus. Whereas viroids are replicated by host polymerases, RNA satellites are replicated by the polymerase of a virus, referred to as the helper virus (HV). Satellites have been found associated with DNA and RNA viruses, and in the latter case, with both ssRNA and dsRNA viral genomes, the satellites being of the same nucleic acid type as the HV. While, in general, the HV can exist independent of the satellite, there are exceptions where a satellite contributes to the transmission of the HV and thus is referred to as being satellite-like. In addition, some viral RNAs are found in association with other viral genomes on which they depend for their encapsidation and transmission, but not their replication. These viral RNAs are referred to here as virus-associated RNAs. Satellites are divided basically into two main groups; those that encode their own capsid protein (CP) are called satellite viruses, while those that require their HV for both replication and encapsidation are referred to as satellite RNAs or DNAs. There are also satellites of satellites, in which some satellite RNAs are replicated by the HV, but are encapsidated by the CP of a satellite virus. In addition, in the case of the carmovirus turnip crinkle virus (TCV), which replicates both satellite RNAs and DI RNAs, it also produces a chimeric RNA (referred to as satC) that is in part a DI RNA and in part a satellite RNA (satD). While the vast majority of satellites are found in association with plant viruses, a few have been found in association with animal or fungal viral genomes. Most plant viruses do not contain satellites associated with them, but as some satellites can significantly affect the disease induced by the HV, the presence of satellites has important consequences for viral-induced diseases.

History

The use of the term satellite as a subviral agent was first conceptualized in 1962 by Kassanis, to describe the relationship of a 17-nm diameter viral particle found in association with some isolates of the 26-nm diameter necrovirus tobacco necrosis virus (TNV). The smaller particle was dependent on TNV for its accumulation, but was serologically unrelated to TNV. It became known as the satellite virus of TNV (now known as tobacco necrosis satellite virus, TNSV). A few other satellite viruses have been described since then, but, in general, they are rare. By contrast, satellite RNAs are more common. The first satellite RNA was described by Schneider in 1969, in association with the nepovirus tobacco ringspot virus (TRSV), the satellite RNA being encapsidated by the CP of the HV. The symptoms induced by TRSV were attenuated dramatically by the presence of the satellite RNA. This is not always the case, with some satellite RNAs having no effect on either the HV accumulation or disease induced by the HV, and a few satellite RNAs exacerbating the HV-induced disease. Most of these satellite RNAs contain ssRNA genomes, while a few contain genomes of dsRNA. Some of the satellite RNAs with ssRNA genomes are translated to produce proteins, which may or may not be required for their replication, depending on the particular satellite RNA. Satellite DNAs were first described in 1997 by Dry and colleagues, in association with the geminivirus tomato leaf curl virus (TLCV). It was isolated from field-infected tomato plants in northern Australia. Satellite DNAs also are encapsidated by the CP of their HV. Since then, satellite DNAs referred to as satellite DNA β have been described in association with many geminiviruses, principally from Asia.

Geographical Distribution

Since satellite RNAs are only found associated with their specific HVs, they are limited to the distribution range of the HV and the vectors of the HV. On the other hand, not all isolates of the HV have satellites associated with them, further delimiting the distribution of satellites. Nevertheless, as many of the HVs are distributed worldwide, so are many of the satellites. The distribution of satellite DNA β has so far been linked to the geminiviruses of the Old World, an exception being DNA β in honeysuckle that appears to have been distributed through vegetative plant material.

Classification

There is no correlation between the taxonomy of their HV and the presence of satellites. Satellites are associated with viruses belonging to at least 17 genera, and with only a limited number of species within those genera. Satellites do not constitute a homogeneous group in terms of their nucleic acid type, size, sequence, structure, or translatability. Most satellites are composed of RNA, but some consist of DNA. Most satellites are linear molecules, but some RNA satellites and all of the DNA satellites are circular in structure. Some satellites may encode proteins, while many do not. Thus, satellites are classified primarily into categories based on the features of the above properties, vis-à-vis their nucleic acid form and their genetic capacity. All satellites are grouped into the following categories, first differentiated on the basis of whether they are satellite viruses (**Table 1**) or satellite nucleic acids (**Table 2**), but

[a]Dependent on a helper virus for replication and encapsidation, but is essential for vector transmission of the helper virus.
[b]Dependent on a helper virus for encapsidation, but not for replication.

having in common the fact that they are not required for the replication of the HV.

1. Satellite viruses:
   - subgroup 1 – chronic bee-paralysis virus-associated satellite virus
   - subgroup 2 – satellites that resemble tobacco necrosis virus
2. Satellite nucleic acids:
   - ssDNA satellites
   - dsRNA satellites
   - ssRNA satellites: (1) subgroup 1 – large, ssRNA satellites; (2) subgroup 2 – small, linear, ssRNA satellites; (3) subgroup 3 – circular, ssRNA satellites.

Some RNAs previously described as satellite RNAs contribute to the natural means of transmission of the HV and thus are considered satellite-like RNAs, rather than true satellites (**Table 3**). In other cases, there are nucleic acids that are dependent on the HV for encapsidation, but

not replication. These subviral agents are considered here as virus-associated nucleic acids (**Table 3**) and will be described and differentiated below.

General Properties and Effects of Satellites

Satellite Viruses

Best characterized of the satellite viruses (**Table 1**) are the satellites that resemble TNSV, all of them depending, for their replication, on plant viruses with ssRNA genomes. All satellite viruses in this subgroup contain an ssRNA of 800–1200 nt. Particles are isometric, 17 nm in diameter, with a $T=1$ symmetry, built of 60 protein subunits. The particle structure has been determined at high resolution by X-ray diffraction for TNSV, tobacco mosaic satellite virus (TMSV), and panicum mosaic satellite virus (PMSV), with ~80% of the encapsidated RNA in stem–loop structures. Particle structure differs from that of their HV. In spite of the different structure of CP and virus particle, the particles of both the satellite and HV may share important properties; for example, the particles of TNSV and TNV are able to bind specifically to the zoospores of the vector fungus *Olpidium brassicae*. The 1000–1200 nt RNA of TNSV does not have a methylated cap structure or a genome-linked protein (VPg) in its 5′ end. Unlike most plant virus RNAs it has a phosphorylated 5′ end. The 3′ termini may share a structure with that of the HV genomic RNA (gRNA); for instance, in both tobacco mosaic virus and TMSV, the 3′ termini form tRNA-like structures and are aminoacylable with histidine. *Cis*-acting sequences necessary for RNA amplification have been mapped at the 5′ and 3′ nontranslated regions (NTRs) of PMSV RNA as well as within the CP open reading frame (ORF), and are conserved in a D RNA, which is maintained by PMSV. A translational enhancer domain has been mapped in the 3′ NTR of TNSV. In addition to the ORF encoding the CP, some satellite viruses contain other ORFs; it remains unclear if the encoded products have any role *in vivo*.

Interference with the accumulation of the HV has been described for TNSV. Satellite viruses can also modify the symptoms induced by the HV, as is the case with PMSV, which in co-infection with panicum mosaic virus (PMV) enhances the mild symptoms of PMV to cause a severe mosaic and chlorosis. Symptom induction is due to the PMSV CP, and a chlorosis-inducing domain has been mapped. In addition to its structural and symptom-inducing functions, the CP of PMSV is involved in systemic movement, binds PMV particles, and counters the effects of post-transcriptional gene silencing suppressors.

The particles of TNSV may contain a noncoding satellite RNA of about 620 nt, which depends on TNV for replication and on TNSV for encapsidation. A satellite RNA with similar dependence relationships has been described for PMV and PMSV. These systems are good examples of the complexity of dependence relationships in satellitism.

The other subgroup of satellite viruses contains satellites found associated with chronic bee-paralysis virus (CBPV). The satellites consist of three RNA species of about 1.1 kbp, which can be encapsidated either in 17-nm isometric particles by the satellite-encoded CP, or by the CP of the HV, CBPV. The satellites interfere with CBPV replication.

Satellite Nucleic Acids

ssDNA Satellites

All the DNA satellites reported to date are associated with a single virus genus, *Begomovirus*, in the family *Geminiviridae* (**Table 2**). This group of over 100 viruses is transmitted by whiteflies and their geminate particles encapsidate either one or two ssDNA species, each of about 2700 nt, as well as satellite DNAs that may occur. The first satellite DNA was found in association with TLCV and is a single-stranded (ss), circular DNA molecule of 682 nt, which can be supported for replication by a number of begomovirus species. It lacks any significant ORF or identifiable promoter element and does not contribute to the infection of TLCV. More recently, a large group of ss, satellite DNAs termed DNA β has been isolated. They are related to TLCV satellite DNA but are about twice the size of the TLCV satellite DNA and encode a protein known as βC1. The C1 protein is expressed from a single complementary-sense transcript with conserved regulatory elements.

The search for the causal agents of Ageratum yellow vein disease led to the discovery of the first DNA β satellite because it was required for disease symptom expression. Subsequently, a similar role was established for cotton leaf curl virus (CLCuV) DNA β, which is part of a disease complex causing major crop losses in Pakistan. Some geminivirus satellite DNAs reported as DNA β are of similar size to TLCV satellite DNA and lack a βC1 gene. Geminivirus satellite DNAs therefore can be considered a single group in which some species are defective for encoding a protein.

Geminivirus satellite DNAs can exert a drastic effect on the symptoms produced by their HV. The pathogenesis is mediated by the βC1 protein. The mechanism of βC1-mediated pathogenesis is not clear; however, the protein causes a drastic disease-like phenotype when expressed transgenically. This severe effect on host plants suggests changes to growth pattern and is accompanied by vein thickening, enations, and development of leaf-like structures. The protein has been demonstrated to be a suppressor of gene silencing, raising the possibility that it may control host functions by microRNA regulation.

Geminivirus satellite DNAs do not show a strict affinity for HV. TLCV satellite DNA is supported for

replication by viruses as diverse as tomato yellow leaf curl virus, African cassava mosaic virus, and even beet curly top virus, which belongs to a different genus. In another case, the DNA β associated with Ageratum yellow vein disease was found to be maintained in experimental plants infected with Sri Lankan cassava mosaic virus (SLCMV), which has a bipartite genome. This interaction altered the host range of SLCMV to include Ageratum. Interestingly, the satellite could substitute for DNA B component implying a functional similarity. Other evidence supporting the role of geminivirus satellite DNAs in movement has also been obtained. The DNA A component of tomato leaf curl New Delhi virus (TLCNDV) is not capable of systemic infection in the absence of DNA B and remains confined to the sites of inoculation where it is capable of replication; however, CLCuV DNA β can substitute DNA B of TLCNDV to restore systemic infection in tomato. Surprisingly, systemic infection of DNA A component alone, accompanied by symptoms, could also be mediated by transient expression of the βC1 protein.

dsRNA Satellites

A number of examples of dsRNA satellites have been described, but only two are recognized officially at this time (**Table 2**): one group is associated with the yeast *Saccharomyces cerevisiae* and is designated the M satellites of L-A dsRNA virus; the other group of three dsRNAs is associated with the Trichomonas vaginalis T1 virus (TVTV) of the eponymous protozoan. Both HVs are in the family *Totiviridae*. In the case of the three TVTV satellite RNAs of 497, ~700, and ~1700 bp, the ds satellite RNAs are maintained only by some isolates of TVTV, which both replicate and encapsidate these dsRNAs. The L-A dsRNA virus M satellites consist of several dsRNAs varying from 1.0 to 1.8 kbp in size. These dsRNA satellites are dependent on genes of the HV for both replication and encapsidation. The M1 dsRNA satellite encodes a toxin which kills other yeasts not harboring this dsRNA. In its prototoxin form, this protein provides immunity to the yeast secreting the toxin. Other L-A dsRNA viruses have different M satellites associated with them, all of them also encoding toxin and immunity systems.

All of the putative dsRNA satellites were found with fungi, in association with dsRNA viruses in the families *Hypoviridae*, *Narnaviridae*, *Partitiviridae*, and *Totiviridae*. One of these dsRNA satellites, from Ophiostoma novo-ulmi mitovirus 3a (OnuMV3a) in the genus *Mitovirus*, of the family *Narnaviridae* consists of a group of dsRNAs of 738–767 bp, designated OnuMV3a S-dsRNA (**Table 2**). These dsRNA satellites did not affect the hypovirulence associated with their HV in the fungus *Sclerotinia homeocarpa*. Their nucleotide sequences indicate that these OnuMV3a S-dsRNAs did not have the coding capacity for their own replicase, and thus presumably depend on the replicase of the HV.

ssRNA Satellites

Subgroup 1: Large ssRNA satellites

Subgroup I satellites have messenger RNA properties. These satellite RNAs are between 0.8 and 1.5 kb in size and encode nonstructural proteins that are expressed *in vivo* (**Table 2**). Most satellites in this subgroup are associated with nepoviruses. Large ssRNA satellites of nepoviruses share the 5′ and 3′ structural features of the gRNAs of the HV: a 3′-terminal poly(A) sequence and a 5′-terminal VPg that, in the analyzed instances, is indistinguishable from that on the HV genome and thus, is encoded by it. The encoded nonstructural protein of different satellite RNAs are basic proteins of 36–48 kDa. For the satellite RNAs of tomato black ring virus (TBRV), grapevine fanleaf virus (GFLV), and arabis mosaic virus (ArMV), it has been shown that the encoded proteins are needed for the replication of the satellite RNA. Most large satellite RNAs of nepoviruses do not seem to have an effect on the accumulation or pathogenicity of the HV. However, this may depend on the experimental system, as the large satellite RNA of ArMV was shown to modulate the symptoms of the HV depending on the species of host plant.

Large satellite RNAs (1342–1347 nt) have been found to be associated with many isolates of the benyvirus beet necrotic yellow vein virus (BNYVV). These satellite RNAs, designated BNYVV RNA 5, encode a protein of 26 kDa, which is responsible for intensification of the rhizomania disease induced by infection of BNYVV RNAs 1 and 2, plus its two satellite-like RNAs 3 and 4.

Another large satellite RNA has been found to be associated with the potexvirus bamboo mosaic virus (BaMV), the only satellite RNA encapsidated into rod-shaped particles. BaMV satellite RNA encodes a 20-kDa protein that is expressed *in vivo* but is not needed for satellite RNA replication. Interestingly, this protein shares significant sequence similarity with the structural protein of the PMSV, and binds cooperatively to RNA, with a preference for the satellite RNA. The presence of BaMV satellite RNA significantly reduces the accumulation of BaMV RNA. *Cis*-acting sequences required for BaMV satellite RNA replication have been mapped at the 5′ NTR, and comprise a stem–loop structure that is conserved among BaMV satellite RNA variants.

Subgroup 2: Small, linear ssRNA satellites

This subgroup contains ss satellite RNAs associated with seven genera of plant viruses (**Table 2**), although many of the members are associated with nepoviruses. There are no circular forms of these satellite RNAs present in infected cells, although dimer or higher multimer forms may be detected in virions and/or in infected cells. These satellite RNAs vary in size from ~200 to ~800 nt and do not appear to encode proteins, although isolates of some satellite RNAs contain nonconserved ORFs. These RNAs

appear to have highly ordered secondary structures, which is probably responsible for the high stability and infectivity of these RNAs, as well as their biological properties. Most of the small ss satellite RNAs either have no effect on or reduce the accumulation of their HV. This reduction in HV accumulation often, but not always, results in a decrease in the disease symptoms induced by the HV. Moreover, in a few cases, the presence of the satellite RNA reduced or had no effect on the HV accumulation, but intensified the disease induced by the HV. One of the latter, a tomato necrosis-inducing satellite RNA of the cucumovirus cucumber mosaic virus (CMV), could even induce necrosis in tomato independent of the HV, if expressed in the complementary-sense orientation within the genome of virus vector but not when expressed as a transgene; however, in the case of other satellite RNAs of CMV, different strains of CMV and the related HV tomato aspermy virus (TAV) have been used to show that the HV makes a contribution to the disease syndrome associated with the satellite RNA. The basis for satellite RNA-mediated attenuation of disease symptoms is not clear, but may not be due simply to reduction of the HV titer, since CMV satellite RNAs supported by TAV show an attenuation of symptoms, but no effect on the accumulation of the HV. Similarly, the reduction of HV level may not be due simply to competition between the HV and the satellite RNA for the same replicase, since data from TCV and CMV satellite RNAs indicate that satellite RNAs may affect the suppression of RNA silencing function of their associated HV, leading to a reduction in the titer of the virus due to RNA silencing. A general model for satellite- and viroid-mediated intensification of disease symptoms has been proposed, caused by silencing inducing RNAs generated from such subviral RNAs acting on specific host mRNAs.

Subgroup 3: Small, circular ssRNA satellites

This subgroup of satellite RNAs contains members that vary in size from 220 to 388 nt, and are associated with three genera of plant viruses (**Table 2**). The satellite RNAs exist in circular as well as linear forms in infected plant cells, but only the circular satellite RNA form is encapsidated by the helper sobemovirus, while only the linear satellite RNA form is encapsidated by the helper polerovirus and nepoviruses. Multimeric, linear forms of these satellites are produced in infected cells and, in some cases, these are also packaged into virus particles. The multimeric forms are generated via a rolling-replication mechanism and the unit-length linear as well as circular forms are generated via ribozymes. There is no mRNA activity associated with these various satellite RNAs, and they all have a high degree of secondary structure. The satellite RNAs either have no effect on (sobemovirus satellites) or reduce (nepovirus and polerovirus satellites) the accumulation of their HV. In addition, the presence of satellite RNAs either reduces (nepovirus and polerovirus satellites) or exacerbates (sobemovirus satellites) the symptoms induced by the helper virus. The molecular basis for symptom attenuation or intensification is unknown.

Satellite-Related Nucleic Acids

A number of subviral nucleic acids have been described that have in some instances been referred to as satellite RNAs or DNAs. However, as these nucleic acids either contribute to the infection cycle of the HV, or are not dependent upon an HV for their replication, they are better described as satellite-like or virus-associated nucleic acids, respectively (**Table 3**).

Satellite-like ssRNAs

This group of subviral RNAs includes the satellite RNAs of groundnut rosette virus (GRV) and RNAs 3 and 4 of BNYVV. In the case of satellite RNAs of GRV, they are required for transmission of GRV by the luteovirus groundnut assistor virus. How these satellite RNAs of 895–903 nt affect transmission is unknown, since they do not code for any functional proteins. Some of the satellite RNAs of GRV also affect accumulation of the HV and the symptoms induced by the HV, causing either attenuation due to severely reduced replication of the HV, or exacerbation, producing unique symptoms. In the case of BNYVV, where only RNAs 1 and 2 are essential for replication, movement within leaves and particle assembly, RNA 3 (1774 nt) is required for spread of the virus into roots and RNA 4 (1467 nt) is essential for virus transmission by the soil-fungus vector of BNYYV. Thus, BNYYV RNAs 3 and 4 are considered satellite-like, in that they contribute to the natural infection cycle of the virus. By contrast, BNYYV RNA 5 is a true satellite, in that it is not required for any phase of the infection cycle of BNYYV, although its encoded 26 kDa protein in combination with the 25 kDa protein encoded on RNA 3 intensifies symptom expression of the disease rhizomania.

Virus-associated nucleic acids

This group of subviral agents does not fit the above definition of satellites, but as they are peripheral to but dependent on an HV for their encapsidation, they have sometimes been referred to as satellite-like RNAs or DNAs. However, as a functional distinction exists between these subviral nucleic acids and those of the satellite-like agents described above, which are dependent on an HV for their replication, these subviral agents are collectively referred to as (virus-) associated nucleic acids.

Hepatitis delta virus

Hepatitis delta virus (HDV) is a subviral agent of the human pathogen, hepatitis B virus (HBV). HDV is replicated in the nucleus by the host DNA-dependent RNA

polymerase II, but is dependent upon the envelope proteins of HBV for its encapsidation and transmission, and is thus not a satellite. The HDV (1679 nt) RNA folds into an unbranched rod-like structure similar to that of viroids, and in common with the circular ssRNA satellites, contains ribozymes that are involved in the processing and maturation of this RNA during replication. The HDV RNA encodes two forms of a protein designated the delta antigen (δAg). The smaller, 22 kDa form (δAg-S), which is a nuclear phosphoprotein, is required for replication of HDV RNA, while the 24 kDa larger form (δAg-L), which contains an additional 19 aa at the C-terminus and is produced late in infection, is required along with δAg-S for assembly of the HDV RNA into HBV envelope particles. δAg-L also acts as an inhibitor of HDV replication. HDV intensifies the severity of liver disease caused by HBV.

Luteovirus-associated RNAs

Some isolates of two luteoviruses, beet western yellows virus and carrot red leaf virus (CRLV) were found to have associated with them additional RNAs of size 2.8 kb. These associated RNAs encoded their own viral replicases, but required the respective luteoviruses for their movement, encapsidation, and transmission. These RNAs, designated BWYVaRNA (2843 nt) and CRLVaRNA (2835 nt), have similar genome organizations, are about 50% similar in sequence, and both intensify the disease caused by their HV. CLRVaRNA together with CLRV and the umbravirus carrot mottle virus induced carrot motley dwarf disease.

Begomovirus- and nanovirus-associated DNAs

Circular ssDNA species of about 1300 nt, unrelated to geminivirus genomes, have been isolated from plants infected with some Old World begomoviruses. These molecules, named DNA 1, resemble a DNA component of nanoviruses. CLCuV-associated DNA1 is an example (**Table 3**). They encode their own replicase-associated protein (Rep) and replicate independent of the HV. In the absence of a nanovirus CP which allows aphid transmission, the virus-associated DNAs are encapsidated in helper geminiviruses and are transmitted by their whitefly vector. Nanoviruses themselves may also contain virus-associated DNAs. These are about 1.0 or 1.1 kbp in size and capable of autonomous replication but require the respective nanovirus for their movement, encapsidation, and transmission by aphids.

Replication and Structure

Satellite DNAs

The replication of geminivirus satellite DNAs mimics that of the HV. Unlike RNA viruses, geminiviruses do not encode a polymerase and depend on host DNA polymerases for replication. The only geminivirus-encoded protein essential for replication is Rep. Geminivirus satellite DNAs utilize the HV Rep and contain the conserved sequence for DNA nicking by the Rep. Replication takes place by a combination of rolling circle and recombination dependent mechanisms and the DNA is encapsidated in the HV virion. The replication is independent of βC1 expression.

Sequence comparisons at the nucleotide and amino acid levels reveal a number of conserved structural features, despite a significant level of sequence divergence. These include an A-rich region, a sequence of about 80 nt referred to as the satellite conserved region, and putative stem–loop structure containing a mononucleotide motif, also present in geminivirus genomes.

Satellite RNAs

A general property of satellite RNAs is that their replication depends on the replication machinery of the HV, which involves virus- and host-encoded factors. Hence, replication of satellite RNAs depends on interactions with both the HV and the host plant. Satellite RNAs may or may not share structural features at their 5′ and 3′ termini in common with the HV RNA. For instance, the large satellite RNAs of the nepoviruses have an HV-encoded VPg at the 5′ end and a poly(A) tail at the 3′ end, as do their HV RNAs, but the satellite RNAs of CMV have a 5′ cap structure, as do the CMV RNAs, but unlike the HV, the satellite RNAs do not have a tRNA-like structure that can be valylated at the 3′ end. Structural differences and, often, differences in the replication process between the satellite RNA and the HV RNA, indicate that the replication machinery of the HV may need to be adapted to replicate the satellite RNA, in ways which are not completely understood. The HV replication complex could be modified by satellite-encoded factors, as has been hypothesized for the large satellite RNAs of nepoviruses, or by unidentified host factors. It should be pointed out that in the best characterized systems, the efficiency of replication depends on the host plant. For CMV satellite RNAs, replication efficiency also depends on the strain of HV. Similarly, while the expression of the HV RNA-dependent RNA polymerase was enough for the replication of cereal yellow dwarf virus (CYDV) satellite RNA in the homologous host, this was not the case for cymbidium mosaic virus satellite RNA in a heterologous host system, in which, however, a DI RNA was amplified.

Replication has been studied best in the small noncoding satellite RNAs. For the small linear satellite RNAs of TCV and CMV, multimeric forms of both positive (arbitrarily defined as the encapsidated sense) and negative sense are found in infected tissues. The junction between monomers can be perfect or have deletions. Circular forms are not found, and replication does not proceed through

a rolling-circle mechanism. Regulatory sequences for RNA replication have been mapped in detail in the satellite RNAs of TCV. In the hybrid satC molecule, a hairpin structure is a replication enhancer and has a role in depressing the accumulation of the HV. Also, structural motifs favoring recombination have been analyzed extensively in satD and satC of TCV.

The replication of small, circular satellite RNAs is by a rolling-circle mechanism; upon, infection, linear, multimeric forms of the negative strand are synthesized. The multimeric plus strand is then synthesized on this template or on negative strand circular monomers, depending on the satellite RNA. The positive strand multimer is cleaved autocatalytically and ligation occurs for those satellite RNAs that are encapsidated as a circular form. Hammerhead and hairpin ribozyme structures are found in these satellite RNAs monomers or dimers, which catalyze hydrolysis or hydrolysis and ligation, respectively. Other structures required for replication and encapsidation have been mapped in CYDV satellite RNA.

For one circular satellite RNA, a DNA counterpart has been shown to occur in the host genome, as a retroid element. HDV, which depends on HBV for encapsidation, shares structural features and replication mechanisms with the small, circular satellite RNAs.

Structural analyses have been done mostly with small satellite RNAs. Models for the *in vitro* secondary structure have been proposed for several satellite RNAs (e.g., CMV satellite RNA, TCV satellite RNAs, TRSV satellite RNA, and CYDV satellite RNA) based on nuclease sensitivity and chemical modification of bases data. For CMV satellite RNA, *in vivo* models have also been proposed. All analyzed satellite RNAs have a high degree of secondary structure, with more than 50% and up to 70% of bases involved in pairing. The high degree of secondary structure could explain the high stability of these molecules as well as the very high infectivity reported for some of them, such as CMV satellite RNA and TCV satellite RNA. The high degree of secondary structure may also be related to their biological activity, which for these noncoding molecules must depend on structural features. As has been detailed in other sections, sequences, structural domains, and tertiary interactions involved in pathogenicity and replication have been well characterized for some small satellite RNAs.

Sequence Variation and Evolution

Sequence variation and evolution has been analyzed most for CMV satellite RNA. Early experiments under controlled conditions showed a high variability and genetic plasticity. Populations started from cDNA clones rapidly evolved to a swarm of sequences whose master sequence changed upon passage on different hosts. Analysis of genetic variants from natural populations showed again a high diversity for CMV satellite RNA. In natural populations, satellite RNA diversification and evolution proceeded by mutation accumulation and by recombination. Constraints to genetic variation were analyzed, and were related to the maintenance of base pairing in secondary structure elements. Population diversity of CMV satellite RNA was higher than for the HV, and the population structures of CMV and the satellite RNA were not correlated. These analyses also showed that CMV satellite RNA behaved in nature as a molecular hyperparasite spreading epidemically on the CMV populations. The incidence of CMV satellite RNA in CMV populations has been shown to be low, except during episodes of epidemics of tomato necrosis. High diversity of natural populations has also been shown for PMSV RNA and for BaMV satellite RNA. For BaMV satellite RNA, the diversity was highest in the NTRs. Conversely, the population of rice yellow mottle virus satellite RNAs over sub-Saharan Africa showed little sequence diversity. The incidence of these three satellite RNAs in the analyzed populations of the respective HV was, in all cases, high.

Phylogenetic analyses divide geminivirus satellites broadly into two categories, those isolated from host plants of the family Malvaceae and the rest isolated from other plants, mostly in the Solanaceae. Compared to satellite RNAs, satellite DNAs do not exhibit a wide diversity. They are structurally similar, and lack strict specificity for HV species. Geminivirus satellite DNA sequences analyzed exhibit a minimum overall similarity of about 47% and 37%, at the nucleotide level and amino acid level, respectively. To date, over 120 DNA β sequences have been reported in data banks; however, many of these are members of the same species because their overall sequence similarity is well above 90%. Some examples of distinct geminivirus satellites that have been adequately characterized are listed in **Table 2**.

There has been much speculation on the origin of satellite RNAs. For CMV satellite RNA and TCV satellite RNA, it has been suggested that they could have been generated out of small sequences synthesized upon the HV RNA as a template by the HV polymerase. This hypothesis is no longer sustained by those that proposed it. Whatever the mechanism of generation of the satellite RNAs, it seems that the satellitism as a phenomenon, that is, the dependence on a certain virus for replication, has evolved independently several times. This is suggested by the lack of correlation between satellite and HV taxonomy, and by the existence of subviral nucleic acids with different degrees of dependence on an HV. For instance, an evolutionary line from nondependent viruses to satellites such as BaMV satellite RNA through satellite viruses could have proceeded by size and information content reduction. A phylogenetic relationship between viroids and small circular satellite RNAs has also been proposed.

Expression of Foreign Sequences from Satellite Vectors

The satellite RNAs of BaMV and BNYVV, as well as the satellite DNA of tomato yellow leaf curl China virus isolate Y10 (TYLCCNV-Y10), all of which express proteins not required for the replication or spread of the satellite or HV, have been used as expression vectors of foreign sequences. In the case of the satellite RNA of BaMV, the expression of such sequences and the accumulation of the satellite RNA were reduced considerably in systemically infected leaves. Nevertheless, this satellite expression system has been useful for studying *cis*- and *trans*-acting replication signals. The 26 kDa protein encoded by RNA 5 of BNYYV has been replaced with the sequence encoding the green fluorescent protein, which was expressed in both the inoculated leaves and systemically infected leaves. The small size of the satellite DNA of TYLCCNV-Y10 precludes use of this system for expression of most genes, but the system has been used to express plant gene segments inducing RNA silencing in several plants species. The TMSV system also has been used to express plant gene sequences, in place of its CP, resulting in RNA silencing of those plant genes, but not of the satellite virus or its HV. The modified TMSV expression vector was able to spread through the plant in the absence of its CP.

Satellite-Mediated Control of Viruses

The ability of some satellite RNAs to attenuate the symptoms induced by their HV has been utilized to develop strategies for disease control. In one strategy, the satellite RNA of CMV has been used in combination with mild strains of CMV as a 'vaccine', to pre-inoculate tomato plants and ameliorate symptoms induced by the replicating challenge virus (through the attenuating ability of the vaccine satellite RNA), in fields and greenhouses. Moreover, the vaccine could also prevent or reduce the frequency of infection of both the HV (through cross-protection by the HV of the vaccine strain) and of satellite RNAs that exacerbate the disease caused by the HV (through cross-protection by the vaccine satellite RNA). In a second strategy, the satellite RNAs of CMV, TRSV, and GRV have been expressed in transgenic plants, and provided either resistance to infection by the respective HV, or tolerance to the disease induced by the HV and/or related pathogenic satellites.

Glossary

Arthralgia Joint pain.
Cerebral palsy Disability resulting from damage of the brain before, during, or shortly after birth and manifested as muscular and speech disturbances.
Hemiplegia Total or partial paralysis of one side of the body resulting from an affliction of the motor centers in the brain.
Myalgia Muscle pain.
Viremia The presence of virus in the blood.

Introduction

The family *Reoviridae* includes 12 recognized genera and 3 proposed genera (**Table 1**). The genera *Coltivirus*, *Seadornavirus,* and *Orbivirus* include arboviruses that can cause disease in animals (including humans).

In 1991, the International Committee for the Taxonomy of Viruses (ICTV) formally recognized the genus *Coltivirus* (sigla from Colorado tick virus) containing the 12-segmented double-stranded RNA (dsRNA) animal viruses that were previously classified within the genus *Orbivirus*. *Colorado tick fever virus* is the prototype species of the genus *Coltivirus* and includes strains of several tick-borne viruses (including isolates of Colorado tick fever virus (CTFV) from humans and ticks; California hare coltivirus (CTFV-Ca) from a hare in northern California; and Salmon River virus (SRV) from humans in Idaho). The genus *Coltivirus* also contains a second distinct species: *Eyach virus* (EYAV) isolated from ticks in Europe.

The seadornaviruses are 12-segmented mosquito-borne dsRNA viruses that were initially considered as tentative species within the genus *Coltivirus*. However, based on their antigenic properties and nucleotide sequence comparisons to the coltiviruses and other members of the *Reoviridae,* their taxonomic status was reassessed. They are now formally recognized as members of the genus *Seadornavirus* (sigla: from *South East Asian Dodeca RNA virus*; genus recognized in 2000), which includes the type species *Banna virus* (BAV), isolated from humans; two other species, *Kadipiro virus* (KAD) and *Liao ning virus* (LNV); and several unclassified isolates from mosquitoes. The seadornaviruses have been implicated in a variety of pathological manifestations in humans, including flu-like illness and neurological disorders, as described below.

Historical Overview of Seadornaviruses

The first seadornaviruses were reported in 1980 and 1981, when numerous isolates of 12-segmented dsRNA viruses were made from pooled homogenates of mosquitoes in Indonesia and were initially designated as JKT-6423, JKT-6969, JKT-7043, and JKT-7075. These original viruses were recently renamed as Banna virus (BAV) and Kadipiro virus (KDV). Shortly after the initial identification of BAV in Indonesia, a similar virus was isolated from the serum and cerebrospinal fluid (CSF) (2 isolates) and sera (25 isolates) of human patients with encephalitis in Yunnan province in the south of China and BAV was reported as a causative agent of human viral encephalitis. Seadornaviruses have subsequently been isolated on several occasions from humans, cattle, pigs, and mosquitoes and are vectored by *Anopheles*, *Culex,* and *Aedes* species. BAV is now regarded as endemic in southeast Asia, particularly in Indonesia and China.

Table 1 Twelve recognized genera and the three proposed genera of family *Reoviridae*

	Type species			*No. of segments*	*Hosts of the member viruses*
Genus					
1. *Idnoreovirus*	*Diadromus pulchellus reovirus*			10	Insects
2. *Cypovirus*	*Cypovirus type 1*			10	Insects
3. *Oryzavirus*	*Rice ragged stunt virus*			10	Plants
4. *Fijivirus*	*Fiji disease virus*			10	Plants
5. *Orthoreovirus*	*Mammalian orthoreovirus*			10	Primates, ruminants, bats, birds, reptiles
6. *Orbivirus*	*Bluetongue virus*			10	Ruminants, equids, rodents, bats, marsupials, birds, humans
7. *Rotavirus*	*Rotavirus A*			11	Mammals, birds
8. *Aquareovirus*	*Aquareovirus A*			11	Aquatic animals
9. *Mycoreovirus*	*Mycoreovirus-1*			11 or 12	Fungi
10. *Phytoreovirus*	*Wound tumor virus*			12	Plants
11. *Coltivirus*	*Colorado tick fever virus*			12	Mammals including man

Figure 1 The known world distribution of seadornaviruses (shaded areas): BAV and LNV in China and BAV and KDV in Indonesia.

Distribution and Epidemiology

BAV was initially isolated from mosquitoes and mammalian species in 1980–81, between latitudes of 39° N and 38° S, in southeast Asia (**Figure 1**). BAV was subsequently isolated from humans in the Yunnan province of southern China (Xishuangbanna prefecture in 1987). A virus identified as BAV was also isolated in 1987 from patients with fever and flu-like manifestation, in Xinjiang province of western China province. In 1992, two 12-segmented dsRNA viruses were isolated from serum of patients with an unknown fever in Mengding county of Yunnan province. Eight further isolates of antigenically Banna-like viruses were made from the sera of 24% of patients with an unidentified fever and viral encephalitis in Xinjiang province of northwest China in 1992. Twelve-segmented dsRNA viruses that are described as antigenically related to BAV have also been isolated from humans in various other provinces in China, including Beijing, Gansu, Hainan, Henan, and Shanshi and consequently BAV is now classified as a BSL3 arboviral agent.

Four viruses initially identified as JKT-6423, JKT-6969, JKT-7043, and JKT-7075, were isolated from *Culex* and *Anopheles* mosquitoes in central Java in Indonesia. The first three isolates were isolates of BAV, while JKT-7075 represents the only known strain of the *Kadipiro virus* species.

Recently, isolates of two distinct serotypes of *Liao ning virus* (LNV) were obtained from *Aedes dorsalis* mosquito in the Liaoning province of north eastern China.

Vectors, Host Range, and Transmission

BAV is the only seadornavirus that has been isolated from humans. Experimentally, seadornaviruses have also been shown to infect and replicate in adult mice and can be detected in the infected mouse blood from 3 to 5 days post infection. LNV replicates readily in several mammalian cell lines with massive lytic effect and kills adult mice. KDV and LNV have only been isolated only from mosquitoes. Indeed seadornaviruses are thought to be transmitted by mosquitoes and have been isolated from *Culex vishnui, Culex fuscocephalus, Anopheles vagus, Anopheles aconitus, Anopheles subpictus*, and *Aedes dorsalis*.

BAV, KDV, and LNV all occur in tropical and subtropical regions, where other mosquito-borne viral diseases, including Japanese encephalitis (JEV) and dengue, are endemic. This suggests that conclusive diagnosis and differentiation of these diseases may be difficult, based on clinical signs alone. Indeed several cases were diagnosed as JE in China (Henan province, Naijing city, and Fujian province in summer–autumn season of 1994), despite the absence of detectable JEV, or JEV-specific antibodies. However, a proportion of these patients (7/98) did show a 4- to16-fold rise in anti-BAV immunoglobulin G (IgG) by enzyme-linked immunosorbent assay (ELISA), indicating a BAV infection. A further 130 sera (from 1141 patients diagnosed with JE or viral encephalitis) from Chinese health institutes were also positive for BAV-specific immunoglobulin M (IgM).

In the summer of 1987, 16 BAV-like isolates were recovered from sera of 53 cattle (30% of the tested animals) and 4 isolates recovered from sera of 13 pigs (30% of the tested animals) collected in a slaughterhouse in the Dai nationality autonomous prefecture of the Xishuangbanna area of Yunnan province, where BAV has been previously isolated from humans.

BAV is regarded as 'a common cause of viral encephalitis and fever in humans during summer–autumn in

China. Its high isolation rate and wide geographical distribution make BAV an important public health problem in China. It is likely that seadornaviruses are also endemic in other countries within Southeast Asia.

Virion Properties, Genome, and Replication

Seadornavirus particles, like those of many of the 'unturreted' reoviruses, are approximately spherical in appearance with icosahedral symmetry. The intact virion is 60–70 nm in diameter and has three concentric capsid layers, containing a total of seven structural proteins. The double-layered core-particle contains five proteins (VP1, VP2, VP3, VP8, and VP10) and is approximately 50 nm in diameter, with a central cavity that contains the 12 segments of the viral genome.

VP1 (the polymerase) and VP3 (the capping enzyme) form the transcriptase complex that is present within the core as a dimer of VP1 and a monomer of VP3. This complex is located at each of the 12 fivefold axes of the viral particle. The subcore layer is composed of 120 copies of VP2 and represents the $T = 2$ layer. The outer layer of the core is made of 780 copies of VP8 and represents the $T = 13$ layer. Based on sequence comparison to other viruses of the *Reoviridae* and in particular the rotaviruses, the seadornavirus VP10 proteins are thought to be anchored at the core surface. The outer capsid layer, which is composed of only two proteins (VP4 and VP9) (**Figure 2**), completely surrounds the core particle.

The BAV genome encodes five nonstructural proteins which are the VP5, VP6, VP7, VP11, and VP12. VP7 contains sequences which are found in various protein kinases. VP12 contains a dsRNA-binding domain and might play a role in circumventing cell defense mechanisms, possibly acting as an anti-PKR component.

Negative staining and electron microscopy have shown that the surface of the virus particles has a well-defined capsomeric structure and icosahedral symmetry. The outer surface also has spikes that are similar to those of the rotaviruses (**Figure 3(a)**). The virus core has a smooth outline that is typical of the nonturreted members of the family *Reoviridae* (**Figure 3(b)**).

Like the orbiviruses, the seadornaviruses are unstable in CsCl and readily lose their outer coat proteins. However, intact virus particles have been purified from infected tissue culture supernatant by ultracentrifugation on colloidal silica gradients (Percoll). Purified virus particles are stable at 4 °C and approximately pH 7.0 for up to 3–4 months. However, increased acidity decreases their infectivity, which is abolished at pH 3.0. The virus is more stable as an unpurified cell culture lysate at 4 °C, which is a convenient way for medium-term storage. For longer periods of storage, viruses are stable at –80 °C, and infectivity can be further conserved by addition of 50% fetal calf serum.

The infectivity of seadornaviruses is decreased considerably by heating to 55 °C. Treatment with sodium dodecyl sulfate (SDS) disrupts the virus particle and consequently abolishes infectivity completely. Infectivity is very significantly reduced by treatment with butanol,

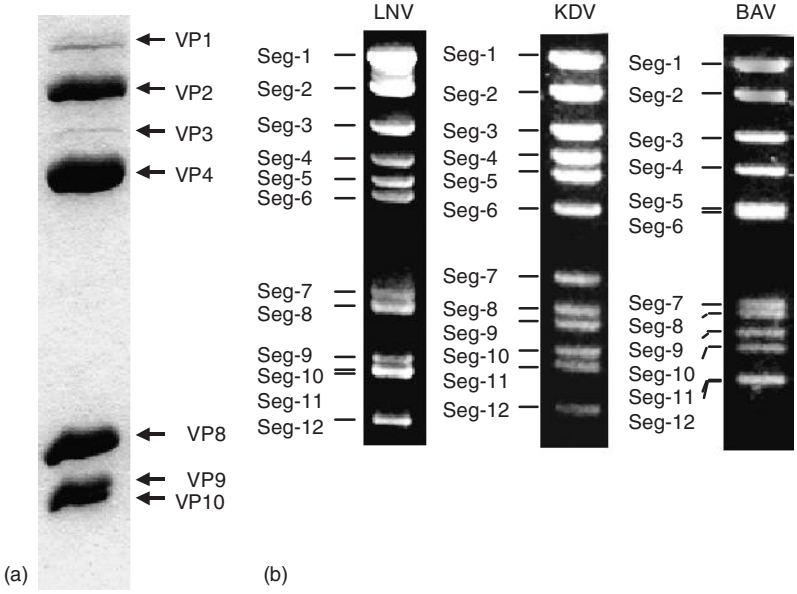

Figure 2 The PAGE profile of the structural proteins of Banna virus and the AGE profile of the genomes of seadornaviruses. (a) The PAGE profile of the structural proteins of Banna virus separated on a 10% polyacrylamide gel: VP4 and VP9 are the outer coat proteins. (b) The AGE profile of the genomes of Liao ning virus (LNV), Kadipiro virus (KDV), and Banna virus (BAV) run in a 1% agarose gel. The distinct electropherotypes of the three species allow to distinguish them.

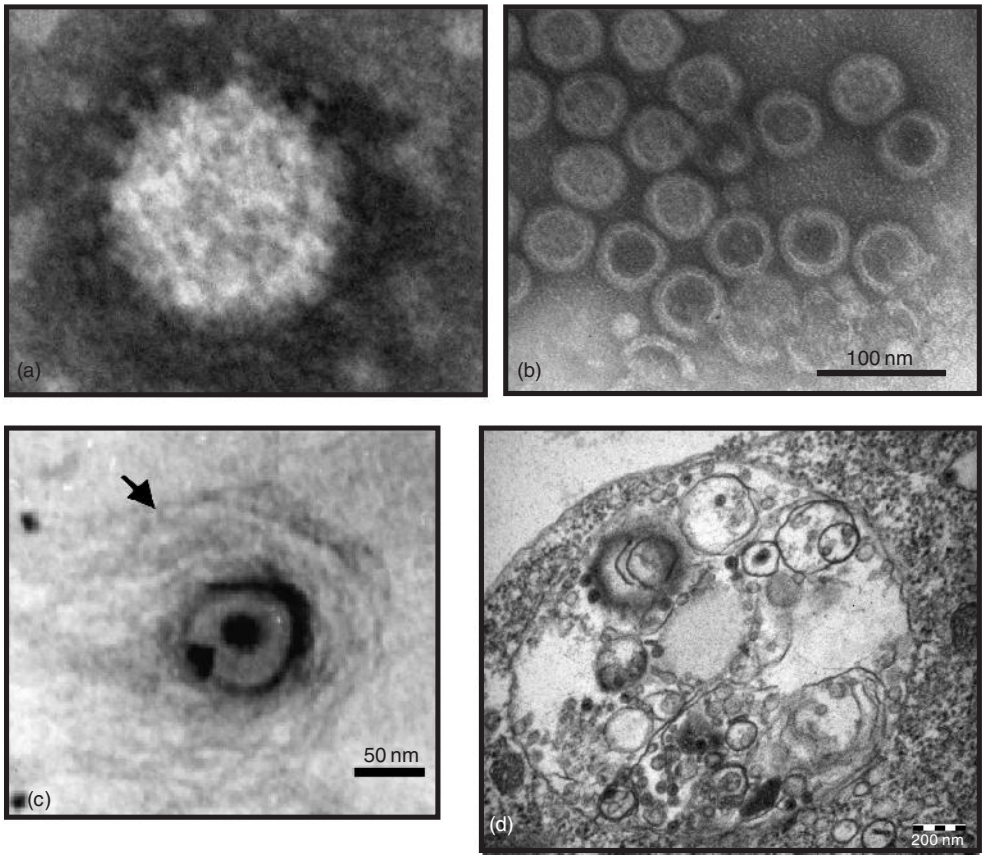

Figure 3 Electron micrographs of Banna virus particles. (a) A whole particle with spike proteins at the surface; (b) double-layered purified cores with smooth outlines; (c) particles surrounded by temporary envelope structure; and (d) thin section of infected C6/36 cells with virus particles seen within vacuole structures.

although organic solvents such as Freon 113 or Vetrel XF do not affect virion structure or infectivity and have been used successfully during purification of virus particles from cell lysates.

During replication, core-like particles are found within vacuole-like structures in the infected cell cytoplasm (**Figure 3(c)**), and are thought to be involved in virion morphogenesis. These structures appear similar to those found in cells infected with rotaviruses, where progeny particles bud into the endoplasmic reticulum, acquiring the outer coat components and generating mature virus particles.

Seadornaviruses replicate in a number of mosquito cell lines, including C6/36 and AA23 (both from *Aedes albopictus*), A20 (*Aedes aegypti*), and Aw-albus (*Aedes w albus*). Over 40% of the progeny virus particles are liberated in the culture medium (as determined by titration), prior to cell death and massive cytopathic effect (CPE) (fusiform cells), which (with BAV, LNV and KDV) is evident at 48–72 h post infection. Infected cells do not lyse initially and the virus is released by budding, acquiring a temporary membrane envelope in the process (**Figure 3(d)**). However, cell lysis does occur late in infection, as a result of cell death. Intracellular radiolabeling of viral polypeptides has shown that label is incorporated predominantly into viral polypeptides, even in absence of inhibitors of DNA replication such as actinomycin D, demonstrating 'shut off' of host-cell protein synthesis.

Like the other members of the genus, LNV can replicate in several mosquito cell lines, but it is the only seadornavirus that readily replicates in a variety of transformed or primary mammalian cells, including BHK-21, Vero, BGM, Hep-2, and MRC-5, leading to massive cell lysis after 48 h post infection.

The seadornavirus genome consists of 12 segments of dsRNA that are identified as Seg-1 to Seg-12 in the order of decreasing molecular weight and order of migration during agarose gel electrophoresis (AGE). The full-length genome sequence of BAV, KDV, and LNV has been determined. The genome comprises approximately 21 000 bp and the segment length ranges between 3747 and 862 bp. The genomic RNA of BAV and LNV show 6–6 electrophoretic profiles in 1% agarose gel electrophoresis (**Figure 2**). The genome of KDV migrates in 6–5-1 profile. Each genome segment encodes a single protein with an open reading frame spanning almost the whole length of the segment (**Figure 4**).

BAV, Banna virus, KDV, Kadipiro virus, and LNV, Liao ning virus. The copy number was determined by radiolabeling of the proteins using ^{35}S methionine. The encoded putative proteins are indicated between brackets followed by the nomenclature that is used in the *Eighth Report of the ICTV* and presented on the website www.iah.bbsrc.ac.uk/dsRNA_virus_proteins/protein-comparison.htm.

Antigenic and Phylogenetic Relationships between Seadornaviruses

The earliest data that was generated concerning the relationships between different seadornaviruses were obtained by RNA cross-hybridization analyses, which identified BAV and KDV as members of distinct genogroups. Antigenic relationships between different seadornaviruses were also investigated using polyclonal mouse immune-sera. BAV from southern China and Indonesia, LNV from northeast of China, and KDV from Indonesia, which are classified as distinct species, show no cross-reaction in neutralization tests. Subsequent comparisons of nucleotide and amino acid sequences confirmed that BAV, KDV, and LNV represent three distinct virus species, with AA identities between homologous proteins of 24–42% (**Table 2**). A neighbor-joining tree based on an alignment of the most highly conserved seadornavirus protein, VP1 (the viral

polymerase), shows BAV, KDV, and LNV as three distinct phylogenetic groups, confirming their status as distinct species (**Figure 5(a)**).

Antigenic variation between different BAV strains was also investigated using immune-sera, and identified two distinct serotypes, that did not cross-neutralize. These have been named as BAV serotypes A and B. A seroneutralization epitope was identified on the outer coat protein VP9. Sequence analysis of Seg-9 showed only 40% amino acid identity between BAV serotypes A and B, identifying two genotypes: genotype A (represented by isolates BAV-Ch (China) and BAV-In6423 (Indonesia)); and genotype B (represented by isolates BAV-In6969 and BAV-In7043 (Indonesia)) (which match with virus serotypes A and B).

Seg-7, which codes for nonstructural protein VP7, also shows a significant variation, between the genotypes/serotypes, with only 70% amino-acid-sequence identity between types A and B. The amino-acid-sequence identity (VP1–VP12) between different BAV isolates within a single serotype ranged from 83% to 100%, while sequence identity between different serotypes ranged from 73% to 95% (excluding VP9). This level of genetic divergence is comparable to that observed between serotypes in other insect-transmitted arboviruses of family *Reoviridae*, in particular the orbiviruses. The two identified serotypes of LNV have nucleotide sequence identities ranging between 81% and 90%, while amino acid identity ranging between 80% and 96%. The lowest AA identity (80%) was found in the proteins of the outer capsid VP10 (the homolog of BAV VP9), which defines virus serotype in the seadornaviruses. A neighbor-joining tree, comparing the sequences of cell-attachment outer capsid proteins of

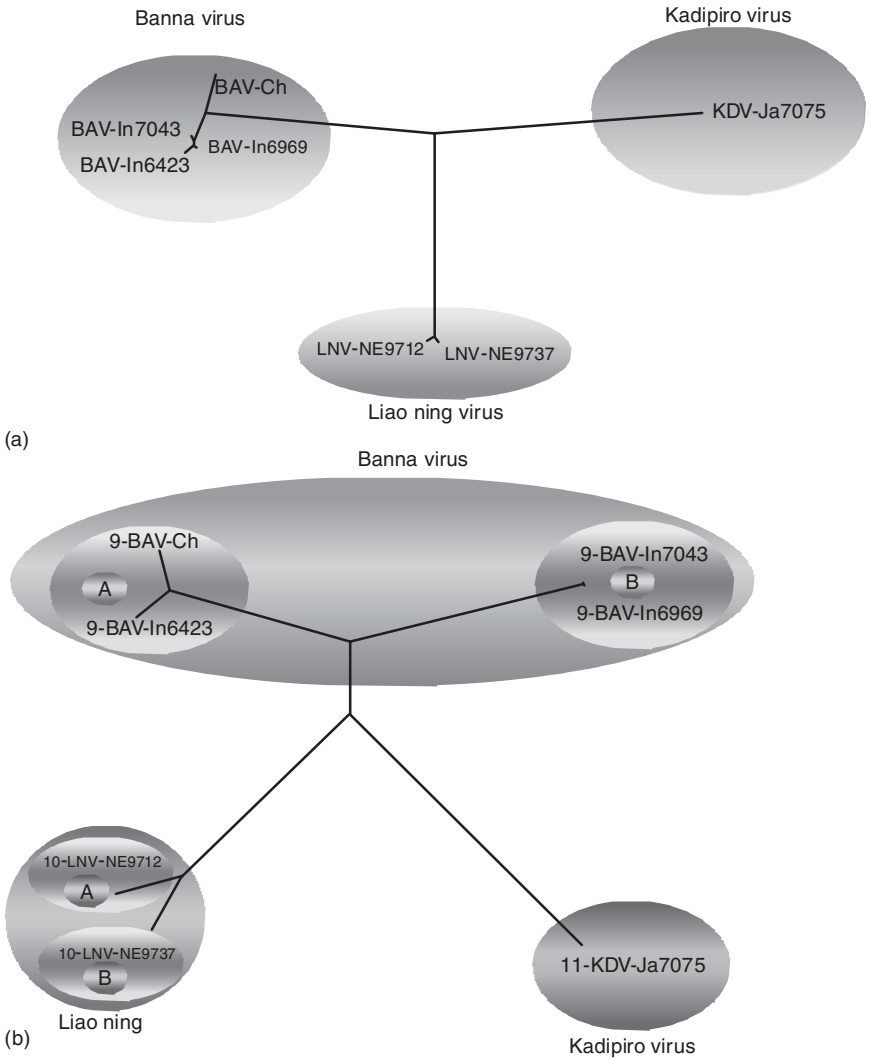

Figure 5 Phylogenetic tree for seadornaviruses based on (a) the polymerase gene and (b) on the cell-attachment (and seroneutralization) protein. The phylogenetic comparison based on the cell-attachment (and seroneutralization) protein distinguishes the the two genotypes (serotypes) of BAV and also those of LNV.

BAV (VP9), KDV (VP11), and LNV (VP10) clearly identifies the two serotypes of BAV (A and B) and distinguishes the A and B serotypes of LNV (**Figure 5(b)**).

All 12 segments of BAV, KDV, and LNV have conserved sequences, located at their 3′ and 5′ termini. The motifs 5′-GUAU$^{A}/_{U}{}^{A}/_{U}$A$^{A}/_{U}{}^{A}/_{U}{}^{A}/_{U}$-3′ and 5′-C$^{C}/_{U}$GAC-3′ (+ve strand) were found in the 5′ noncoding region (NCR) and the 3′ NCR of BAV, respectively, while in KDV, these motifs were 5′-GUAGAA$^{A}/_{U}{}^{A}/_{U}{}^{A}/_{U}{}^{A}/_{U}$-3′and 5′-$^{C}/_{U}$GAC-3′ (+ve strand) and in LNV they were 5′-GUUAU$^{A}/_{U}{}^{A}/_{U}{}^{A}/_{U}$-3′ and 5′-$^{C}/_{U}{}^{C}/_{U}$GAC-3′ (+ve strand), respectively. For the BAV and KDV viruses, the 5′ and 3′ terminal trinucleotides of all segments are inverted complements. LNV has a difference in position 3 of the 5′ ends and therefore only the 5′ and 3′ terminal dinucleotides of all segments are inverted complements.

The genetic relation between BAV, LNV, and KDV is reflected in their morphological characteristics. Electron microscopic analysis showed that the three viruses are morphologically identical.

Within the family *Reoviridae*, the most conserved gene between different genera encodes the RNA-dependent RNA polymerase (RdRp). Values for amino acid identity of lower than 30% can be used to distinguish members of distinct genera. A tree constructed from the alignment of polymerase sequences of representative members of the family *Reoviridae* (**Table 3**) is shown in **Figure 6**. Calculations of amino-acid-identity values based on this alignment show that the coltivirus polymerases exhibit a maximum of 15% identity with those of the seadornaviruses, confirming the status of *Coltivirus* and *Seadornavirus* as a distinct genera. In contrast amino acid identities as high as 28% were detected between the seadornaviruses and the rotaviruses (members of a distinct genus of 11-segmented viruses also within the family *Reoviridae*).

Evolutionary Relationships between BAV and Rotaviruses

A sequence comparison of the structural proteins of BAV (VP1, VP2, VP3, VP4, VP8, VP9, and VP10) to those of other members of the *Reoviridae*, have shown similarities between VP9 and VP10 of BAV and the VP8* and VP5* subunits of the outer coat protein VP4 of rotavirus A, with amino acid identities of 21% and 26%, respectively. This suggests that an evolutionary jump has occurred between the two genera, involving the expression of two BAV proteins (VP9 and VP10) from two separate genome segments rather than the generation of VP8* and VP5* by the proteolytic cleavage of a single gene product (as seen in the cleavage of rotavirus VP4). VP3 of BAV, which is the guanylyltransferase of the virus also exhibits significant identity (21%, AA identity) with the VP3 (guanylyltransferase) of rotavirus.

Structural Features and Relation to Rotaviruses

Electron micrographs of purified, intact BAV particles show striking similarities to those of the rotaviruses. Numerous protein spikes were observed on the surface of BAV, reminiscent of those of rotaviruses. This morphological resemblance has not previously been reported between rotaviruses and other members of family *Reoviridae*. The evolutionary relationship between the seadornaviruses and rotaviruses was further confirmed when the atomic structure of BAV VP9 was determined by X-ray crystallography. VP9 is a trimeric molecule that is held together by an N-terminal helical bundle (**Figure 7**). The N-terminal tail of the BAV VP9 monomer is reminiscent of the coiled-coils structures of the HIV gp41 protein, and the carboxy terminal of the VP5* of rotavirus (**Figure 7**). In contrast the monomer of BAV VP9 has a head domain made mainly of β-sheets (**Figure 7**), which shows significant structural similarities to rotavirus VP8*. However, VP8* does have a sialic acid-binding domain, which is absent from the head domain of the VP9 of BAV. This might explain why rotavirus infectivity can be decreased when cells are pretreated with sialidases although BAV infectivity, to C6/36 mosquito cells, is not altered by a similar treatment.

Functional Studies

Expressed BAV VP9 was used in competition assays with intact virus particles, in an attempt to decrease their infectivity, as demonstrated with the outer capsid proteins of some other reoviruses (e.g., the avian orthoreoviruses). Surprisingly, however, pretreatment of cells with VP9 increased the infectivity of BAV by 10–100 times. VP9 is thought to act as a membrane fusion protein and the N-terminal coiled-coils may be responsible for such an activity. This may explain why soluble trimeric VP9 can increase viral infectivity. VP9 trimers not only bind receptor but also initiate endocytosis, perhaps by receptor oligomerization. The initiation of endocytosis facilitates penetration by virus particles present at or near the cell surface and thereby increases their infectivity.

BAV VP9 also carries the virus seroneutralization epitopes. Anti-VP9 antibodies are highly neutralizing and define the two serotypes A and B of BAV. Animals immunized with VP9 failed to replicate the virus when challenged with the homologous type. Animals immunized with VP9 of the heterologous serotype showed unaltered virus replication and viremia. Similar results were obtained in cell cultures. VP9 could therefore be used as a vaccine subunit for immunization. Sequence analysis of BAV VP3 suggests that it is the viral capping enzyme (CaP).

This has been confirmed experimentally by incubating virus particles with α-^{32}P GTP. VP3 was covalently

labeled with α-^{32}P derived from GTP. The reaction was found to be dependent on the presence of divalent ions such as magnesium. The recombinant VP3 also covalently bound α-^{32}P GTP and exhibited an inorganic pyrophosphatase activity, possibly as a detoxifying mechanism which removes the inorganic pyrophosphate accumulated during RNA and Cap structure synthesis by the virus-core-associated enzymes. Similar properties were described for the capping enzyme VP4 of Bluetongue virus (genus *Orbivirus*).

Clinical Features and Diagnostic Assay for Seadornaviruses

As mentioned earlier, the only seadornavirus that has been isolated from humans and associated with human disease (to date) is BAV. Humans infected with BAV develop flu-like manifestation, myalgia, arthralgia, fever, and encephalitis. Reports of children born to infected mothers (as revealed by serological assays) show various manifestations including cerebral palsy, hemiplegia, delay of development, and viral encephalitis.

A diagnostic serological assay was developed for different serotype of BAV, based on outer coat protein VP9 (which is responsible for cell-attachment and sero-neutralization). Molecular diagnostic assays have also been developed for BAV and KDV. These are RT-PCR-based assays, which have been validated using an infected murine model in which viral RNA could be detected in blood as early as 3 days post infection. These RT-PCR assays can also be used to distinguish genotypes A and B of BAV, based on distinct amplicons of different lengths, that are obtained by specific primers at different locations in

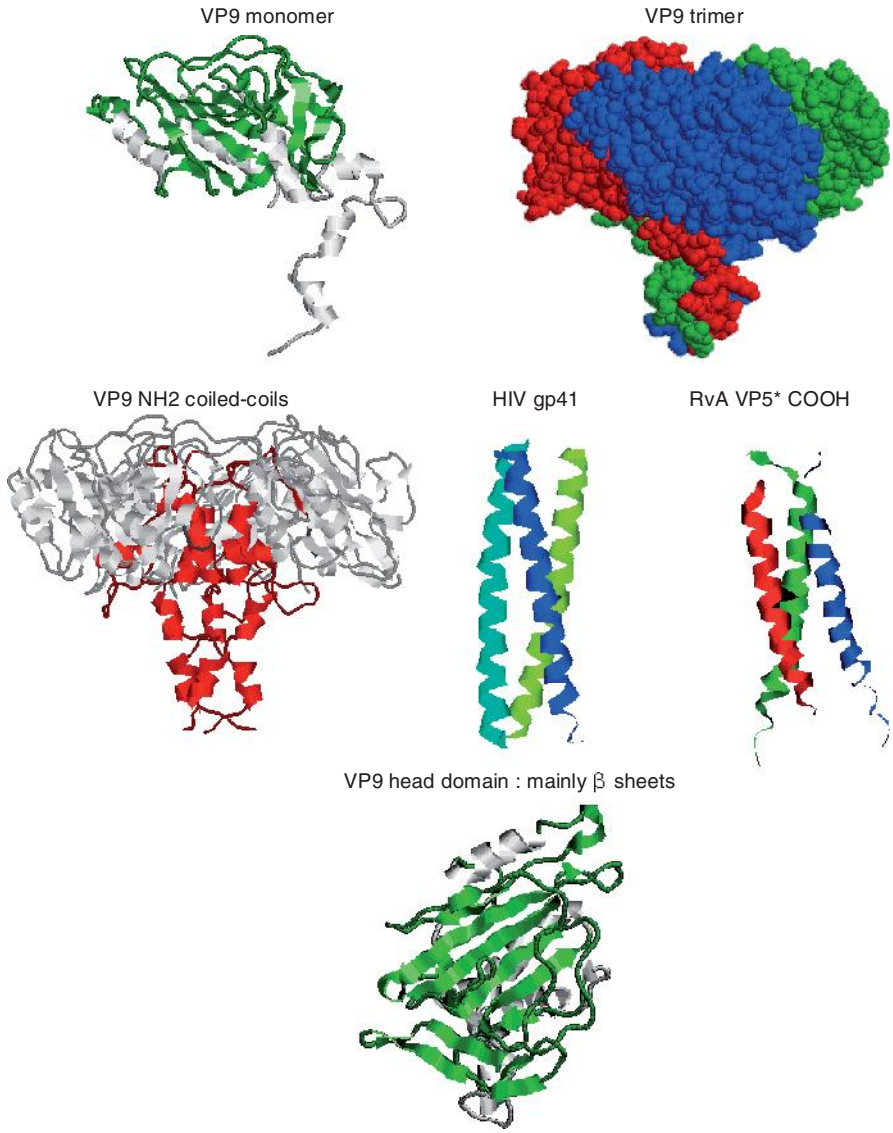

Figure 7 The structure of the VP9 outer capsid protein of Banna virus determined by X-ray crystallography at a resolution of 2.6 angstrom. The NH2 terminal of the BAV VP9 is organized in the form of coiled-coils that are similar to those found in fusion active proteins such as HIV gp41 and VP5* of rotavirus. RvA, Rotavirus A.

Seg-9. A quantitative PCR assay has also been developed for BAV based on the sequence of Seg-10. A standard RT-PCR assay was recently developed for LNV based on the sequence of Seg-12, which can be used to detect viral RNA in infected mouse blood.

Severity of Infection in Animal Model and Diversification of Genome Sequence after Replication in Permissive Animals

Banna, Kadipiro, and Liao ning viruses all replicate in mice after intraperitoneal injection. The viral genome can be detected in mouse blood 3 days until 5–7 days post injection. Clearance of the viremia is accompanied by the appearance of antibodies. When animals were injected on a second occasion with the same virus, BAV and KDV failed to replicate, demonstrating the immune status of the mice. However, LNV replicated in the immunized mice causing death with a severe hemorrhagic syndrome. An analysis of the PCR amplicons from the infected mice blood showed very few changes in the sequences of the BAV and KDV genomes. However, there was considerable diversification in the genome of LNV, as demonstrated by analyses of the sequence of Seg-12, leading to formation of a diverse quasispecies. This might explain why LNV can continue to replicate in the immunized mice, as diversification of the sequence might help the virus to 'escape' the immune system.

Treatment and Immunity

There is no specific treatment for BAV infection. Patients infected with BAV have shown a fourfold rise in the anti-BAV antibody titers in paired sera tested by ELISA, showing that an immune response is developed to the virus infection. Mice experimentally infected with BAV developed viremia. The clearance of the virus from the blood circulation occurred concomitantly with the appearance of anti-BAV antibodies. Based on the mouse model, immunization with a recombinant expressed VP9 is likely to provide a significant level of protection against an initial infection with the homologous virus type. Immunization with VP9 could therefore provide a significant level of protection in high-risk areas and it might form the basis for an effective subunit vaccine.

Glossary

Helper component A viral-encoded protein that mediates the transmission of viruses by vectors.
Semipersistent transmission A mode of vector-mediated transmission of plant viruses in which viruses are usually acquired within few minutes, and retained up to several days by vectors. Viruses do not multiply in vectors and often require a helper component during semipersistent transmission.

Introduction

Sequiviridae is a relatively newly recognized family of viruses, although the viruses classified into this family had been reported already in the early 1970s. Viruses belonging to the family *Sequiviridae* were often referred to as 'plant picorna-like viruses' due to their similarities to picornaviruses in virion morphology and genome structure. They have a monopartite single-stranded RNA (ssRNA) genome encapsidated in isometric particles. They infect plants and are usually transmitted by insect

vectors in nature. Special attention has been given to two of the members, maize chlorotic dwarf virus (MCDV) and rice tungro spherical virus (RTSV), since they are involved in major diseases of important cereal crops. Chlorotic dwarf disease is considered to be the second most important viral disease of maize in the USA, and tungro disease is the most serious threat to rice production in South and Southeast Asia. One of the unique biological features found in these viruses is that most of them act as or require a helper virus for transmission by insect vectors. The name of the family comes from the Latin word *sequi* which means to follow or accompany, in reference to the dependent insect transmission of parsnip yellow fleck virus (PYFV), one of the type members in this family.

Taxonomy

The family *Sequiviridae* is divided into two genera, *Sequivirus* and *Waikavirus*. At present the genus *Sequivirus* has two species *Parsnip yellow fleck virus* (type species) and *Dandelion yellow mosaic virus*. Three species, *Rice tungro spherical virus* (type species), *Maize chlorotic dwarf virus*, and *Anthriscus yellows virus* are classified as members of the genus *Waikavirus* (**Table 1**). In addition, lettuce mottle virus is considered as a tentative member of the genus *Sequivirus*.

Viruses belonging to the genus *Sequivirus* infect mesophyll and epidermal cells and are able to be transmitted by mechanical inoculation and insect vectors, while those belonging to the genus *Waikavirus* are usually limited in phloem tissue and transmitted only by insect vectors. Sequiviruses are dependent on a helper virus for their transmission by insect vectors. Waikaviruses are independently transmitted by insect vectors and presumably encode a helper component in their genomes. The viruses in the family *Sequiviridae* are primarily classified on the basis of their biological and physical characteristics, but conspicuous differences are also found in their genome features. The genomes of MCDV and RTSV are approximately12 kb in length and polyadenylated at the 3′ end, whereas that of PYFV is about 10 kb and devoid of the 3′ poly(A) region.

Properties of Virions

Viruses belonging to *Sequiviridae* have nonenveloped isometric particles of approximately 30 nm in diameter (**Figure 1**). The sedimentation coefficients of the virions are 153–159S for sequiviruses and 175–183S for waikaviruses. The buoyant density of PYFV virions in CsCl is 1.49 g ml^{-1}, and that of waikaviruses is 1.51–1.55 g ml^{-1}. Genome sequences and immunodetection of the viruses belonging to the family *Sequiviridae* indicate that the virions consist of three capsid proteins (CPs). The sizes of CPs range from 22 to 35 kDa, depending on virus species and isolates. The virion of RTSV (Philippine-type strain A) consists of three proteins of 22.5 (CP1), 22 (CP2), and 33

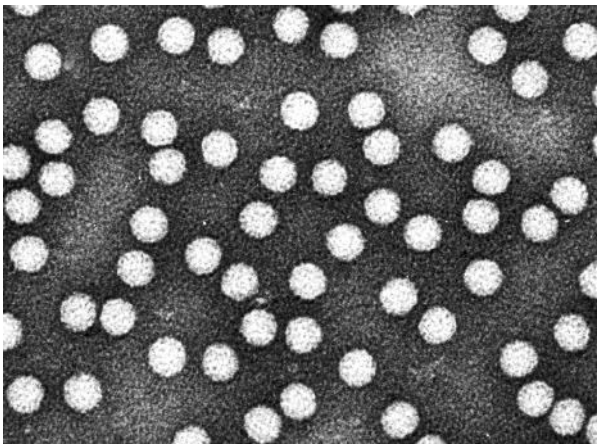

Figure 1 Virions of RTSV. The estimated size of particles is approximately 30 nm.

Table 1 Virus members in the family *Sequiviridae*

Genus/virus	*Genome size (kb)*	*Geographical distribution*	*Major natural host*	*Transmission vector*
Sequivirus				
Parsnip yellow fleck virus	9.9	Europe	Parsnip, hogweed, cow parsley	Aphids (*Cavariella aegopodii, C. pastinacae*)
Dandelion yellow mosaic virus	10.0[a]	Europe	Lettuce, dandelion	Aphids (*Acyrthosiphon solani, Myzus ornatus, M. ascalonicus, M. persicae*)
Waikavirus				
Rice tungro spherical virus	12.2	Asia	Rice, *Oryza* species	Green leafhoppers (*Nephotettix virescens* and four other species)
Maize chlorotic dwarf virus	11.8	USA	Maize, Johnson grass	Deltocephaline leafhopper (*Graminella nigrifrons*)
Anthriscus yellow virus	10.6[a]	Eurasia, UK	Cow parsley	Aphid (*Cavariella aegopodii*)

[a]Estimated size (nucleotide sequence not determined).

(CP3) kDa. The predicted molecular masses for the CP of MCDV (Tennessee (TN) isolate) are 22, 23, and 31 kDa, and those of PYFV (P-121 isolate) are 22.5, 26, and 31 kDa.

Genome Structure

The genomes of viruses belonging to the family *Sequiviridae* are positive-sense, monopartite ssRNA. The length of genomes varies significantly, ranging from approximately 10 kb for sequiviruses to 12 kb for waikaviruses. The genomes contain a large open reading frame (ORF) encoding a polyprotein presumably proteolytically processed by viral-encoded protease(s) during translation (**Figure 2**). The large ORF in the genome of PYFV (P-121 isolate) putatively encodes a polyprotein consisting of 3027 amino acid residues with the predicted molecular mass of about 336 kDa. The large ORF in the genomes of waikaviruses encodes a polyprotein of approximately 400 kDa, which has about 3440–3470 amino acid residues. In addition to the ORF for the polyprotein, short ORFs were also identified near the 3′ and the 5′ ends of MCDV and RTSV genomes. Two RNA species which seemingly correspond to subgenomic transcripts from the short ORFs locating near the 5′ end of the RTSV genome (strain A) were detected from infected plants. However, the lengths and locations of the short ORF in the genomes of waikaviruses vary considerably among viruses and isolates, and the presence of products translated from these ORFs was not confirmed in plants. The 5′-untranslated region (UTR) in the genome of PYFV (P-121 isolate) is about 0.28 kb in length, while those of waikaviruses are longer, about 0.43 kb in MCDV and 0.52 kb in RTSV. The 5′-UTR in the genomes of MCDV and RTSV has several AUG sequences upstream of the putative polyprotein start site, and appeared to form extensive secondary structures. As observed in the genome of picornaviruses, such secondary structures may serve as the internal ribosomal entry site to avoid the interference on translation by upstream AUG sequences. No stable secondary structures are recognized in the 5′-UTR of the PYFV genome; however, several short stretches of pyrimidines (UCUCUY) are present in the region. The 3′-UTR in the genomes of waikaviruses are polyadenylated and unusually long. The length of 3′-UTR in the genomes of MCDV and RTSV are approximately 1.0 and 1.2 kb, respectively, provided that the short ORFs near the 3′ end of genomes are not translated. The 3′-UTR in the genome of PYFV is approximately 0.5 kb in length. Unlike the genomes of waikaviruses, that of PYFV is not polyadenylated, but a part of 3′-UTR is likely to form a stem–loop structure which is similar to that found in the genomes of flaviviruses.

Properties of Viral Proteins

Based on the protein sequences predicted from the large ORF, and the actual sequences of the N-termini of CPs, it was predicted that the polyproteins of viruses belonging to the family *Sequiviridae* are cleaved into at least seven proteins through proteolytic maturation. It appears that the N-terminal half of the polyprotein contains regions for a leader protein and three CPs. Protein regions showing similarities to helicase, protease, and RNA-dependent RNA polymerase (RdRp) of picornaviruses and comoviruses are recognized in the central to carboxyl (C)-terminal regions of the polyproteins. The arrangement of functional domains in the polyproteins of the viruses belonging to *Sequiviridae* shows significant similarity to that of picornaviruses, indicating that the strategies of genome replication and expression for the viruses of *Sequiviridae* might be analogous to those of picornaviruses.

Comparative sequence analysis indicated that the polyproteins of the viruses belonging to the family *Sequiviridae*

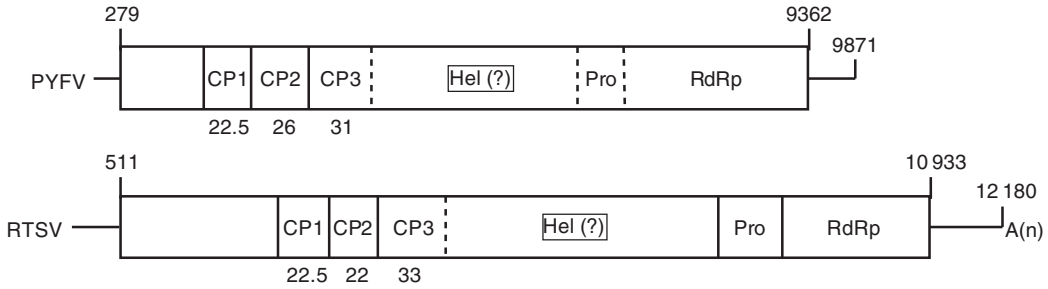

Figure 2 Genome structure of PYFV (P-121 isolate) and RTSV (strain A). The ORFs for polyprotein are indicated with rectangles. Horizontal lines at both ends of the ORFs represent the 5′- and 3′-UTR of the genome. Solid vertical lines dividing the ORF correspond to the positions of proteolytic cleavage sites in the polyproteins when translated, while the positions corresponding to predicted cleavage sites are indicated with dotted lines. Positions of translation start and stop codons for the polyproteins and the length of the entire genomes are indicated with the numbers above the genomes. Numbers below the regions encoding CP1–CP3 are the predicted molecular weight (kDa) for the respective CP. Shadowed areas represent the approximate region encoding NTP-binding domain. The regions in the ORF are shown with Hel (?) for putative NTPase/helicase, Pro for 3C-like cysteine proteinase, and RdRp for RNA-dependent RNA polymerase. A(n) indicates the polyadenylation at the 3′ end of the RTSV genome.

contain a protease region similar to the 3C cysteine protease of picornaviruses and other viral proteases resembling the 3C protease such as the 24 kDa protease of cowpea mosaic virus (CPMV) and the NIa protease of tobacco etch virus. For example, considerable similarity was found between the region delimited by the amino acid residues 2643 and 2853 in the polyprotein of RTSV (strain A) and a region in the 24 kDa protease of CPMV. Immunodetection using an antiserum raised against a protein containing the putative protease region of RTSV indicated that the size of mature protease in infected plants is approximately 35 kDa. The sequence context of cleavage site for the 3C cysteine protease and the results from *in vitro* translation from partial genomic RNA templates defined the region of the protease in the RTSV polyprotein to be from amino acid residues 2527–2852. The RTSV protease presumably acts *in cis* to cleave itself from the adjacent protein regions, but *trans*-cleavage by the RTSV protease was also observed to occur between the protease and the putative helicase regions *in vitro*. Based on the sequence alignment among the 3C-type proteases, amino acid residues such as His^{2680}, Glu^{2717}, Cys^{2811}, and His^{2830} in the RTSV polyprotein were predicted to constitute the catalytic triad or substrate-binding pocket of the cysteine protease. Substitutions of these amino acid residues abolished or drastically reduced the proteolytic activity, substantiating their critical roles in the cysteine protease. Conserved amino acid residues which may constitute the catalytic triad were also identified in the protease regions of MCDV and PYFV, although the involvement of the individual residues in the protease activity has not been experimentally demonstrated.

The C-terminal region in the polyproteins of viruses belonging to the family *Sequiviridae* shows extensive similarity in amino acid sequence to RdRp of picornaviruses and comoviruses. The RdRp region of RTSV (strain A) was defined in the region between amino acid residues 2853 and 3473 with the conserved YGDD motif at amino acid residues 3270–3273. The RdRp region of MCDV (isolate TN) has the conserved YGDD motif at amino acid residues 3238–3241. In addition, motifs such as DYSXFDG (amino acid residues 3129–3135 in the MCDV polyprotein) and $PSGX_3TX_3NS$ (amino acid residues 3189–3200) were identified to be conserved among the RdRp regions of MCDV, CPMV, and tomato black ring virus (TBRV). Multiple alignment of the RdRp region of PYFV (isolate P-121) with those of CPMV, TBRV, and poliovirus showed that they share several conserved motifs including sequences YGDD (amino acid residues 2629–2632 in the PYFV polyprotein), $PSGX_3TX_3NS$ (amino acid residues 2580–2591), and FLKR (amino acid residues 2684–2687).

The central region flanked by the CP and the protease regions in the polyproteins of viruses belonging to the family *Sequiviridae* contains sequence motifs GX_4GKS and DD, which are conserved among proteins with NTP-binding domain. The NTP-binding domain of the central polyprotein regions shows extensive similarity to the corresponding domains in the 58 kDa protein of CPMV and the 2C proteins of picornaviruses. The 58 kDa protein and the 2C protein presumably function as a nucleoside triphosphatase (NTPase)/helicase required for the initiation of negative-strand RNA synthesis. Antibodies specific to protein segments from the central region of the MCDV polyprotein reacted with three protein species in extracts from infected plants. The sizes of the proteins detected were smaller than predicted from the intact central region, indicating that the protein in the central region might be processed into smaller proteins.

It appeared that the polyproteins of viruses belonging to *Sequiviridae* have a region for putative leader protein(s) at the N-terminal region. Although the predicted sizes of the putative leader proteins are about 40 kDa in PYFV, and 70–78 kDa in waikaviruses, the sizes of proteins detected with the antisera specific to the putative leader proteins are significantly smaller than predicted. An antiserum specific to the putative RTSV leader protein detected a protein of about 32 kDa in extracts from infected plants. Meanwhile, proteins with apparent sizes of 50, 35, and 25 kDa in the extracts from plants infected with MCDV (severe (S) strain) reacted with the antibody specific to the putative MCDV leader protein. These results suggest that the putative leader proteins of waikaviruses may be processed post-translationally in plants. The function associated with the leader protein region is still unclear. However, such leader protein found in the polyprotein of aphthoviruses in the family *Picornaviridae* has a protease activity which cleaves itself autocatalytically from the polyprotein. It was proposed that the 35 kDa protein of MCDV is generated from the leader protein region through autoproteolysis at the putative cleavage site ALVRLFHGSAE (amino acid residues 150–160), while the 25 kDa protein results from the cleavage at Q^{445}/S^{446} and Q^{686}/S^{687} by a cysteine protease. The 25 kDa protein may function as the helper component in the insect transmission of MCDV since the protein was observed to accumulate in vector insects after feeding on plants infected with MCDV. This observation is consistent with the result from a serological blocking experiment showing that the helper component is not the virion or CP.

Three consecutive regions of CPs are present in the N-terminal half of the polyproteins of the viruses belonging to the family *Sequiviridae*. The proteolytic cleavage sites for the RTSV CPs determined by N-terminal amino acid sequencing were mapped to Q^{644}/A^{645}, Q^{852}/S^{853}, and Q^{1055}/D^{1056} for the junctions between leader protein/CP1, CP1/CP2, and CP2/CP3, respectively. The context of these cleavage sites suggests that the CPs are processed *in trans* by a cysteine protease. However, the cleavage at these sites with the RTSV protease was not detected *in vitro*. The difference in the reactivity among the CPs of

RTSV with the antibody raised against the virus particles indicated that the 33 kDa CP (CP3) is the major antigenic determinant on the surface of particles, although the structural details of virus particles have not been elucidated yet. The size of CP3 of RTSV (Philippine isolate) in the crude extract from infected plants detected by the antibody specific to CP3 appeared to be 40–42 kDa, markedly larger than that detected from purified virus preparation or that expected from the genome sequence. It is likely that the size of CP3 in infected cells is larger due to post-translational modification, but the modified moiety appeared to be cleaved off probably by the treatment with cellulolytic enzymes during virion purification.

Phylogenetic Relationships

Comparison of amino acid sequences revealed that the sequence similarities of the MCDV (isolate TN) polyprotein to those of RTSV (strain A) and PYFV (isolate P-121) were 51% and 35%, respectively. Overall similarity in genome organization and the presence of several conserved motifs in the polyproteins indicate that the viruses of the family *Sequiviridae* are closely related to picornaviruses and comoviruses. The NTP-binding domain appeared to be the most conserved region in the polyproteins among the viruses belonging to the family *Sequiviridae*, picornaviruses and comoviruses. The NTP-binding domain in the polyprotein of MCDV (TN isolate) showed significant sequence similarity to those of viruses such as RTSV (strain A, 79%), PYFV (isolate P-121, 55%), CPMV (46%), hepatitis A virus (HAV, 47%), and poliovirus (45%). The regions of RdRp also show significant similarities to one another among members of the family *Sequiviridae*, picornaviruses and comoviruses. For instance, the sequence similarities in the RdRp region of MCDV (TN isolate) to those of related viruses are 75% for RTSV, 50% for PYFV, 48% for CPMV, 44% for TBRV, and 40% for HAV. Phylogenetic analysis based on the sequences of NTP-binding domains indicates that PYFV and RTSV are not noticeably similar to each other compared to their relatedness to picornaviruses and comoviruses. However, phylogenetic analysis based on the regions of RdRp suggests that PYFV and RTSV are more closely related to each other than to picornaviruses and comoviruses. Unlike the region of RdRp and NTP-binding domain, the CPs of viruses belonging to the family *Sequiviridae* show no sequence similarities to those of comoviruses, and only limited similarities to those of some picornaviruses. The 26 kDa CP of PYFV and the 22.5 kDa CP of RTSV contain amino acid sequences resembling those in VP3 of encephalomyocarditis virus and human rhinovirus 14. The closer relatedness of nonstructural protein regions in members of the family *Sequiviridae* to those of comoviruses, and the similarity in the CP sequences among PYFV, RTSV, and some picornaviruses imply that the family *Sequiviridae* may fit taxonomically between *Comoviridae* and *Picornaviridae*.

Variation of Isolates and Strains

Isolates of PYFV are largely divided into two groups. One is the parsnip serotype which includes isolates from parsnip, celery, and hogweed, while those from carrot and cow parsley belong to the other group, the *Anthriscus* serotype. The two groups of isolates are distinguishable by reciprocal immunodiffusion tests with antisera raised against isolates belonging to either group. In addition to the difference in natural hosts, the artificial inoculation of test plants with the respective isolates showed evident difference in host ranges between the two groups of isolates, although minor differences in host range and symptoms on certain plants were also observed among the isolates within each serotype.

Examination of nucleotide sequences of the RTSV CP revealed broad genotypic variation among and within geographic isolates, although the relationship of genotypic variation with the pathogenicity is not understood yet. Isolates of RTSV from the Philippines and Malaysia show about 95% sequence similarity, while those from Bangladesh and India differ from the Philippine isolate by about 15%. The CP3 of the Indian isolate was distinguishable from that of the Philippine isolate in electrophoretic mobility and the response to cellulolytic enzyme. Genotypic survey on the CP sequences of RTSV field isolates collected from various sites in the Philippines and Indonesia indicated that a high degree of genetic diversity exists among the field isolates, and that infections with mixed genotypes in single sites are not uncommon. Phylogenetic analysis based on the CP sequences of the RTSV field isolate suggested that the clustering of genotypes found in the Philippines sites was significantly different from that found in the Indonesia sites, indicating geographic isolation of RTSV populations. Strain Vt6 of RTSV was found to possess enhanced virulence, showing infectivity to some rice cultivars which the type strain A may not be able to infect. Amino acid sequence of strain Vt6 was approximately 95% identical to that of strain A, with greater dissimilarity in the leader protein region and the putative small ORF found near the 3′ end.

Few isolates of MCDV with distinctive biological and genotypic characteristics have been reported. The S isolate of MCDV was observed to produce more pronounced symptoms than the type (T) isolate. The mild (M1) isolate usually exhibits mild symptoms by itself, but it develops severe symptoms by synergistically interacting with other MCDV isolates. The deduced amino acid sequences of isolates S and T show 99.5% identity, while that of isolate M1 has only 61% identity to that of isolate T. In fact, antisera raised against isolate T react strongly with isolate

S, but not with isolate M1. Isolate TN of MCDV is also significantly divergent from isolate T, showing only 60% of amino acid sequence identity. The low levels of amino acid sequence identity among the isolates of MCDV raised the possibility that they may represent distinct virus species.

Interactions between Viruses

Viruses belonging to the family *Sequiviridae* are often detected in plants infected with other viruses, for instance, cow parsley infected with PYFV and anthriscus yellows virus (AYV), and rice plants infected with rice tungro bacilliform tungrovirus (RTBV) and RTSV. Such mixed infections appear to be the outcome of the dependent insect transmission of one virus on the other. Incidences of mixed infection in lettuce with dandelion yellow mosaic virus and lettuce mosaic virus were also reported, but their relationships in aphid-mediated transmission are still unclear.

PYFV is transmitted by mechanical inoculation, but AYV is not. Both viruses are also transmitted by aphids in a semipersistent manner. However, the aphid-mediated transmission of PYFV is dependent on AYV. PYFV is transmitted by aphids from plants infected with both viruses or by aphids previously fed on plants infected with AYV. Aphids seem to retain PYFV and AYV for up to 4 days. Even though AYV cannot infect parsnip, PYFV can be transmitted to parsnip by aphids fed on other plants infected with AYV and PYFV. Therefore, AYV apparently acts only as the helper virus for aphids to acquire PYFV, and is not necessary for the infection process of PYFV.

Rice tungro disease is caused by the interaction between RTSV and RTBV. Both viruses are transmitted by green leafhoppers (GLHs) in a semipersistent manner. GLHs transmit RTSV and RTBV simultaneously or singly from source plants infected with both viruses. RTSV is independently transmitted by GLHs, but RTBV can be transmitted by GLHs which feed on plants infected with RTSV. Although GLHs retain RTSV for only 3–4 days, their ability to acquire and transmit RTBV may persist for 7 days. Neutralization of RTSV-viruliferous GLHs with anti-RTSV immunoglobulin markedly reduced the ability to transmit RTSV but still retained the ability to acquire and transmit RTBV. These observations indicate that RTSV is the helper virus for the GLH-mediated transmission of RTBV, but the helper function is associated with factors other than RTSV virions or CP. Rice plants infected with RTBV alone exhibit symptoms such as stunted growth, yellow to yellow-orange discoloration of leaves, and reduced tillering. The symptoms become more severe when plants are simultaneously infected with RTBV and RTSV, despite the fact that RTSV alone does not cause conspicuous symptoms except occasional slight stunted growth (**Figure 3**). Such synergistic effects of RTSV on symptom development are also observed when RTSV co-infects plants with viruses such as rice grassy stunt virus and rice ragged stunt virus.

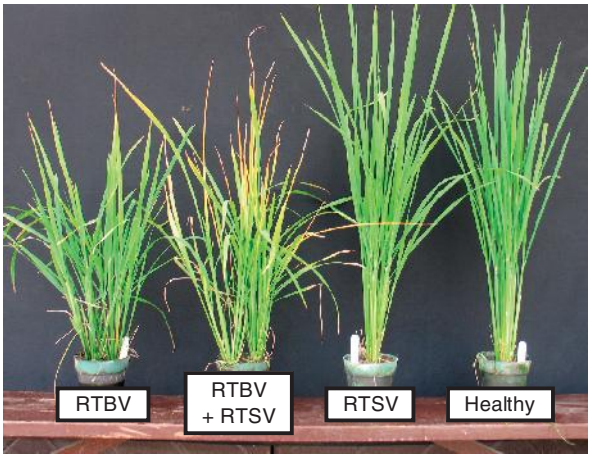

Figure 3 Synergistic effects between RTSV and RTBV on the symptom development in rice. Rice plants shown (left to right) were infected with RTBV alone (RTBV), both RTBV and RTSV (RTBV + RTSV), RTSV alone (RTSV), or not infected (healthy). Plants infected with both RTBV and RTSV were stunted and showed severe discoloration of leaves.

Glossary

Bioavailability A measurement of the proportion of the orally administered dose of a therapeutically active drug that reaches the systemic circulation and is available at the site of pathology.
Coryza A runny nose.
Desquamation Shedding of epithelialium.
Lymphopenia Reduction of lymphocytes in the circulating blood below the normal range for age.
Myalgia Muscle pain.
Pathognomonic Characteristic and diagnostic of a particular disease.
PEGylated An adjective for describing molecules conjugated with polyethylene glycol (PEG).
Radiological abnormalities Atypical findings observed by medical imaging procedures (e.g., chest X-ray).

History

From November 2002 to January 2003, cases of an unusually severe atypical pneumonia were being observed in Guangdong Province, China. The disease was characterized by the lack of response to conventional antibiotic therapy and the occurrence of clusters of cases within a family or healthcare setting. In retrospect, these were the first known cases of the disease that was later to be called severe acute respiratory syndrome (SARS). Through January, the numbers of cases of this unusual 'atypical pneumonia' continued to increase with examples of 'super-spreading incidents' that were to punctuate the course of the subsequent SARS epidemic. Between 16 November and 9 February, 305 cases were identified, one-third of them in healthcare workers (**Table 1**).

On 21 February 2003, a 65-year-old doctor working in a hospital in the city of Guangzhou, the provincial capital of Guangdong, arrived in Hong Kong and checked into Hotel M. He had treated patients with 'atypical pneumonia' in Guangzhou and had been ill himself since 15 February. His 1-day stay on the ninth floor at this hotel led to the infection of at least 17 other guests or visitors, some of whom traveled on to Hanoi, Toronto, Vancouver, Singapore, USA, Philippines, Guangzhou, and Australia. Five of these secondary cases initiated clusters of infection in Hanoi, Singapore, Toronto and two clusters of infection within Hong Kong. This was the most significant single event in the global spread of SARS, and arguably the most dramatic known event in the global spread of any infectious disease. However, because the secondary cases had largely dispersed outside of Hong Kong, this cluster of cases remained 'invisible' until the epidemiological linkages were reconstructed in mid-March.

Between 26 February and 10 March, disease outbreaks were recognized in the Hanoi-French Hospital in Vietnam and in Prince of Wales Hospital in Hong Kong. Dr. Carlo Urbani, a World Health Organization (WHO) communicable diseases expert stationed in Vietnam, examined the first cases of the disease outbreak in Hanoi and provided WHO with the first case descriptions of this new disease. Later, Dr. Urbani was himself one of the victims who succumbed to this disease. On 12 March, the WHO issued a Global Health Alert regarding an atypical pneumonia that was a particular risk to healthcare workers. Subsequently, Singapore and Toronto also reported clusters of cases. On 15 March, the WHO issued a Travel Advisory. The new disease was named SARS and a preliminary case definition was provided. The WHO set up virtual networks of virologists, clinicians, and epidemiologists to rapidly collate, evaluate, and disseminate information about the new disease.

Within weeks, SARS had spread to affect 8096 patients in 29 countries across five continents with 744 fatalities, an overall case–fatality rate of 9.6%. Healthcare facilities served as a major amplifier of infection, constituting 21% of all reported cases.

By 21–24 March, the etiological agent of SARS was identified to be a novel coronavirus, subsequently termed SARS coronavirus (SARS CoV). Serological tests demonstrated that the human population had no prior evidence of infection with SARS CoV, indicating that this virus had newly emerged in humans and implying a likely zoonotic origin.

Early case detection and isolation of infected individuals reduced and interrupted SARS CoV transmission across the world. By 5 July 2003, the WHO announced that all chains of human transmission of SARS were broken and the outbreak was at an end. This was indeed a historic triumph for global public health. Although SARS was subsequently to re-emerge to cause limited human disease (and in one instance, limited human-to-human transmission) as a result of laboratory escapes and zoonotic transmission from the live game animal markets of Guangdong in December 2003–January 2004 (**Table 1**), the human outbreak of SARS had been controlled.

Table 1 A chronology of events in the emergence of SARS

Date	*Key events*
16 November 2002	45-year-old man in Foshan city, Guangdong Province, mainland China becomes ill with fever and respiratory symptoms and transmits the disease to four other relatives.
10 December 2002	35-year-old restaurant chef working in Shenzhen is admitted to Heyuan City People's Hospital. Transmits disease to eight healthcare workers.
January 2003	Pneumonia outbreaks in Guangzhou (capital city of Guangdong Province). These include number of healthcare workers infected through the care of patients with the disease.
11 February 2003	Guangdong health authorities report an outbreak of respiratory disease in Guangdong with 305 cases and five deaths, one-third of the cases being in healthcare workers caring for patients with the disease. Cases were reported from Foshan, Heyuan, Zhongshan, Jiangmen, Guangzhou, and Shenzhen municipalities of Guangdong Province.
21 February 2003	A 65-year-old doctor from Guangdong arrives and checks in at Hotel M in Hong Kong. His stay of 1 day at this hotel leads to the infection of at least 17 other guests or hotel visitors who initiate clusters of infection within Hong Kong, Vietnam, Singapore, and Toronto.
26 February 2003	A 48-year-old 'Hotel M contact' is admitted to Hanoi-French Hospital in Vietnam and is the source of an outbreak there. Seven healthcare workers were ill by 5 March.
1 March 2003	A 22-year-old 'Hotel M contact' is admitted to Tan Tock Seng Hospital, Singapore. She will pass on infection to 22 close contacts.
4 March 2003	A 26-year-old Hotel M contact admitted to Prince of Wales Hospital, Hong Kong. His illness is relatively mild and is not categorized as severe pneumonia. He transmits infection to 143 persons including 4 members of his family, 67 healthcare workers or medical students, and 30 other patients.
5 March 2003	A 78-year-old 'Hotel M contact' dies at home in Toronto, Canada. Four family members are infected. They are the source for the subsequent Toronto outbreak.
5–10 March 2003	Outbreaks are recognized in Hanoi and Hong Kong.
12 March 2003	WHO issues a Global Alert about atypical pneumonia in Guangdong, Hong Kong, and Vietnam that appears to place healthcare workers at high risk.
13–14 March 2003	Singapore and Toronto report clusters of atypical pneumonia. In retrospect, both groups have an epidemiological link to Hotel M. One of the doctors who had treated develops symptoms while traveling and is quarantined on arrival in Germany on 15 March.
15 March 2003	WHO has received reports of over 150 cases of this new disease, now named severe acute respiratory syndrome (SARS). An initial case definition is provided. Travel advisory issued.
17 March 2003	WHO multicenter laboratory network on SARS etiology and diagnosis is established.
21–24 March 2003	A novel coronavirus is identified in patients with SARS.
12 May 2003	The genome sequence of the SARS coronavirus is completed.
June 2003	A virus related to SARS CoV is detected in civets and other small mammals in live game-animal markets in Guangdong.
5 July 2003	Lack of further transmission in Taiwan, the last region to have SARS transmission, signals the end of the human SARS outbreak.
September 2003	Laboratory-acquired SARS coronavirus infection in Singapore.
December 2003–January 2004	Re-emergence of SARS infecting humans from animal markets in Guangdong. Laboratory-acquired SARS coronavirus infections in Taiwan.
February 2004	Laboratory-acquired SARS leads to community transmission in Beijing and Anhui in China.

Virology

SARS Virus

SARS coronavirus is a member of the genus *Coronavirus* within the family *Coronaviridae* and the order *Nidovirales*. Coronaviruses are classified on genetic and antigenic characteristics into three groups and SARS CoV is presently regarded as a group 2b coronavirus. It is an enveloped, positive-sense, single-stranded RNA virus with a genome size of approx 29.7 kbp. The virus particle is approximately 100–160 nm in diameter with a distinctive corona of petal-shaped spikes on the surface which is comprised of the spike glycoprotein (S). The S protein is in a trimeric form on the viral surface. It has an N-terminal variable subdomain (S1) which contains the motifs responsible for receptor binding. A more conserved subdomain (S2), which contains heptad repeats and a coiled-coil structure, is important in the membrane fusion process. The S1–S2 subdomains remain in a noncleaved form in the intact SARS CoV virion and cleavage is believed to occur within the endocytic vesicle during the viral entry process. The envelope also contains a transmembrane glycoprotein M and in much smaller amounts, an envelope (E) protein. The M protein is a

triple-spanning membrane protein and has a key role in coronavirus assembly. The hemagglutinin-esterase (HE) glycoprotein, found in some group 2 coronaviruses, is absent in SARS CoV. The nucleocapsid protein (N) interacts with the viral genomic RNA to form the viral nucleocapsid. Viral replication complexes are believed to be localized within double-membraned vesicles or autophagosomes.

SARS CoV Genome

The genome of SARS CoV is that of a typical coronavirus. The viral genomic RNA has at least 14 open reading frames (ORFs) (**Figure 1**). The genome codes for 16 nonstructural proteins (nsp1–16), 5 structural proteins, and 7 accessory proteins. The genomic RNA encoding the replicase gene functions as mRNA to generate polyproteins 1a and 1ab. The translation of ORF1b is directed by a –1 ribosomal frameshift (RFS) signal that contains a nucleotide slippery sequence (5′-UUUAAAC-3′) and an RNA pseudoknot. By contrast, the structural and accessory proteins are products derived from subgenomic RNA (sgRNA 2–9) which are synthesized by discontinuous RNA transcription. Translated products from ORF2 (S), ORF4 (E), ORF5 (M), and ORF9a (N) are viral structural proteins as described above. Recently, it was reported that the protein encoded by the ORF3a, which is able to interact with S and contains ion channel activity, is also a structural protein. However, the full function of this protein is yet to be determined.

The polyproteins 1a and 1ab generated from the replicase gene are cleaved by a papain-like proteinase (part of nsp3) and a 3C-like proteinase (nsp5) to generate 16 nonstructural proteins (**Figure 1(b)**). Nsp12 is a primer-dependent RNA-dependent RNA polymerase (RdRp), whereas nsp8 is a noncanonical RdRp (nsp8) synthesizing primers utilized by nsp12. In addition, eight nsp7 and eight nsp8 subunits are able to form a hexadecamer with a hollow, cylinder-like structure. RNA-binding studies and the overall architecture of this nsp7–nsp8 complex suggest that it might encircle RNA and confer processivity of nsp12. The nsp9 is a single-stranded RNA-binding protein and is able to interact with nsp8. The nsp13 is a helicase and unwinds duplex RNA (and DNA) in a 5′-to-3′ direction. The nsp3, nsp14, nsp15, and nsp16 have been shown to have ADP-ribose 1′-phosphatase, 5′-to-3′ exonuclease, endoribonuclease, and 2′-*O*-ribose methyltransferase activities, respectively. These four proteins are distantly related to cellular enzymes involved in RNA metabolism. These observations may be relevant to viral RNA processing. The nsp10 contains two zinc finger motifs and is suggested to be a regulator of vRNA synthesis. The biological functions of nsp1, nsp2, nsp4, nsp6, and nsp11 are largely unknown. The nsp1 is reported to induce chemokine dysregulation and host mRNA

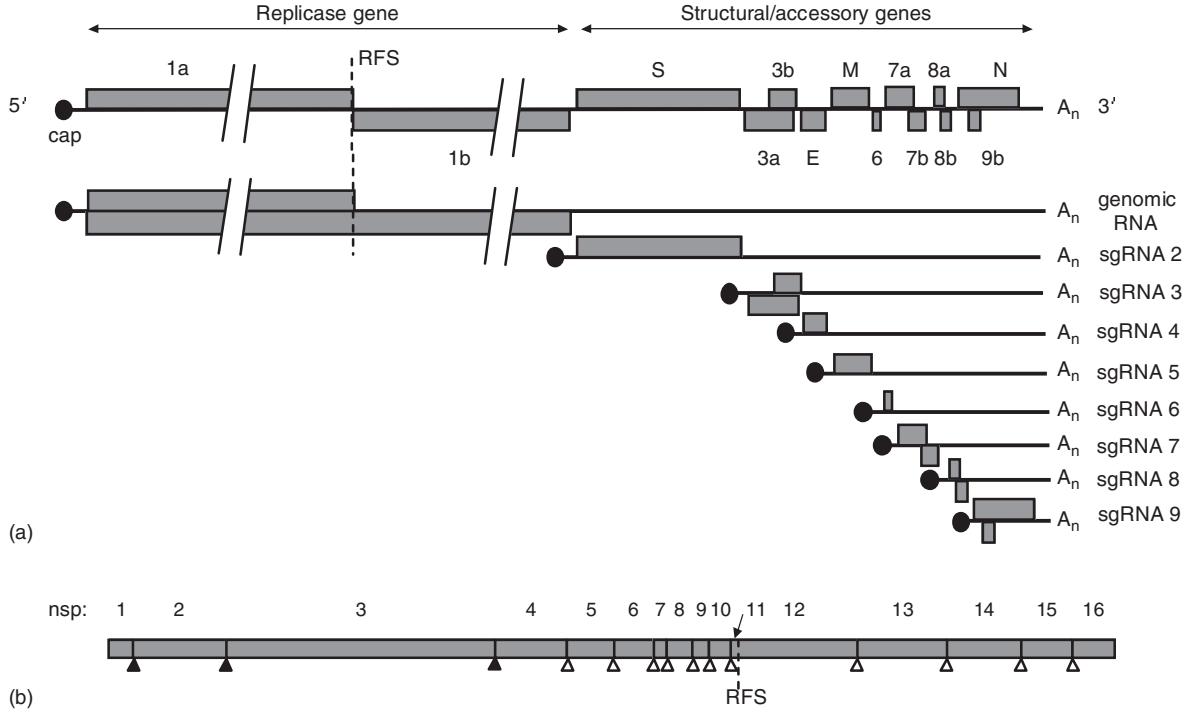

Figure 1 SARS CoV genome. (a) Genomic organization of SARS CoV. The 14 ORFs are expressed from the genome RNA and a nested set of subgenomic mRNA (sgRNA 2–9) that all have a common leader sequence derived from the 5′ end of the genome. The genomic RNA and all sgRNA contain a 5′ cap and a polyadenylated tail at the 3′ end. (b) Domain organization of the proteins for ORF1ab. Black and white arrow heads represent the sites cleaved by papain-like and 3C-like proteinases, respectively. The ribosomal frameshift (RFS) site is highlighted by a broken line.

degradation. The nsp2 is dispensable for virus replication. The nsp4 and nsp6 each contain a putative transmembrane domain.

Apart from the ORFs encoding the replicase and structural proteins, the viral genome contains additional ORFs that code for accessory proteins (3b, 6, 7a, 7b, 8a, 8b, and 9b). Genetically modified recombinant viruses without these accessory ORFs have been shown to be replication competent in cell cultures, indicating that the accessory ORFs may not be essential for virus replication *in vitro*. However, recombinant viruses with deletions in these regions are attenuated, suggesting that these proteins might have functions that are important for viral replication and pathogenesis *in vivo*. The accessory proteins from ORF3b and ORF7a induce apoptosis in transfected cells. There is also evidence suggesting that the 7a protein is incorporated into virions. The protein encoded in ORF6 has been shown to inhibit the nuclear import of STAT-1 and function as an interferon antagonist in infected cells. These properties might relate to virus virulence. Interestingly, comparative sequence analysis of SARS CoV isolated from palm civets (see below) and humans showed that all animal isolates contained a 29-nucleotide (nt) sequence which is absent from most human isolates obtained in the later phase of the SARS outbreak. As a result, the ORF8 in these human SARS CoVs encodes 8a and 8b proteins, whereas the corresponding ORF in the animal isolates encodes a single protein, known as the 8ab protein. These proteins from the animal and human ORF8 have differential binding affinities to various SARS CoV structural proteins. Furthermore, the expression of E can be downregulated by 8b but not 8a or 8ab in infected cells. These observations may suggest that the 29-nt deletion might modulate the replication or pathogenesis of the human SARS CoV. The crystal structure of the 9b protein suggests that it might be a lipid binding protein but its function is yet to be identified. Overall, these accessory proteins may play roles in viral replication and pathogenesis.

Ecology and Animal Reservoir

Until the end of January 2003, 39% of patients with SARS in Guangdong had handled, killed, or sold wild animals or prepared and served them as food. However, such risk factors were found in only 2–10% of cases from February to April 2003 when the virus had adapted to efficient human-to-human transmission. Thus, the early epidemiological evidence pointed to the live game animal trade as a potential source of the SARS CoV. SARS-like coronaviruses were identified in a number of small mammalian species sold in the live game animal markets in Guangdong, including the palm civet (*Paguma larvata*), raccoon dog (*Nyctereutes procyonides*), and the Chinese ferret badger (*Melogale moschata*). A high proportion of individuals working in these markets were observed to have developed antibodies to SARS CoV, although none of them had a history of the disease. Viruses isolated from the re-emergent SARS cases in Guangdong in December 2003–January 2004 were more similar to those found in civets in these markets, rather than to viruses causing the global outbreak in early 2003. These observations strongly implicated the live game animal trade as the interface for interspecies transmission of a precursor animal SARS-like coronavirus to humans.

SARS CoV can be shed for weeks in experimentally infected palm civets but many of the other species appear to clear the virus rapidly. While civets in live animal markets were often observed to be positive for SARS-like coronavirus RNA, civets tested in the farms that supply these markets and those caught in the wild rarely have evidence of infection. Thus, palm civets were believed not likely to be the natural reservoir of the precursor SARS CoV (see below). More recently, group 2b coronaviruses related to SARS CoV have been identified in *Rhinolophus* bats in Hong Kong and mainland China. Such bats are also sold live in these game animal markets. It is now believed that these or related bat coronaviruses may be the precursor from which SARS CoV originated (see below).

Phylogeny

SARS CoV and the SARS-like civet and bat coronaviruses form a distinct phylogenetic subgroup (2b) within the group 2 coronaviruses (**Figure 2**). Genetic and phylogenetic analysis indicates that the viruses associated with the early phase of the human SARS outbreak are more closely related to the viruses found in palm civets and other small mammals in the live game animal markets in Guangdong. The genomes of viruses in the early phase of the human outbreak in 2003 were observed to be under strong positive selective pressure, suggesting that the virus was rapidly adapting in a new host. Furthermore, virus in civets was also found to be under strong positive selective pressure, supporting the view that civets were not the natural host of the precursor SARS-like coronavirus. The search for the precursor of SARS CoV led to the discovery of a number of novel coronaviruses in bats which are related to group 1 and group 2 coronaviruses. Some of these bat coronaviruses are genetically related to SARS CoV (group 2b) and are likely to be the direct or indirect precursor of SARS CoV (see below).

Interestingly, considered overall, the recently discovered group 1 and group 2 (including SARS CoV-like) bat coronaviruses appear to be in evolutionary stasis while many other mammalian coronaviruses still appear to be under evolutionary selection pressure, raising the intriguing possibility that bats may in fact be the precursors, not only of SARS CoV, but also of most other mammalian coronaviruses.

Virus Receptors

The functional receptor for SARS CoV on human cells is the angiotensin-converting enzyme 2 (ACE-2) which

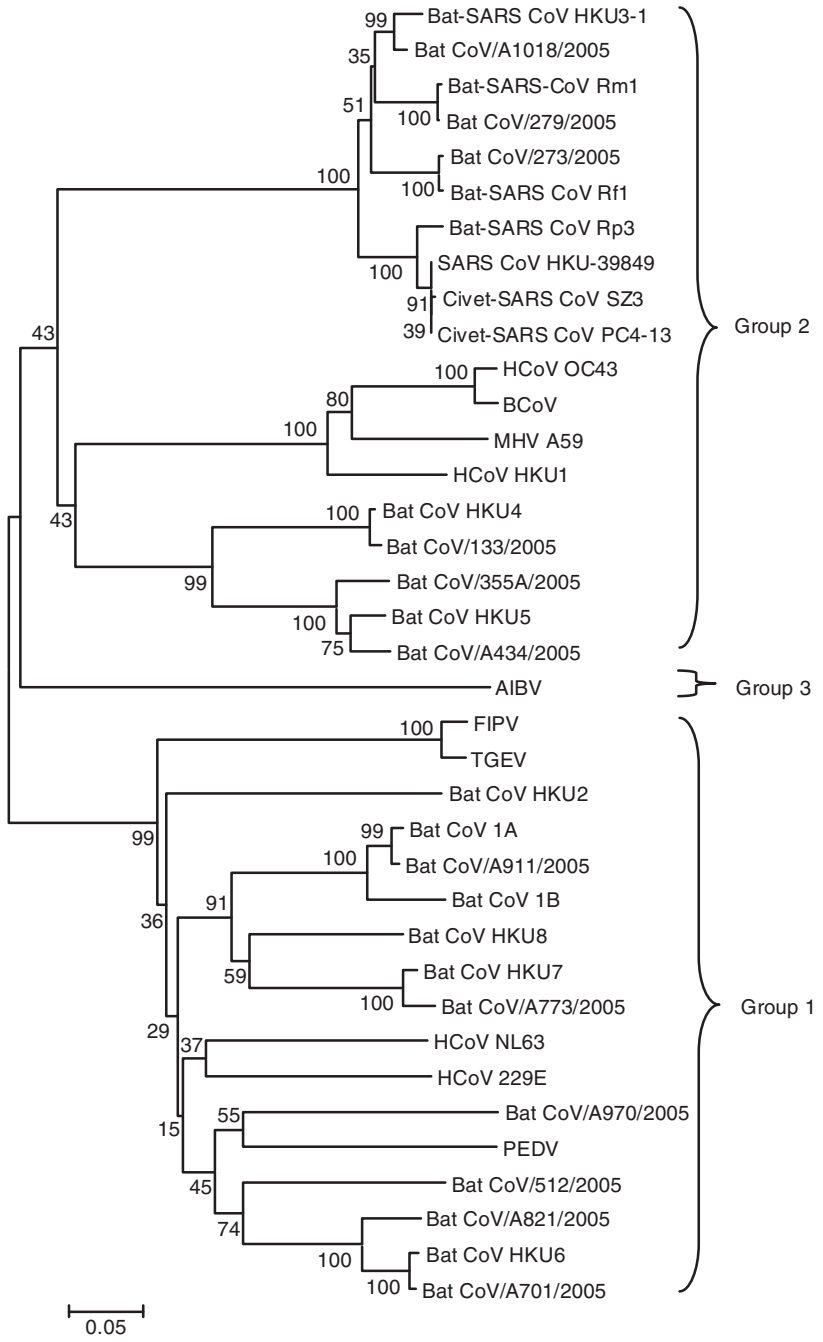

Figure 2 Phylogenetic analysis of RNA sequences coding for the RNA-dependent RNA polymerase (partial sequence). The phylogenetic tree was constructed by the neighbor-joining method and bootstrap values were determined with 1000 replicates. Human SARS CoV (GenBank accession AY278491.2), SARS CoVs isolated from palm civets in 2003 (AY304486.1) and 2004 (AY613948.1) and bat CoVs [Bat CoV 1A (DQ666337.1), Bat CoV 1B (DQ666338.1), Bat CoV HKU2 (DQ249235.1), Bat-SARS CoV HKU3–1 (DQ022305), Bat CoV HKU4 (DQ249214.1), Bat CoV HKU5 (DQ249217.1), Bat CoV HKU6 (DQ249224.1), Bat CoV HKU7 (DQ249226.1), Bat CoV HKU8 (DQ249228.1), Bat-SARS CoV Rp3 (DQ071615), Bat-SARS CoV Rm1 (DQ412043), Bat-SARS CoV Rf1 (DQ412042), Bat CoV/A434/2005 (DQ648819.1), Bat CoV/A701/2005 (DQ648833.1), Bat CoV/A773/2005 (DQ648835.1) Bat CoV/A821/2005 (DQ648837.1), Bat CoV/A970/2005 (DQ648854.1) Bat CoV/A911/2005 (DQ648850.1), Bat CoV/A1018/2005 (DQ648795.1), Bat CoV/133/2005 (NC_008315), Bat CoV/273/2005 (DQ648856), Bat CoV/279/2005 (DQ648857), Bat CoV/355A/2005 (DQ648809.1), Bat CoV/512/2005 (DQ648858)] were aligned with references sequences as indicated. Reference sequences are: transmissible gastroenteritis virus, TGEV (DQ811789); HCoV 229E (AF304460); HCoV NL63 (AY567487); HCoV-OC43 (AY391777); HCoV-HKU1 (DQ415903 HKU1); porcine epidemic diarrhea virus, PEDV (AF353511); avian infectious bronchitis virus, AIBV (AY646283); mouse hepatitis virus, MHV (AY700211); bovine coronavirus, BCoV (AF220295); feline infectious peritonitis virus, FIPV (AY994055).

binds the receptor-binding motif (amino acid residues 424 to 494) of the SARS CoV spike (S) protein. While the human SARS CoV S protein binds efficiently to both human and civet ACE-2, the civet-like SARS CoV S protein binds efficiently to ACE-2 from civets but poorly to human ACE-2. The spike protein of the bat SARS-like coronavirus lacks the ACE-2 receptor-binding motif and is therefore unlikely to bind to human ACE-2.

These findings explain the increased human transmissibility of SARS CoV in the later stages of the SARS outbreak, the observation that human SARS CoV efficiently infects civets under experimental conditions, and the failure of civet SARS CoV or bat SARS-like CoV to replicate productively in primate (Vero-E6, FRhK4) cells that support replication of human SARS CoV. This finding also explains the poor virulence and transmissibility of re-emergent SARS in December 2003–January 2004 when humans are believed to have been infected with a civet-like SARS CoV.

Other cell-surface molecules such as L-SIGN, DC-SIGNR, DC-SIGN (CD209), and L-SECtin may serve as binding receptors but do not appear to be functional viral receptors in the absence of ACE-2. They may, however, promote cell-mediated transfer of the virus to other susceptible target cells. On the other hand, binding to L-SIGN appears to lead to proteasome-dependent viral degradation and it may function as a scavenger receptor (see below).

Human Disease

Transmission

Respiratory droplets are the major source of infectious virus for transmission of SARS. However, aerosol exposure has probably contributed to disease transmission, at least in some defined instances where aerosol-generating procedures (e.g., nebulizers, high-flow oxygen therapy, intubation) have been used. The unusual stability of SARS CoV also suggests that contaminated surfaces and fomites may contribute to disease spread. As SARS CoV is present in feces and urine (and possibly other body secretions), these body fluids may also play a part in disease transmission. The largest single outbreak of SARS at the Amoy Gardens apartment block in Hong Kong, where over 300 individuals were infected from a single index case, is believed to have been caused by aerosols generated from infected body secretions (e.g., feces).

The estimated incubation period for SARS is 2–14 days. During the 2003 outbreak, the majority of cases did not transmit disease at all and only a few patients accounted for a disproportionately large number of secondary cases. Host factors may have played a role in these super-spreading events but, in many cases, there was a unique combination of host factors and environmental circumstances that facilitated transmission. In contrast to the high transmission rates in these super-spreading events and within hospitals, there was less evidence of secondary transmission within the family or within households (e.g., 15% in Hong Kong). Notwithstanding the 'super-spreading phenomenon' that has characterized SARS, the basic reproduction number (Ro) of SARS is estimated to range from 2 to 4.

Seroepidemiological studies of contacts of SARS patients (both adults and children) have revealed that asymptomatic infection was uncommon. The absence of large numbers of asymptomatic transmitters and the paucity of transmission during the first 5 days of illness explain the success of the public health measures of aggressive case detection and isolation in interrupting transmission of human-adapted SARS CoV and the control of the global disease outbreak. These features of SARS have been attributed to the observation that, unlike many other acute viral respiratory infections, SARS transmission has mostly occurred only after the fifth day of illness. This is, in turn, probably related to the low viral load in the upper respiratory tract during the early phase of the illness (see below).

Clinical Features

As the clinical features of SARS are not pathognomonic, a contact history and virological evidence of infection are important for confirmatory diagnosis. SARS typically starts with myalgia and loose stools around the time of onset of fever without coryza or sore throat (seen in 70% of patients). The upper respiratory manifestations are less commonly observed. Radiological abnormalities have been observed in >60% of cases at initial presentation and preceded lower respiratory tract symptoms in approximately 41% of patients.

Children have had much milder illness than adults and mortality rates progressively increase with age. Some patients, particularly those with progressive lower respiratory tract involvement have had a watery diarrhea. Other extrapulmonary manifestations included hepatic dysfunction and a marked lymphopenia involving both B, T (CD4 and CD8 subsets), and natural killer (NK) cells. High serum levels of chemokines (interleukin 8 (IL-8), CCL2, and CCl10) and pro-inflammatory cytokines (IL-1, IL-6, IL-12) have been observed.

The overall case–fatality rate was 9.6% and the terminal events were severe respiratory failure associated with acute respiratory distress syndrome (ARDS) and multiple organ failure. Age, presence of co-morbidities, and viral load in the nasopharynx and serum during the first 5 days of illness correlated with an adverse prognosis.

Autopsy findings of those who died in the first 10 days of illness were diffuse alveolar damage, desquamation of pneumocytes, and hyaline membrane formation. Viral

RNA was detected by quantitative polymerase chain reaction (PCR) at high copy number in the lung, intestine and lymph nodes, and at lower levels in spleen, liver, and kidney. In lung biopsy tissue or in autopsy tissue of patients dying in the first 10 days after disease onset, viral antigen and viral nucleic acid were demonstrated by immunohistochemistry and *in situ* hybridization methods respectively, in alveolar epithelial cells and to lesser extent in macrophages. A few unconfirmed studies have also reported the detection of virus particles or viral RNA in multiple organs but these findings require independent confirmation.

Laboratory Diagnosis

Highly sensitive and specific real-time PCR assays for detection of viral RNA remain the best choice for early SARS diagnosis. Viral RNA has been detected in respiratory specimens, feces, serum, and urine. Specimens from the lower respiratory tract such as endotracheal aspirates have higher viral load than those from the upper respiratory tract and are better diagnostic clinical specimens. As viral load is low during the first 5 days of disease, a negative PCR result from specimens collected at this time does not exclude the diagnosis. Testing multiple specimens improves the detection rate of SARS. Virus culture on Vero E6 or FRhK-4 cells and viral antigen detection tests are much less sensitive than reverse transcriptase PCR (RT-PCR) for detecting the virus. While viral RNA remains detectable in the respiratory secretions and feces for many weeks after the onset of illness, specimens rarely yield a virus isolate after the third week of illness.

Sero-conversion by immunofluoresence or neutralization occurs during the second week of illness and can provide reliable retrospective diagnosis. Enzyme-linked immunoassays using inactivated whole virus or recombinant antigens are convenient alternatives for serological screening, but any positive results must be confirmed by the more specific immunofluoresence or neutralization tests.

Pathogenesis

The primary mechanism of lung damage appears to be due to infection of type 1 and type 2 pneumocytes which are key target cells of the virus. Type 2 pneumocytes are important in the repair of lung injury and infection of these cells can potentially impair the regenerative responses of the lung and aggravate the respiratory impairment.

Whereas mice deficient in NK, T or B lymphocytes display similar kinetics of viral replication to normal mice, infection of mice with defects in the STAT1 signaling pathway results in more prolonged viral replication and more severe disease. These findings indicate the importance of innate immune responses in the control of infection, at least in the mouse. Infection of epithelial cells, macrophages, and myeloid dendritic cells fails to induce a type 1 interferon response although other interferon response genes are activated. Viral proteins expressed from ORF3b, ORF6, and the N gene have interferon antagonist effects *in vitro*. In contrast, macrophages and dendritic cells respond to infection *in vitro* with strong chemokine responses, including those (e.g., CCL10) that are elevated in the serum of SARS patients, and macrophage-chemoattractant chemokines (CCL2). This may explain the predominantly macrophage infiltrate in the lung.

There is evidence of viral replication within intestinal epithelial cells but there is minimal cellular infiltrate or disruption of intestinal architecture and the pathogenesis of diarrhoea in SARS remains unclear.

Treatment

As SARS emerged as a disease of unknown etiology, empirical therapeutic options were initially tested including broad spectrum antivirals and immunomodulators such as ribavirin, intravenous immune globulin, type 1 interferon, SARS convalescent plasma, and corticosteroids. However, in the absence of controlled clinical trials, no conclusions can be drawn on the efficacy of these interventions.

Anti-SARS CoV activity *in vitro* has been demonstrated for several therapeutics already in clinical use for other conditions, including lopinavir–nelfinavir, glycyrrhizin, baicalin, reserpine, and niclosamide. There are contradictory reports on the *in vitro* activity of ribavirin, interferon beta, and interferon alpha. In summary, taking into account bio-availability of these compounds and *in vitro* data, interferon alpha *n*1/*n*3, leukocytic interferon alpha, interferon beta and nelfinavir appear to be worthy of animal studies and randomized placebo-controlled clinical trials if SARS was to return.

A clinical trial of lopinavir 400 mg with ritonavir 100 mg orally every 12 h (added to an existing regimen of ribavirin and corticosteroid therapy) appeared to provide clinical benefit compared to historical controls. However, the lack of concurrent controls makes it difficult to draw conclusions. Similarly, a limited clinical trial of 13 patients using interferon alfacon-1 treatment showed a trend toward improved radiological and clinical outcomes, but without achieving statistical significance.

Studies in primate models have demonstrated prophylactic or therapeutic benefit from PEGylated recombinant interferon alpha-2b and from small interfering RNA therapy. More recently, screening of combinatorial chemical libraries *in vitro* has identified potential inhibitors of the viral protease, helicase, and spike protein-mediated entry.

Animal Models

Experimental SARS CoV infection leads to virus replication in a number of animal species including nonhuman primates (e.g., cynomolgous and rhesus macaques, African

green monkeys, and marmoset monkeys), mice (BALB/c, C57/BL6), Golden Syrian hamsters, ferrets, and cats. Only some of these develop pathological lesions in the lungs (cynomolgous macaques, ferrets, hamsters, marmosets, aged BALB/C mice).

Interestingly, whereas SARS CoV replicates in the lung of both young and aged (12–14 months) BALB/c mice, only aged mice manifest clinical symptoms and histological evidence of lung pathology. This is reminiscent of disease in humans in which children have mild illness (see above). Furthermore, few animal models reproduce the gastrointestinal manifestations of the illness.

While the ideal animal model for understanding SARS pathogenesis is lacking, those that support viral replication (with or without clinical disease) are adequate for evaluating the efficacy of vaccines.

Vaccines and Immunity

A wide range of strategies have been explored for development of SARS vaccines. These have included: inactivated whole virus vaccines; subunit vaccines including baculovirus expressed S1 subdomain or the complete trimeric spike protein of the virus expressed in mammalian cells; DNA vaccines expressing S (full-length and fragments), N, M, or E proteins; and vectored vaccines based on modified vaccinia Ankara (MVA) virus, vesicular stomatitis virus, adenoviral vectors carrying S, M, or N proteins, and attenuated parainfluenza virus type 3 vectored vaccines carrying S, E, M, and N proteins. Neutralizing antibody responses and, where appropriate, cell-mediated immune responses have been measured as correlates of immunity. Some of these vaccines have been evaluated in experimental models by challenging with infectious SARS CoV.

Trials in hamsters of attenuated parainfluenza virus type 3-vectored vaccines individually expressing SARS CoV S, E, M, and N proteins have indicated that only the S protein construct elicits neutralizing antibody and protects against experimental challenge. Furthermore, passive transfer of serum containing S protein neutralizing antibody has been shown to be sufficient to induce protective immunity in mice. It is concluded that neutralizing antibody to the S protein is an important correlate of protection. The receptor-binding determinant of the S1 subdomain is an immuno-dominant epitope and a critical determinant for virus neutralization.

As antibody can enhance rather than protect against the coronavirus disease feline infectious peritonitis, antibody-dependent enhancement has been a concern for SARS-Co vaccine development. However, no evidence of vaccine-enhanced disease has been observed to date, with two possible exceptions. There is a report that a modified vaccinia Ankara virus S protein vaccine has led to hepatitis in vaccinated ferrets but this has not been independently confirmed. There is also a report that S protein antibody elicited by a subunit vaccine enhances entry of pseudo-particles carrying S spike into lymphoblastoic cell lines which lack ACE-2 and are not normally permissive to infection. However, in the challenge experiments in hamsters, the vaccine did not induce protection and there is no evidence of disease enhancement.

Passive immunization with human monoclonal antibodies to the S protein has been successful at protecting mice and ferrets from experimental challenge by reducing viral load in the lung but not in the nasopharynx.

Most of these active and passive immunization studies have evaluated protection from challenge using the homologous human-adapted SARS CoV. However, a newly emergent SARS outbreak will probably arise from the animal reservoir and it is therefore important to investigate cross-protection against animal SARS-like CoV. As none of the civet or bat SARS CoV has yet been successfully grown *in vitro*, the cross-reactive neutralizing antibody response has been studied using lentiviruses pseudotyped with CoV S protein from a civet virus (SZ3), a civet-like virus causing re-emergent SARS in humans in December 2003 (GD03), and from a human SARS CoV (Urbani-strain) isolated from the major human SARS outbreak in 2003. The viruses pseudotyped with human Urbani virus S protein were neutralized by antibodies to the civet SARS-like virus but pseudotypes with the civet-like S protein were not neutralized by antibodies to the human SARS CoV (Urbani). On the contrary, antibody to the Urbani virus appeared to enhance the infectivity of the GD03 and SZ3 pseudotyped viruses. These findings appear to reflect receptor usage of these viruses as it has been shown that GD03 and SZ3 bind poorly to human ACE-2 (see above). The development of vaccines that can prevent re-emergence of SARV CoV from its zoonotic reservoir remains a challenge.

Conclusion: Will SARS Return?

Like many recent emerging infectious diseases that threaten human health, SARS was a zoonosis. The SARS CoV that was responsible for the global outbreak in 2003 was well adapted to bind to human ACE-2 and was efficiently transmitted human-to-human. Laboratories remain a potential source of infection from such viruses and, as occurred in February 2004, laboratory escape can lead to a community outbreak.

The SARS-like coronavirus found in civets (and other mammals) in live game-animal markets is very closely related to SARS CoV, but it binds inefficiently to the human ACE-2 receptor (see above). Consequently, when human infection with the civet SARS-like CoV occurred in December 2003–January 2004, there was no human-to-human transmission and clinical disease was mild. While SARS-like coronaviruses have been found in bats, they are

genetically distinct to SARS CoV and the bat SARS-like CoV S protein appears unable to bind to human or civet ACE-2. Thus, it is likely that re-emergence of a virus capable of causing human disease from this source probably requires extensive adaptation in an intermediate host (e.g., small mammals such as civets). While it is difficult to assess the likelihood of SARS re-emergence, this possibility cannot be excluded.

The rapid expansion of the live game-animal trade and the development of large markets in southern China which house a diversity of wild and domestic animal species were probably important in facilitating the emergence of SARS CoV. It is therefore possible that, like Ebola, SARS may re-emerge at intervals in the future. However, a number of epidemiological characteristics of SARS (see above) should allow it to be contained by public health interventions, once the disease is diagnosed. Indeed, the chain of community transmission arising from a laboratory escape of SARS CoV in February 2004 was contained by such public health measures and community transmission was aborted. However, if the dynamics of transmission of a re-emergent virus are different, and particularly if transmission occurs earlier in the illness and there are more asymptomatic infections, the options for control and the ultimate consequences may be very different. It remains important, therefore, to understand better the ecological and viral factors that predispose to interspecies transmission and the emergence of animal viruses with efficient competence for transmission in humans. Attention should be directed toward the adaptation strategies and the ecological factors that are important in determining interspecies transmission, rather than focus on the disease itself (i.e., SARS). Efforts to understand better the molecular basis for interspecies transmission that led to the genesis of SARS CoV will help us to prepare better for the next emerging infectious disease challenge; whether this comes from SARS CoV, avian influenza H5N1, or a yet unknown virus.

Shellfish Viruses

T Renault, IFREMER, La Tremblade, France

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Aquaculture Cultivation of aquatic animals or plants.
Bivalve Marine or freshwater mollusks having a soft body with plate-like gills enclosed within two shells hinged together.
Gills Respiratory organ of aquatic animals that breathe oxygen dissolved in water.
Hatchery A place where eggs are hatched under artificial conditions.
Hemocyte Any blood cell especially in invertebrates.

Larva The immature free-living form of most invertebrates which on hatching from the egg is fundamentally unlike its parent and must metamorphose.
Mantle A protective layer of epidermis in mollusks that secretes a substance forming the shell.
Mollusk Invertebrates having a soft unsegmented body usually enclosed in a shell.
Nursery A place for the cultivation of juveniles under controlled conditions.
Shellfish Aquatic invertebrates belonging to the crustacean or mollusk families.
Velum Membrane of mollusk larvae that allows swimming activity.

Introduction

A natural abundance of shellfish was common in many areas of the world until the early twentieth century. However, industrial and urban development and population growth in coastal areas, coupled with extreme harvest pressure, appear to have contributed to a steady decline in natural shellfish populations. This decline in wild harvests, together with a greater demand for seafood from an increasing world population, have driven the development of technology for the intensive management and cultivation of shellfish. As a result, global shellfish production, the greatest proportion of which is bivalves, was estimated to be 10 732 000 metric tons in the year 2000. However, as husbandry practices have developed, the significant impact of infectious diseases on productivity and product quality has been increasingly recognized. Numerous examples worldwide have demonstrated that entire shellfish industries in coastal areas are susceptible to diseases and that the production of healthy shellfish is a key to the economic viability of mollusk farming.

The study of shellfish diseases is a relatively young science and the discovery of viruses in marine mollusks is a fairly recent event. Viral diseases have seriously affected the aquaculture industry during the last decades. Viral pathogens are often highly infectious and easily transmissible, and are commonly associated with mass mortalities. Viruses interpreted as members of the families *Iridoviridae*, *Herpesviridae*, *Papovaviridae*, *Reoviridae*, *Birnaviridae*, and *Picornaviridae* have been reported as associated with disease outbreaks and causing mortality in various mollusks. However, there is currently a lack of information concerning the occurrence of mollusk viruses worldwide, and the basic method for identification and examination of suspect samples is still predominantly histopathology. This technique enables the identification of cellular changes associated with infection but does not provide conclusive identification of mollusk viruses unless completed by other methods such as transmission electron microscopy. Moreover, as there is a lack of marine mollusk cell lines and, since invertebrates lack antibody-producing cells, the direct detection of viral agents remains the only possible approach to diagnosis.

As filter feeders, bivalves may also bioaccumulate viruses from humans and other vertebrates, acting as a transient reservoir. The consumption of raw or undercooked shellfish can result in human disease and contamination of shellfish cultivated in coastal marine waters by microorganisms that are pathogenic to humans is a public health concern worldwide. The association of shellfish-transmitted infectious diseases with sewage pollution has been well documented since the late nineteenth and early twentieth centuries. Human enteric viruses, including rotaviruses, enteroviruses, and hepatitis A virus, are the most common etiological agents transmitted by shellfish. These enteric viruses are associated with several human diseases ranging from ocular and respiratory infections to gastroenteritis, hepatitis, myocarditis, and aseptic meningitis. Many of these viruses are transmitted by the fecal–oral route and are highly prevalent in locations with poor sanitation. There is considerable literature on the implications for human health. However, this is not the subject of the present article.

Irido-Like Viruses

Hosts and Locations

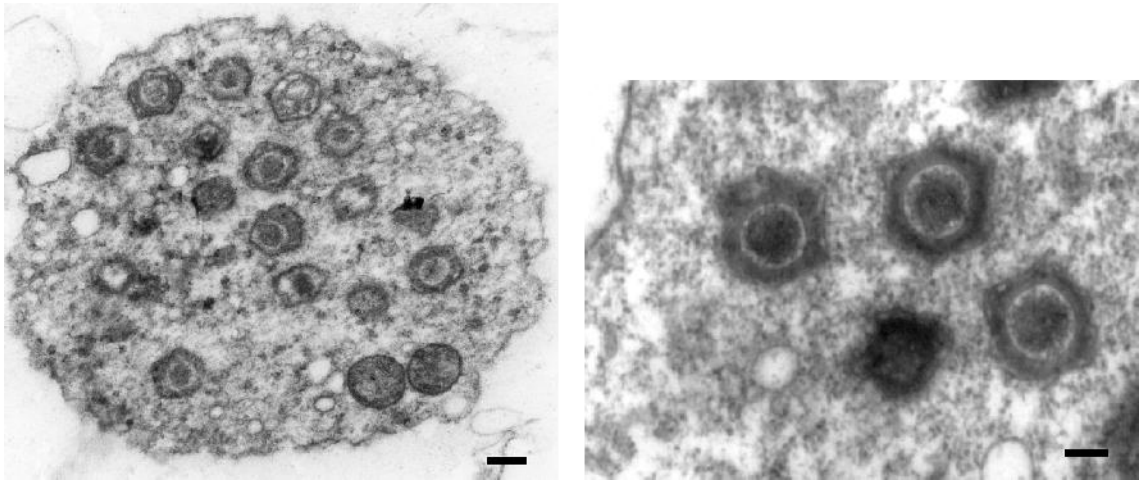
Infections by irido-like viruses have been reported in oysters in France and in the USA. Two distinctive conditions have been associated with mass mortalities in adult Portuguese oyster, *Crassostrea angulata*, along French coasts: gill necrosis virus disease and hemocytic infection virus disease. A viral infection similar to the latter was reported in the Pacific oyster *Crassostrea gigas* during summer mortalities in the Bay of Arcachon (Atlantic coast, France) long after the disappearance of the Portuguese oyster. A third type of irido-like virus, the oyster velar virus (OVV), has been reported from hatchery-reared larval Pacific oysters on the west coast of North America (Washington State, USA).

Disease Manifestations and Epizootiology

Gill necrosis virus disease is regarded as the primary cause of disease outbreaks and mortalities that occurred in the late 1960s among Portuguese oysters on the Atlantic coast of France. The disease appears to have affected up to 70% of oyster populations with maximum losses reported in 1967. Losses subsequently declined and survivors recovered from the disease. The first gross signs were small perforations in the center of yellowish discolored

zones of tissue on gills and labial palps. Further development and extension of the lesions resulted in larger and deeper ulcerations. In advanced stages, total destruction of affected gill filaments was observed. Yellow or green pustules also developed on the adductor muscle and mantle.

In 1970, high mortality rates were again reported in *C. angulata* oysters in France. Mortality was first observed in the basin of Marennes Oleron (Altantic coast) and in Brittany. The high mortality rates that occurred during this epizootic led to almost total extinction of French *C. angulata* by 1973. The disease affected adult oysters. No distinctive clinical signs were noted (e.g., no gill lesions). Histological observations included an acute cellular infiltration consisting of atypical virus-infected hemocytes. Pacific oysters seemed to be resistant to the vius and subsequently replaced *C. angulata* in France. However, a morphologically similar virus was reported from Pacific oysters during an outbreak of summer mortality in the Bay of Arcachon (Atlantic coast, France) in 1977. Although affected Pacific oysters exhibited virtually no gross signs, the presence of atypical cells interpreted as infected hemocytes and degeneration of connective tissues were reported in infected animals.



Oyster velar virus disease (OVVD) of the Pacific oyster occurred in the USA from mid-March through mid-June each year from 1976 to 1984, suggesting that the expression of the disease may be related to particular environmental conditions. When cultured at 25–30 °C, mortalities in oyster larvae greater than 170 μm in shell length typically begin at about 10 days of age. The infection results in the sloughing of ciliated velar epithelial cells and detachment of infected cells from the velum. Other cells lose cilia and infected larvae become unable to move normally.

Descriptive Histopathology

Histologically, gill necrosis virus disease is characterized by tissue necrosis with massive hemocytic infiltration around the lesions. The most distinctive lesion is the occurrence of giant polymorphic cells which may be up to 30 μm in size and contain large fuchsinophilic granules in the cytoplasm. In some giant cells, a voluminous basophilic inclusion (5–15 μm) occupies the greatest part of the cytoplasm in which finer basophilic granules (0.4–0.5 μm) are also present. Electron microscopy indicates that the inclusions are the viroplasm, and the fine granules are large viral particles. The most characteristic histological lesion of hemocytic infection virus disease is an acute cellular infiltration with the presence of atypical hemocytes in the connective tissues. Basophilic intracytoplasmic inclusion bodies are found in atypical blood cells in which irido-like virus particles can be observed in ultrathin sections. OVVD disease manifests histologically by the presence of intracytoplasmic inclusion bodies, 1.2–4 μm in diameter, located most commonly in the ciliated velar epithelium. The presence of DNA in the inclusion bodies is suggested by a positive Feulgen and Rosenbeck reaction.

Viruses

Mature icosahedral virions (380 nm diameter) are scattered throughout the cytoplasm of infected cells (**Figure 1(a)**). The outer shells of virions appear to consist of two trilaminar layers. The electron-opaque core (250 nm diameter) is limited by a three-layered fringe of definite width and surrounded by a layer of dense material

(a) (b)

Figure 1 Transmission electron micrographs of irido-like particles infecting *Crassostrea angulata* oysters. (a) Intracytoplasmic irido-like virus particles in an infected *C. angulata* cell (gill necrosis virus disease). Scale = 200 nm. (b) Irido-like virus particles from *C. angulata*. Virions are icosahedral in shape with a central electron-dense core, surrounded by an electron-lucent zone followed by another dense layer. Two unit membranes separated by a clear zone enclose the particle. Scale = 100 nm.

(**Figure 1**(**b**)). Morphogenesis takes place in the cytoplasm. Oyster irido-like viruses have not been isolated from infected tissue and have not been characterized biochemically. However, the presence of viral DNA was demonstrated by histochemical techniques including acridine orange staining and the Feulgen and Rosenbeck reaction. The characteristic morphology and cytoplasmic localization of these large DNA viruses suggest that they may eventually be classified as members of the family *Iridoviridae*. However, no molecular characterization has yet been conducted and there remains a need for definitive demonstration of viral etiology for the reported diseases.

Herpesviruses

Hosts and Locations

Herpes-like virus infections have been identified in various marine mollusk species throughout the world, including the USA, Mexico, France, Spain, the UK, New Zealand, Australia, and Taiwan. The first description of a virus morphologically similar to members of the family *Herpesviridae* in a bivalve mollusk was reported in 1972 in the eastern oyster, *Crassostrea virginica*. Since then, a wide host range has been reported for herpes and herpes-like viruses infecting bivalve species, including the Pacific oyster *C. gigas*, the European oyster *Ostrea edulis*, the Antipodean flat oyster *Ostrea angasi*, the Chilean oyster *Tiostrea chilensis*, the Manila clam *Ruditapes philippinarum*, the carpet shell clam *Ruditapes decussatus*, the Portuguese oyster *C. angulata*, the Suminoe oyster *C. ariakensis*, and the French scallop *Pecten maximus*. It is noteworthy that recently a herpes-like virus has also been observed by transmission electron microscopy in the gastropod mollusk *Haliotis diversicolor supertexta* in Taiwan associated with high mortality rates.

Disease Manifestations and Epizootiology

Herpesvirus and herpes-like virus infections have been associated with high mortalities of hatchery-reared larvae and juveniles stages of several bivalve mollusk species. Observations by transmission electron microscopy indicate that larvae exhibit generalized infections, whereas focal infections usually occur in juveniles. Although viral infections have also been observed in adult bivalves, they are apparently less sensitive than younger stages. Infected larvae exhibit velar and mantle lesions. They swim weakly in circles and shortly before death settle at the bottom of the tanks. Infected juveniles exhibit sudden high mortalities in a short period of time (less than 1 week) often during the summer. Histologically, lesions are confined to connective tissues. Fibroblast-like cells exhibit abnormal cytoplasmic basophilia and enlarged nuclei with marginated chromatin. Other cell types including hemocytes and myocytes show extensive chromatin condensation. Peculiar patterns of chromatin, ring-shaped or crescent-shaped, are also observed suggesting that apoptosis may occur. Viral DNA and proteins have been detected in asymptomatic adult oysters. Like other herpesviruses, the *C. gigas* herpesvirus seems to be capable of long-term persistence in the infected host. The pathogenicity of the virus for the larval stages of *C. gigas* has been demonstrated by experimental transmission to axenic larvae. Attempts to reproduce symptoms experimentally in juveniles and adult oysters have so far been inconclusive.

Virus Ultrastructure

Based primarily on virion morphology and aspects of morphogenesis and genome organization, Ostreid herpesvirus 1 (OsHV-1) is currently classified as an unassigned member of the family *Herpesviridae*. Particles present in the nucleus are circular or polygonal in shape. Empty particles are presumed to be capsids; others containing an electron-dense toroidal or brick-shaped core are interpreted as nucleocapsids (**Figure 2**(**a**)). Capsids and nucleocapsids are scattered throughout the nucleus in infected cells (**Figure 2**(**b**)). An electron–lucent gap of approximately 5 nm with fine fibrils is observed between core and capsid. Digital reconstruction of the OsHV-1 capsid based on cryoelectron microscopic images indicates an icosahedral structure with a triangulation number of $T = 16$, which is an architecture unique to herpesviruses. Prominent external protrusions at the hexon sites, and a relatively flat and featureless appearance of the inner surface, reported for OsHV-1 capsids, are also characteristic features of herpesviruses. Extracellular particles are usually enveloped with a trilaminar unit-membrane and measure 100–180 nm in diameter (**Figure 2**(**c**)). Tegument between the outer membrane and the capsid shell of enveloped particles is either absent or minimal (**Figure 2**(**c**)).

Genome Structure and Organization

Virus particles have been purified from fresh infected *C. gigas* larvae and the entire OsHV-1 genome has been cloned and sequenced (GenBank accession number AY509253). The total genome size is 207 439 bp. The overall genome organization is TR_L-U_L-IR_L-X-IR_S-U_S-TR_S (**Figure 3**) in which TR_L and IR_L (7584 bp) are inverted repeats flanking a unique region (U_L, 167 843 bp), TR_S and IR_S (9774 bp) are inverted repeats flanking a unique region (U_S, 3370 bp), and X (1510 bp) is located between IR_L and IR_S. A somewhat similar genome structure has been reported for certain vertebrate herpesviruses (e.g., herpes simplex virus and human cytomegalovirus). A small proportion of OsHV-1 genomes either lacks the X-sequence or contains an additional X-sequence at the left terminus.

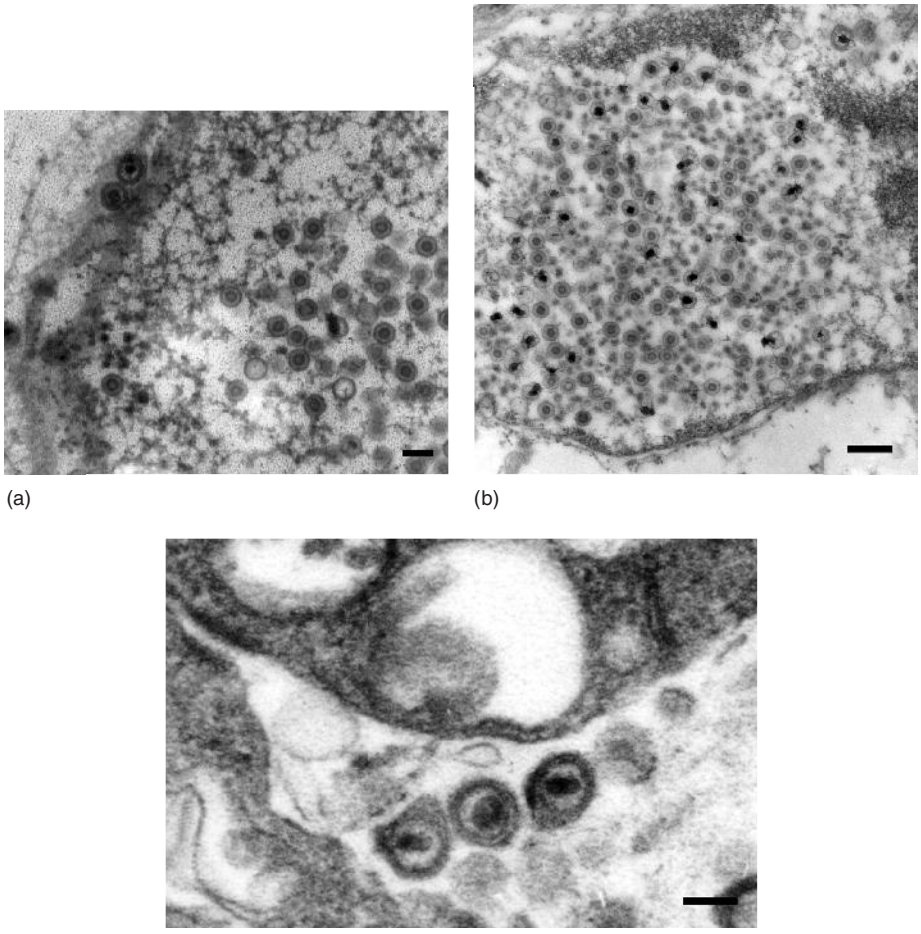


Figure 2 Transmission electron micrographs of ostreid herpesvirus 1 (OsHV-1) infecting Pacific oyster larvae. (a) Intranuclear spherical or polygonal virus particles; some particles appear empty and other contain an electron-dense core. Scale = 100 nm. (b) Nucleus of an infected interstial cell containing empty capsids and nucleocapsids. Scale = 200 nm. (c) High magnification of extracellular enveloped particles. Scale = 100 nm.

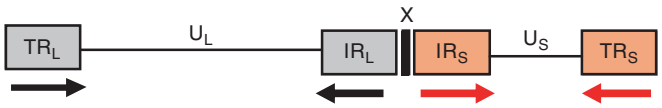

Figure 3 General genome organization of ostreid herpesvirus 1 (OsHV-1). TR_L and IR_L are inverted repeats flanking the unique region U_L. TR_S and IR_S are inverted repeats flanking the unique region U_S.

Since herpesvirus genomes are packaged into capsids from head-to-tail concatemers, this minor genome form may result from rare cleavage of concatemers at X–TR_S rather than at IR_L–IR_S. Moreover, approximately 20–25% of genomes contain a 4.8 kbp region of U_L in inverse orientation. The two orientations of U_L and U_S are present in approximately equimolar amounts in viral DNA, giving rise to four genomic isomers. This is also a feature of the vertebrate herpesvirus genomes with similar structures and results from recombination between inverted repeats during DNA replication. The genome termini are not unique but a predominant form is apparent for each. The IR_L–IR_S junction is also not unique, but the predominant form corresponds to a fusion of the two termini if each possesses two unpaired nucleotides at the 3′-end. Unpaired nucleotides are characteristic of herpesvirus genome termini.

Detailed analysis of the OsHV-1 genome sequence indicates that there are 124 unique open reading frames (ORFs). Owing to the presence of inverted repeats, 12 ORFs are duplicated resulting in a total of 136 genes in the viral genome. These numbers include several fragmented genes, each of which is counted as a single ORF. It is not yet known if splicing contributes to further elaboration of gene expression. A total of 38 genes shares

sequence similarities with other genes of the virus, defining 12 families of related genes. These include one gene family encoding proteins containing helicase motifs, one family encoding product related to inhibitors of apoptosis (IAPs), one family derived from a deoxyuridine triphosphatase gene, three families predicted to encode membrane-associated proteins, two families encoding RING-finger proteins, two families whose products are predicted to be secreted, and two other families. Gene families are also present in all other sequenced herpesviruses. The observation that IAPs are also encoded by baculoviruses and entomopoxviruses (both of which have insect hosts) underscores the importance of the apoptotic responses of invertebrates against viral infections. Vertebrate herpesviruses and poxviruses do not encode IAPs, and subvert the battery of host defenses by other pathways. Amino acid sequence comparisons have provided functional information on 25 genes that are not members of families. Seven genes encode enzymes. These include the catalytic subunit of DNA polymerase, two subunits of ribonucleotide reductase, a helicase, a putative primase, and the ATPase subunit of terminase. Two additional genes encode RING-like proteins. One protein is related to a eukaryotic protein of unknown function which is brain-specific in vertebrates. The ORF30 protein is related in an N-terminal cysteine-rich domain to a protein of unknown function in mammalian herpesviruses. A total of 15 genes encodes proteins which have predicted signal or transmembrane sequences and therefore may be associated with membranes, one specifying a putative ion channel protein.

Evolution and Taxonomy

Even though OsHV-1 shares a similar capsid architecture, amino acid sequence comparisons have failed to identify a single protein that has homologs in proteins unique to herpesviruses, with the exception of ORF30 which contains a domain found to date only in a subset of mammalian herpesviruses. Several OsHV-1 proteins have homologs that are distributed widely in nature (e.g., DNA polymerase), but these are no more closely related to homologs in other herpesviruses or to homologs in other organisms. This finding is also characteristic of comparisons between herpesviruses that infect fish or amphibians and those that infect mammals or birds. The strongest genetic indication of a common origin resides with the ATPase subunit of the terminase, which is involved in packaging DNA into the capsid. Homologs of this gene are present in all herpesviruses, and T4 and related bacteriophages. The T4 and OsHV-1 genes are unspliced, whereas those in herpesviruses of mammals and birds contain one intron and those in herpesviruses of fish and amphibians contain two introns. The available data support the view that herpesviruses of mammals and birds, of fish and amphibians, and of invertebrates form three major lineages of the herpesviruses. The invertebrate herperviruses would have evolved as a separate lineage about a billion years ago, and the fish viruses about 400 million years ago. OsHV-1 is currently the single representative of what may be a large number of invertebrate herpesviruses. Recent data show that OsHV-1 can infect several bivalve species. This contrasts with vertebrate herpesviruses which are generally confined to a single species in nature. Consequently, the true host of OsHV-1 is unknown. The apparent loss of several gene functions in OsHV-1 prompts the speculation that this may have promoted interspecies transmission in the context of introduction of non-native bivalve species and use of modern aquaculture techniques.

Diagnosis and Epidemiological Surveys

Light microscopy remains the preferred method for diagnosis of herpes-like virus infections in suspect samples. However, this method is poorly suited to diagnosis of viral diseases and should be supported by other techniques such as transmission electron microscopy. Even so, microscopic techniques are time consuming and unsuitable for epidemiological surveys. The lack of bivalve cell lines precludes *in vitro* culture and the observation of virus cytopathic effects. The purification of OsHV-1 from fresh infected larval *C. gigas* has served as a platform for the generation of molecular biological reagents for diagnosis. Procedures to detect herpesviruses in oysters using polymerase chain reaction (PCR) and *in situ* hybridization (ISH) have been developed and are suitable for epidemiological surveys of field samples, such as are currently being performed on oyster spat and larvae from commercial hatcheries and shellfish farms in France.

Picorna-Like Viruses and Other Small Virus-Like Particles

Virus-like particles of 27 nm in diameter have been reported in *Mytilus edulis* mussels from Denmark. These particles were enclosed in vesicles and arranged singly or in paracrystaline arrays. Acute cellular infiltrations were associated with virion detection and were interpreted as granulocytomas. Electron-dense, unenveloped virus-like particles (25–45 nm) have also been detected in farmed *Perna canaliculus* and *Mytilus galloprovincialis* mussels suffering mortalities in New Zeland. Extensive hemocytosis and necrosis of interstitial cells, basal cells, and digestive tubule epithelial cells were observed. Small DNA-negative virus-like particles (22–30 nm) were also reported in digestive and secretory cells of scallops, *Pecten novaezelandiae,* and toheroa, *Paphies ventricosum,* from New Zealand. Mass mortalities in Japanese pearl oysters, *Pinctada fucata martensii*, which have occurred in Japan since

1994, have been associated with a nonenveloped virus (25–33 nm) called Akoya virus. The disease was characterized by necosis and degeneration of muscle fibers. A morphologically similar virus was detected in the pearl oyster, *Pinctada margaritifera*, from French Polynesia associated with granulomas and focal necrosis within the adductor muscle. These lesions were similar to those reported in the mussel *M. edulis* suffering from granulocytomas. Paraspherical or polygonal-shaped virus-like particles (40 nm) consisted of a membrane-like envelope coating a central 35 nm electron-dense core. Icosahedrical–spherical (27–35 nm), nonenveloped virus particles have also been detected in the cytoplasm of connective tissue cells from cultured carpet shell clams, *R. decussatus*, suffering mortalities in Galicia (Spain). More recently, nonenveloped, icosahedral (19–21 nm) virus-like particles have been associated with large foci of massive hemocytic infiltration in cockles, *Cerastoderma edule*, from the same area (Galicia, Spain). The detection of red deposits on histological sections after methyl green pyronin staining suggested that this is an RNA virus.

All these virus-like particles are similar to those described first in mussels from Denmark. Due to their size, morphology, and the formation of paracrystalline arrays, they have been assumed to belong to the family *Picornaviridae*. However, no molecular information is available on these viruses to date.

Papova-Like Viruses

Intranuclear, nonenveloped virus-like particles (50–55 nm) with icosahedral symmetry were first reported from the gonadal epithelia of eastern oysters, *C. virginica*, in the USA in 1976 and in Canada in 1994. The virions were interpreted as papova-like viruses. A papova-like virus has also been detected in gonadal tissues during a health survey of cultured Pacific oyster, *C. gigas*, from the southern coast of Korea. More recently, histological examination of *C. gigas* oysters in France has revealed several cases of abnormally large basophilic cells in gonadal tissues. Electron microscopy examination has revealed nonenveloped icosahedral particles 50 nm in diameter.

Reo-Like Viruses and Birnaviruses

A virus tentatively assigned the family *Reoviridae* has been isolated from juvenile eastern oysters, *C. virginica,* using a fish cell line. Virions have been described as slightly oval particles (79 nm in diameter) containing a distinct inner core and clear spike-like projections on the outer capsid. Birnaviruses have been isolated from different bivalve species in Europe and Taiwan. A virus tentatively named 'marine birnavirus' (MABV) has also been isolated during a high mortality episode from oysters cultured in the Uma Sea (Japan). MABVs have been defined as a group within the genus *Aquabirnavirus*. Although the pathogenicity of certain MABV strains appears to be weak in shellfish, it has been observed in some mollusk species (the clam *Meretrix lusoria*, the Agemaki or jack knife clam *Sinovacura constricta*, and the Japanese pearl oyster, *P. fucata*) that stressors such as changes in temperature, spawning, and exposure to heavy metals can result in mortality by increasing host suceptibility. MABVs may thus be opportunistic pathogens that persistently infect marine organisms and become pathogenic under stressful conditions. Birnavirus-like particles were also isolated from the thin telling, *Tellina tenuis*, and the flat oyster, *Ostrea edulis*, from the coast of Britain and east coast of Canada. MABVs isolated from shellfish appear to be pathogenic to fish. Moreover, based on serological and genomic properties, strains isolated from shellfish and fish seem similar. This may indicate that the host range of MABV may be broad. Assays to reproduce experimentally the infection using the reovirus-like and birnavirus-like particles isolated on a fish cell line have shown inconsistent results, and a firm conclusion on the significance of these viruses for shellfish is still unknown.

Conclusion

In some cases, mollusk viruses have been detected only as inconsequential infections in animals that are suffering from another known disease or from an environmental stress such as pollution. However, several mass mortality outbreaks in mollusks have been attributed to viral infections. The almost total extermination of the Portuguese oyster, *C. angulata*, in French and European Atlantic waters in 1973 has been associated with irido-like virus infections. Viruses morphologically similar to members of the *Herpesviridae* have also been associated with high mortality rates in various marine mollusk species around the world.

The production of healthy shellfish from hatcheries and nurseries is a critical aspect of the conservation and management of natural populations and extensive farming areas. Selective breeding of hatchery stock will also be important for aquaculture development. This may lead to a substantial international trade in bivalve gametes and larvae to allow distribution of genetically improved seed stock. However, significant production problems including the elimination of viral diseases must be solved before hatcheries can become a major supplier for the industry. High-density production systems including commercial hatcheries and nurseries are an important source of viral diseases in aquaculture and the movement of stock must be considered as one of the major risks of disease spread. The risk of viral disease in invertebrate aquaculture

species is accentuated by the lack of specific chemotherapies and vaccines. Improved knowledge and understanding of shellfish viruses is needed to develop new tools for disease control.

Shrimp Viruses

J-R Bonami, CNRS, Montpellier, France

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Cephalothorax The shrimp head, containing the main organs, hepatopancreas, stomach, foregut and midgut, gonads, heart, gills.

Epizootic An epidemic in animal populations. Rapid spreading of a disease.

Hepatopancreas Organ of the digestive tract with secretion–absorption functions and located in the cephalothorax (head) of shrimp. Also called the digestive gland.

Postlarvae Stage of shrimp development, after the larval stages.

Introduction

To date, more than 20 viral diseases have been reported in shrimp and prawns. Most of the described viruses are related, but often only on the basis of morphological characteristics to known virus families. Two of the most important pathogens of shrimp have been sufficiently characterized to be accepted by the International Committee on Taxonomy of Viruses (ICTV) as members of new virus families within the classification and nomenclature of viruses. Yellow head virus (YHV), together with closely related gill-associated virus (GAV), have been classified as members of the new genus *Okavirus* in the new family *Roniviridae*. White spot syndrome virus (WSSV) has been classified as the only known member of the new genus *Whispovirus* in the new family *Nimaviridae*. A third major pathogen, Taura syndrome virus (TSV), has been accepted for classification in the family *Dicistroviridae*. Although not yet officially accepted by the ICTV, six other shrimp viruses have been sufficiently well characterized to be considered as possible members of four existing virus families: *Totiviridae* (infectious myonecrosis virus, IMNV), *Nodaviridae* (macrobrachium rosenbergeii nodavirus, MrNV), *Parvoviridae* (infectious hypodermal and hematopoietic necrosis virus, IHHNV, and hepatopancreatic parvovirus, HPV) and *Baculoviridae* (BP-type and MBV-type viruses).

History

Three periods can be defined in the recent history of shrimp virus discovery: the first was during the 1970s, in which observations of viral agents were made by 'chance'; the second period commenced in the 1980s, in which

evidence of viral pathogenic agents was obtained as a result of disease observations or mortalities occurring in shrimp farms; and finally, since the early 1990s with the development of molecular biology, more structured and intensive approaches to the descriptions of the pathogens and the associated diseases were undertaken.

The first virus of Crustacea was reported in 1966 by Vago in the Mediterranean crab *Portunus depurator*. The virus appeared to be related to members of the *Reoviridae*. In shrimp, occluded bacilliform particles were reported in 1973 by Couch during investigations on the effect of pollutants in pink shrimp (*Penaeus duorarum*). The agent was reported to be closely related to members of the *Baculoviridae*.

In 1981, Sano and colleagues reported the detection of a 'nonoccluded baculovirus' in kuruma shrimp (*Penaeus japonicus*) during mortalities in hatchery-reared shrimp in two prefectures in Japan. Two years later (1983), Lightner reported a transmissible disease named infectious hypodermal and hematopoietic necrosis (IHHN) as the Pacific blue shrimp (*Penaeus stylirostris*) as the source of mortalities in ponds. While at first thought to be related to members of the *Picornaviridae*, IHHNV was later assigned to the *Parvoviridae* after investigations on the structure of the genome. Since that time, reports of new viruses have increased in parallel with the rapid development of shrimp farming globally and, to date, more than 20 viruses have been reported in shrimp (**Table 1**).

Table 1 Known shrimp viruses

Genome	*Virus family*[a]	*Acronym*	*Virus name*	*Host*	*Genomic data*

	Nimaviridae	WSSV	White spot syndrome virus	Penaeids and numerous other crustaceans	Complete

[a]Only TSV, GAV, YHV, IHHNV, and WSSV have been formally classified to date.

The major developments in shrimp virus research commenced in the early 1990s following the development and application of molecular tools. Cloning and sequencing of genome fragments allowed construction of specific and sensitive tools for detection and diagnosis. These DNA-based methods, such as the polymerase chain reaction (PCR) and dot-blot hybridization, have led to the use of commercial diagnostic kits for selection of healthy shrimp and the production of specific pathogen-free (SPF) breeding stock. SPF shrimp have proven to be particularly useful, not only in limiting or preventing production losses due to disease on farms, but also as experimental animals for studies on shrimp viruses.

Impact of Viral Diseases on Farmed Shrimp Production

The rapid progress in shrimp virology during the past two decades is clearly related to the high commercial value of these farmed crustaceans. This has significantly increased our understanding of viruses infecting only invertebrates which previously had been confined primarily to insect viruses. However, in contrast to most insect viruses in which investigations were oriented primarily toward biological control of insect pests and their potential use as gene expression vectors, shrimp virus research has focused on disease prevention.

It is difficult to know the impact of viral diseases on shrimp populations in the natural environment. Diseased shrimp are rarely found, essentially due to predation and cannibalism when animals appear weakened. However, under farming conditions, where the density of the shrimp population can easily exceed 300 000 postlarvae per hectare, the consequence of a disease outbreak and associated mass mortalities can be disastrous. In 2003, total world production from shrimp farming was more than 1.6 million metric tons, representing a value of almost US$ 9000 million and accounting for about 25% of marketable shrimp production (capture and farming). Viral disease has been a major problem for this large and expanding industry and the economic and socioeconomic impacts have been severe. For example, a report commissioned by the World Bank in 1996 estimated the annual global cost of disease (primarily viral) to shrimp farming was US$ 3000 million or 40% of production capacity at that time. In China and Thailand alone, annual production losses due to WSSV have reached US$ 500–1000 million. In Ecuador, the emergence of WSSV in 1999 resulted in a 75% drop in annual production and 130 000 industry workers were reported to have lost their jobs. The production records of these major shrimp-producing countries exhibit depressions coinciding with the sequential emergence of major viral pathogens. In contrast, in Brazil, which was free of the major diseases until 2003, shrimp production constantly increased. Nevertheless, Brazil has also experienced significant production losses since that time with the emergence of infectious myonecrosis caused by a new toti-like virus.

Factors Responsible for Viral Disease Emergence in Shrimp

Disease emergence in shrimp aquaculture can be attributed to three primary factors: (1) the common practice in the shrimp farming industry of introducing each season fresh wild broodstock collected from the natural environment as the source of seed (postlarval shrimp) for farms; (2) national and international trade in broodstock and commercial seed (postlarvae) to be transferred to ponds until they reach the marketable size; and (3) the culture of shrimp in earthern ponds in high densities.

The use of wild brooders in hatcheries commonly occurs without adequate knowledge of their health status or adequate quarantine. This often results in the introduction of pathogens into the farming system and it is a practice that persists even though SPF shrimp, bred in biosecure facilities, are now readily available in many countries.

Trade in broodstock and seed also commonly occurs without checking for at least the known pathogens. This practice was responsible for the rapid worldwide spread of the IHHNV, the introduction of TSV to the Eastern Hemisphere, and the rapid spread of WSSV from the Eastern to the Western Hemisphere. The practice of farming in brackish water earthern ponds creates an environment in which new pathogens may be encountered and disease spread rapidly once outbreaks occur. As a result, short explosive epizootics may, in few days, wipe out the whole shrimp population of a farm.

Environmental and host factors also play an important role in the emergence of shrimp disease. Poor-quality pond conditions (e.g., high salinity, pH, or nitrogen) can cause physiological stress in shrimp leading to increased susceptibility to disease. The shrimp culture medium (brackish water) allows very efficient transfer of free viruses, either as free infectious agents or in pathogen vectors. As ectotherms, shrimps are susceptible to water temperature shifts that can stimulate the replication of viruses that commonly persist in shrimp as unapparent infections. Shrimp also lack the sophisticated adaptive immune mechanisms (antibodies, cytokines, T-cells) deployed by vertebrates to combat viral infections and so have less capacity to survive disease.

Characteristics of Some Shrimp Viruses

Shrimp Baculoviruses

Two distinct groups of viruses, sharing numerous characters with members of the family *Baculoviridae*, have been

described in shrimp. They have been improperly called BP-type viruses (BP, baculovirus penaei) and MBV-type viruses (MBV, monodon baculovirus) on the basis of the morphology of their occlusion bodies (OBs). The BP-type group exhibits tetrahedral OBs; the MBV group exhibits rounded OBs. It is classified as a tentative species (*Penaeus monodon* NPV, PemoNPV) in the genus *Nucleopolyhedrovirus* of the family *Baculoviridae*.

General characteristics

All baculoviruses detected in shrimp develop in the nuclei of digestive epithelial cells (hepatopancreas and mid-gut) with the release of OBs within feces. They are bacilliform in shape and comprise a trilaminar envelope surrounding a rod-shaped nucleocapsid. Virions may be occluded in paracrystalline occlusion bodies. Only small fragments of the double-stranded DNA (dsDNA) genome have been cloned and sequenced for a few shrimp baculoviruses. For the BP-type virus, Penaeus duorarum single nuclear polyhedrosis virus (PdSNPV), the genome has been shown by electron microscopy to be a circular structure with an estimated size of 75×10^6 kDa (113–115 kbp). There appear to be different morphotypes of BP-type baculoviruses which were distinguished based on differences in particle size; two different BP genotypes have been reported in the same shrimp tissue section by *in situ* hybridization.

Polyhedra

In contrast to insect baculoviruses, shrimp baculovirus OBs are unenveloped and comprise large subunits (SuOBs) of polyhedrin which are icosahedral in shape (**Figure 1**). The SuOBs are always associated in triplets. They are organized in two different crystalline forms: the BP-type viruses form parallel rows in all three dimensions (**Figure 2(a)**); the MBV-type viruses assemble four triplets to form a 'rosette' (hollow sphere) as the building block of the OB (**Figure 2(b)**). MBV-type OBs are more sensitive to thaw–freezing but each OB type disaggregates spontaneously in CsCl gradients. Compared to insect baculovirus polyhedrin subunits, both BP- and MBV-type SuOBs are larger in dimensions (15–22 nm compared to 6.5–9 nm diameter) and molecular mass (52–58 kDa compared to ~30 kDa).

There is evidence of antigenic cross-reactivity between PdSNPV and MBV SuOBs, but this requires confirmation as, unexpectedly, PdSNPV SuOBs were also found to cross-react with both polyhedrin and granulin from the insect baculoviruses Autographa californica nuclear polyhedrosis virus and and Trichoplusia ni granulosis virus, respectively.

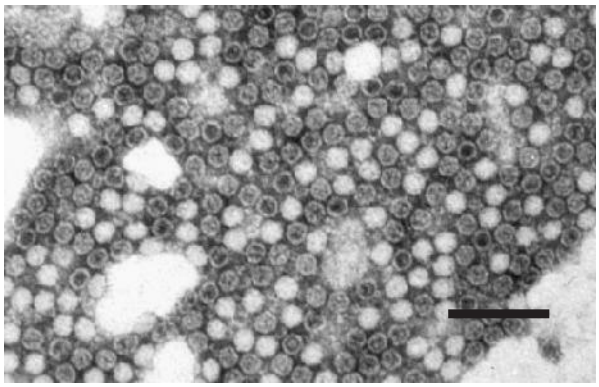

Figure 1 Purified SuOBs (polyhedrin) from PmSNPV (MBV-type virus). Note the full and empty virus-like particles. The particles were negatively stained with 2% phosphotungstic acid (PTA). Scale = 100 nm. Reproduced from Bonami: JB, Aubert H, Mari J, Poulos BT, and Lightner DV (1997) The polyhedra of the occluded baculoviruses of marine decapod crustacea: A unique structure, crystal organization, and proposed model. *Journal of Structural Biology* 120: 134–145, with permission from Elsevier.

The two types of crystal (bullet-like arrangement and rosette formation) are evident. Scale = 100 nm (a, b). Reproduced from Bonami JB, Aubert H, Mari J, Poulos BT, and Lightner DV (1997) The polyhedra of the occluded baculoviruses of marine decapod crustacea: A unique structure, crystal organization, and proposed model. *Journal of Structural Biology* 120: 134–145, with permission from Elsevier.

Viral infection cycle

All life stages of the pink shrimp (*P. duorarum*), white shrimp (*Penaeus setiferus*), and the brown shrimp (*Penaeus aztecus*) are susceptible to BP-type baculovirus, while only larval and postlarval stages of the Pacific white shrimp (*Penaeus vannamei*) and Pacific blue shrimp (*P. stylirostris*) have been observed to be infected. In the black tiger shrimp (*Penaeus monodon*), postlarvae, juveniles, and adults have been observed to be infected with MBV.

For PdSNPV in *P. duorarum*, the major steps in the infection cycle have been described including the appearance of naked nucleocapsids in the cytoplasm of epithelial digestive cells, nucleoprotein release at nuclear pores, followed by all morphogenesis steps in infected nuclei and the development of tetrahedral OBs. Cellular pathological changes include nuclear hypertrophy and perinuclear membranous proliferation. Nuclear hypertrophy associated with increasing size of OBs leads to the release of the nuclear contents into the digestive lumen of hepatopancreatic tubules and gut, and the excretion of OBs in the feces. The infection cycle is completed by oral ingestion and OB dissolution in the digestive tract of the new host. A similar infection cycle is hypothesized for MBV-type baculoviruses. In addition to horizontal transmission, vertical transmission is suspected, based on the presence of OBs in very young postlarvae a few days after hatching.

Geographic distribution and host range

BP-type virus infection is widespread in farmed and wild penaeid shrimp in the Americas. The known distribution is from the Gulf of Mexico in the north through the Caribbean, the east coast of South America as far south as the State of Bahia in Central Brazil. On the Pacific coast, the distribution ranges from Mexico to Peru. BP-type virus has also been observed in wild shrimp from Hawaii. Several penaeid shrimp species have been reported to be infected, both in aquaculture facilities and in the wild environment. These include *P. duorarum*, *P. aztecus*, *P. vannamei*, *P. setiferus*, *P. stylirostris*, *P. penicillatus*, *P. schmitti*, *P. paulensis*, *P. subtilis*, *Trachypenaeus similis*, and *Protrachypene precipua*.

MBV-type virus infections are widely distributed in penaeid shrimp of the Eastern Hemisphere, particularly in the Indo-Pacific countries of China, India, Indonesia, Philippines, Malaysia, Thailand, Sri Lanka, and Australia where the virus is enzootic in wild stocks. The virus has also been reported in Kuwait, Oman, Israel, Italy, and West Africa (Kenya and Gambia). It has been observed in imported penaeid shrimp in Tahiti and Hawaii, Mexico, Ecuador, Brazil, Puerto Rico, and some states of the USA. The known host range includes *P. monodon*, *P. merguiensis*, *P. semisulcatus*, *P. indicus*, *P. penicillatus*, *P. esculentus*, and *P. vannamei*.

Shrimp Parvoviruses

Two viruses sharing the primary characteristics of members of the family *Parvoviridae* have been reported in penaeid shrimp. IHHNV causes a systemic infection of multiple organs of ectodermal and mesodermal origin as and is described in the Pacific blue shrimp (*P. stylirostris*). It is associated with runt and deformity syndrome (RDS) in Pacific white shrimp (*P. vannamei*) and occurs commonly as a low-level persistent infection in apparently healthy black tiger shrimp (*P. monodon*). HPV causes an infection of the digestive system (epithelial cells of hepatopancreas and mid-gut) in black tiger shrimp *P. monodon* and in the fleshy prawn (*P. chinensis*). HPV isolates from *P. monodon* (HPVmon) and *P. chinensis* (HPVchin) represent two distinct genetic lineages. A third parvo-like virus, spawner-isolated mortality virus (SMV) infects *P. monodon* but is less well characterized.

IHHNV and HPV are each nonenveloped icosahedral viruses, 22 nm in diameter and containing a linear single-stranded DNA (ssDNA) genome. IHHNV virions have been reported to contain four polypeptides as detected by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and silver staining (74, 47, 39, and 37.5 kDa). For HPVchin, only one virion structural protein has been observed (54 kDa) but analysis of HPVmon has revealed a doublet protein band (57 kDa major band and 54 kDa minor band). In addition to differences in tissue tropism, the viruses display differences in cytopathology. During HPV infection, cellular lesions correspond to typical densonucleosis in insects with the formation of enlarged, densely stained, and Feulgen-positive nuclei. In IHHNV infections, lesions are discrete, often difficult to detect, and display characteristic eosinophilic intranuclear Cowdry type A inclusion bodies.

Genomic organization

The IHHNV genome comprises 4075 nucleotides (according to a recent GenBank submission) and contains three long open reading frames (ORFs) on the complementary (positive) strand (**Figure 3**). The three ORFs are referred to as left, mid, and right. The left ORF is in a different reading frame (+1) to mid- and right ORFs. As for other parvoviruses, noncoding termini at each end of the genome contain palindromic sequences. The left ORF encodes a 666 amino acid protein with high homology with putative major nonstructural protein (NS-1) of mosquito brevidensoviruses. The mid-ORF overlaps the left ORF and encodes a 363 aa protein of unknown function (possibly an NS-2 protein). The right ORF overlaps the left ORF by 62 nt and encode a 329 aa protein. By analogy to other parvoviruses, it has been speculated that the right ORF encodes the capsid proteins but this is not consistent with the four structural proteins reported in purified virions. The negative strand also contains an ORF with a

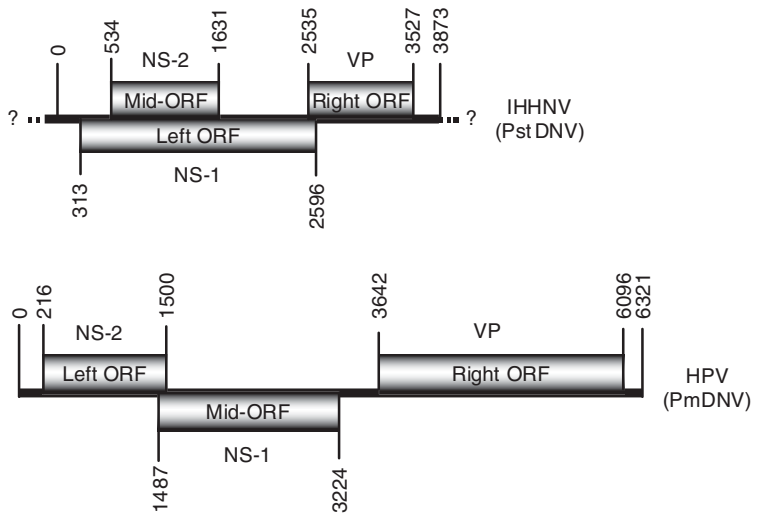

Figure 3 Genome organization of IHHNV and HPV. IHHNV (PstDNV) is according to Shike H, Dhar AK, Burns JC, *et al*. (2000) Infections hypodermal and haematopoietic necrosis virus of shrimp is related to mosquito brevidensoviruses. *Virology* 277: 167–177.

coding capacity of 134 amino acids. Further work is required to define the IHHNV expression strategy.

The HPV genome comprises 6321 nucleotides containing three long ORFs in the complementary (positive) strand and palindromic noncoding termini that form hairpin-like structures, as found in other parvoviruses (**Figure 3**). ORF1 (left ORF) encodes a 428 amino acid putative nonstructural protein-2 (NS-2) of unknown function. ORF2 (mid-ORF), in −1 frame relative to ORF1 encodes a 579-amino-acid polypeptide that contains conserved replication initiator motifs, NTP-binding, and helicase domains similar to NS-1 of other parvoviruses. The right ORF (ORF3), which is in the same frame as ORF1, encodes the 818-amino-acid capsid protein (VP protein).

Taxonomic position

In terms of morphology and genome structure and organization, both IHHNV and HPV share similarities with members of the family *Parvoviridae*. Genomic analysis has clearly indicated that IHHNV is closely related to mosquito densoviruses and it has recently been classified as a tentative species (*Penaeus stylirostris densovirus*), in the genus *Brevidensovirus*. Similarly, HPV was recently proposed as new member of subfamily *Densovirinae* to be designated as the species *Penaeus monodon densovirus*.

Geographic distribution and host range

HPV was first observed in wild and farmed penaeid shrimp in Australia, China, Korea, Philippines, Indonesia, Malaysia, Kenya, Kuwait, and Israel. It has also been reported subsequently from several locations in North and South America (Pacific coast of Mexico and El Salvador). Natural infections have been reported in *P. merguiensis*, *P. semisulcatus*, *P. chinensis*, *P. esculentus*, *P. monodon*, *P. japonicus*, *P. penicillatus*, *P. indicus*, *P. vannamei*, and *P. stylirostris*.

IHHNV is widely distributed in the Americas (Brazil, Ecuador, Central America, Mexico, Peru, southeast USA), the Central Pacific (Guam, Hawaii, Tahiti, and New Caledonia), and Asia and the Indo-Pacific area (Indonesia, Malaysia, Philippines, Thailand, and Australia). Natural infections have been reported in *P. stylirostris*, *P. vannamei*, *P. occidentalis*, *P. californiensis*, *P. monodon*, *P. semisulcatus*, and *P. japonicus*. It is likely that infection with IHHNV or a similar virus also occurs in other penaeid shrimp species.

Recent investigations have revealed evidence of the integration of IHHNV-related sequences within the genomes of *P. monodon* populations from Africa (Madagascar, Tanzania, Mozambique) and Australia. The integrated sequences vary by up to 14% from epidemic IHHNV and do not appear to be associated with the formation of complete or infections virions.

Infectious Myonecrosis Virus

In 2002, a new disease associated with low mortalities was reported in the Pacific white shrimp *Penaeus vannamei* from northeastern Brazil. Clinical signs included necrotic areas in muscles, resulting sometimes in a whitish and opaque appearance to the tail. The causative agent was named infectious myonecrosis virus (IMNV) on the basis of the clinical signs.

General properties

In infected animals, virions accumulate in the cytoplasm of target cells (muscular cells, hemocytes, and connective tissue cells) forming basophilic inclusions. IMNV has a density of 1.366 g ml^{-1} in cesium chloride. It is a nonenveloped icosahedral virus, 40 nm in diameter (**Figure 4**) with a genome consisting of a single segment of double-stranded RNA (dsRNA), 7560 bp in length. The capsid contains a single major polypeptide of 106 kDa.

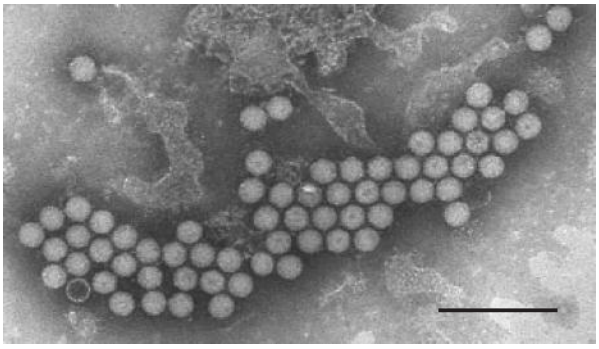

Figure 4 Purified IMNV virions. The particles were negatively stained with 2% phosphotungstic acid (PTA). Scale = 200 nm. From Poulos BT, Tang KFJ, Pantoja CR, Bonami JR, and Lightner DV (2006) Purification and characterization of infectious myonecrosis virus of penaeid shrimp. *Journal of General Virology* 87: 987–996.

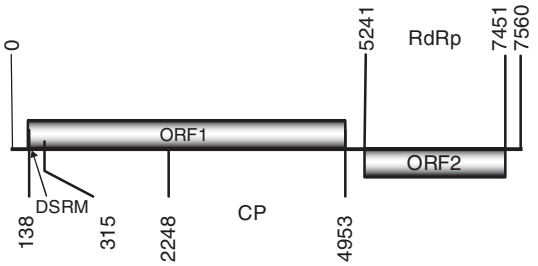

Figure 5 Genome organization of IMNV.

Genomic organization

The IMNV genome organization is illustrated in **Figure 5**. Two large nonoverlapping ORFs in different reading frames (ORF1 and ORF2) are flanked by 3′ untranslated region (UTR) and 5′ UTR of 109 and 135 nt, respectively, and are separated by a noncoding region of 287 nt. ORF1 contains a dsRNA-binding motif (DSRM) of 60 amino acids in the N-terminal region. The translated sequence of 901 amino acids corresponds approximately to the size determined in SDS-PAGE for the major capsid protein (106 kDa). ORF2 encodes an RNA-dependent RNA polymerase (RdRp) with significant sequence similarity to members of the family *Totiviridae*.

Taxonomic position

Phylogenetic analysis of IMNV RdRp clusters this virus within members of the genus *Giardiavirus* in the family *Totiviridae*. The genome structure and organization are also consistent with classification in the *Totiviridae*. However, as known giardiviruses infect only flagellated protozoan parasites (*Giardia lamblia* and *Trichomonas vaginalis*), further consideration of the properties of IMNV will be required before formal classification can be obtained.

Geographic distribution and host range

The disease was, until recently, restricted to farmed *P. vannamei* in northeastern Brazil. However, recently the virus and the disease have been reported at several sites in Indonesia where infected *P. vannamei* postlarvae have been introduced from Brazil. *Penaeus stylirostris* and *P. monodon* shrimps are susceptible to experimental infection with IMNV.

MrNV/XSV Complex

White tail disease occurs in farmed giant freshwater prawns (*Macrobrachium rosenbergii*) and is named after the obvious clinical signs in diseased postlarvae. Two viruses, Macrobrachium rosenbergii nodavirus (MrNV) and a very small virus-like particle named XSV (extra small virus), are each found in diseased prawns. The disease was first observed in a hatchery in Guadeloupe Island in French West Indies where abnormal and sudden mortalities had been recorded since 1994. Losses were variable in intensity (5–90% cumulative mortality), depending on the broodstock used to generate the postlarvae. The first gross sign of the disease is the presence of whitish postlarvae 2–3 days after emergence. The prevalence of opaque and milky postlarvae increases dramatically 1–2 days later and changes are particularly obvious in abdomen (tail). The mortality rate reaches a maximum 5 days after the first observation of gross signs.

In diseased prawns, the most affected tissues are the striated muscles in the abdomen and cephalothorax and the connective tissues of all organs. The cytoplasm of infected cells contains discrete, pale to darkly basophilic inclusions, ranging from <1 to 40 μm in diameter. Muscles exhibit multifocal areas of hyaline necrosis of the fibers, with moderate edema.

General properties of isolated particles

Two types of particles are observed in the cytoplasm of infected cells (**Figure 6**). The larger particles are nonenveloped, icosahedral in shape, and 26–27 nm in diameter, with a density in CsCl of 1.27–1.28 g ml^{-1}. The genome consists of two segments of linear single-stranded RNA (ssRNA) of 3202 (RNA1) and 1250 nt (RNA2). The capsid contains a single major protein of 43 kDa (CP43). The properties of this virus are similar to those of nodaviruses and it has been named Machrobrachium rosenbergii nodavirus (MrNV).

The smaller particles are nonenveloped, icosahedral, and 15 nm in diameter, and have a density in CsCl of 1.325 g ml^{-1}. The genome is composed of a single segment of linear ssRNA 796 nt in length. The capsid comprises coat proteins of 16 kDa (CP16) and 17 kDa (CP17). Because the particles are very small, this agent has been called extra small virus (XSV).

Genomic organization

The organization of the MrNV genome is shown in **Figure 7**. RNA1 and RNA2 each encodes a long ORF

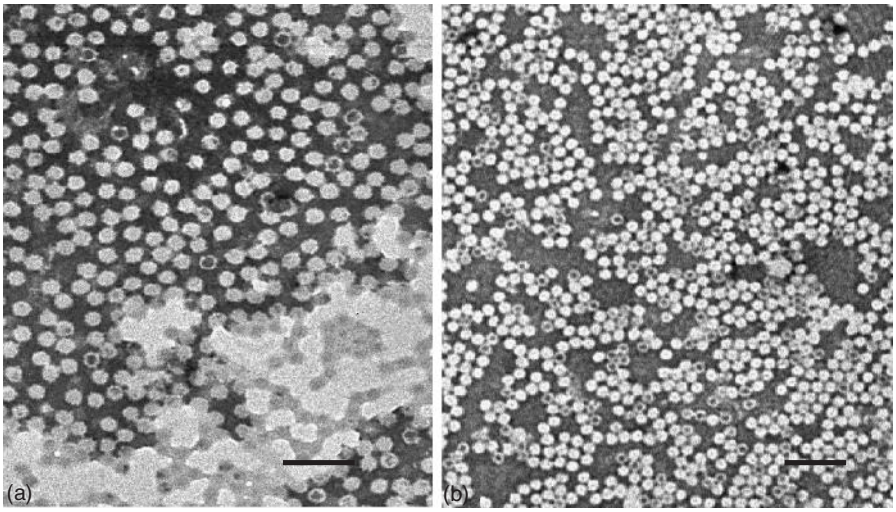

Figure 6 Purified MrNV and XSV particles. The particles were negatively stained with 2% phosphotungstic acid (PTA). Scale = 50 nm. (a, b) Reproduced from Bonami JR, Shi Z, Qian D, and Sri Widada J (2005) White tail disease (WTD) associated virions and characterization of MrNV as a new type on nodavirus. *Journal of Fish Diseases* 28: 23–31, with permission from Blackwell Publishing.

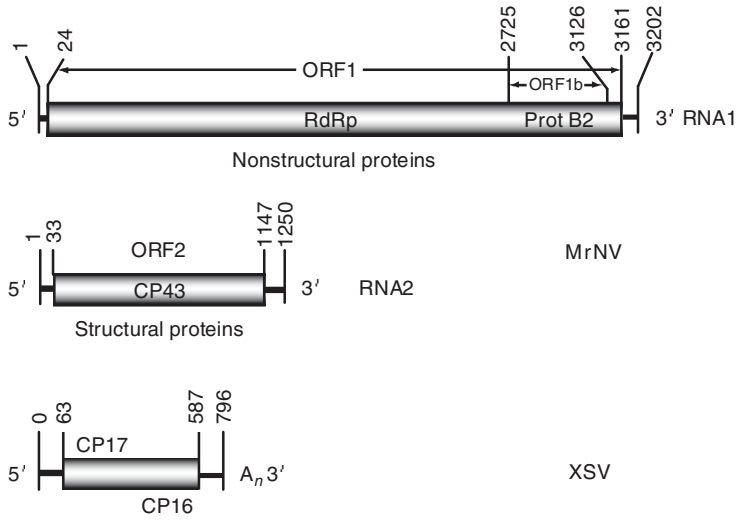

Figure 7 Genome organizations of MrNV and XSV.

flanked by terminal noncoding regions, and lacks a 3′ poly(A) tail. The coding capacity is 1046 and 371 amino acids, equivalent to 122 and 43.5 kDa, for ORF1 and ORF2, respectively. Similar to other nodaviruses, RNA1 contains two long ORFs encoding nonstructural proteins: ORF1 encodes the 1046-amino-acid (~122 kDa) A protein which contains motifs characteristic of the RdRp; and ORF1b, located at the 3′ end of the segment, encodes the 134-amino-acid (~13 kDa) B protein. ORF2 encodes the 371-amino-acid (~43.5 kDa) capsid protein (CP43). The coding assignment of RNA2 has been demonstrated by N-terminal amino acid sequencing of CP43. As for all other nodaviruses, a nonencapsidated RNA3 of 453 nucleotides has also been detected. The MrNV RNA3 is longer than that of any other nodavirus RNA3 (~380–400 nt) and is likely to be a subgenomic mRNA encoding ORF1b.

The 796 nt XSV genome contains a single ORF located between nucleotides 63 and 587, and a short poly(A) tail. A potential polyadenylation signal (AAUAAA) is located 6 nt upstream of the poly(A). The ORF encodes both capsid proteins (CP16 and CP17). Amino acid sequence analysis indicates that CP16 is synthesized by internal initiation at a second methionine residue 11 amino acids downstream of the first initiation codon. The two forms of the capsid protein are synthesized in an equimolar ratio.

Taxonomic position

No formal taxonomic classification of MrNV has yet been assigned. The particle morphology and genome organization are similar to those of members of the family *Nodaviridae*. Amino acid sequence alignments of the RdRp indicate highest homology with members of the genera *Alphanodavirus* (insect nodaviruses) and *Betanodavirus* (fish nodaviruses). Sequence similarities are higher with alphanodaviruses than with betanodaviruses. However, coat protein sequence alignments indicate that the distance between MrNV and alphanodaviruses is similar to those separating alphanodaviruses and betanodavirues. This suggests that MrNV may represent a possible third genus within the family.

The appropriate taxonomic classification of XSV is currently unclear. Sequence similarity searches have not indicated any significant homology with known virus genomes. As the monocistronic genome encodes only the capsid proteins, it is possible that the RdRp required for replication and transcription may be provided by MrNV. This agent meets the primary criteria of satellite viruses and appears more similar to the known satellite viruses infecting plants (e.g., tobacco necrosis satellite virus-like) than those infecting insects (e.g., chronic bee paralysis-associated satellite virus).

MrNV/XSV relationships

MrNV and XSV are each always found associated in white tail disease infections in *M. rosenbergii* in all hatcheries and farms where disease is reported. Analysis by quantitative (real-time) polymerase chain reaction (PCR) has indicated variable proportions of MrNV RNA and XSV RNA in different isolates. However, nothing is known to date about their respective roles in the disease or its severity.

Geographic distribution and host range

White tail disease was first recognized in a hatchery in Guadeloupe Island and was then reported in Martinique Island and in the Dominican Republic. It is suspected that infected postlarvae were introduced to Puerto Rico.

In China, the disease was recorded in Zhejiang, Jiangsu, Shanghai, Guangxi, and Guangdong Provinces and, more recently, it has been reported in Taiwan. In India, the disease has been reported in Andhra Pradesh and Tamil Nadu on the east coast and in Kerala on the west coast where *M. rosenbergii* farming was developed to replace marine (*P. monodon*) culture following the dramatic effects of the WSSV epidemic.

To date, white tail disease has only been reported in the giant freshwater prawn *M. rosenbergii*. However, marine shrimp (*P. monodon*, *P. indicus*, and *P. japonicus*) are susceptible to experimental infection, suggesting a possible role as reservoir. No disease has been reported in marine shrimp species.

Control of Viral Diseases in Shrimp

As invertebrates, marine shrimp and freshwater prawns lack the acquired immune systems that exist in vertebrates. Consequently, a disease control based on vaccination cannot be used. Some antiviral defense reactions (innate immunity) have been reported in Crustacea but the mechanisms by which these occur are largely unknown and prevention appears as the most useful method for control. For this reason, specific and sensitive DNA-based tools for early detection are now available for most of the viral diseases. These tools allow selection of healthy broodstock and a good knowledge of the health status of postlarval seed introduced into ponds. The availability of these tools has also led to the establishment of biosecure breeding programs for commercial production of specific pathogen-free (SPF) broodstock. The more widespread use of SPF stock will significantly reduce the risk of future emergence of devastating viral diseases in shrimp aquaculture.

Glossary

Permissive allele A host allele which allows or participates in viral propagation.
Restrictive allele A host allele which opposes viral propagation.
Stabilized lineage for a virus A female or male host lineage, with infected primordial germinal cells, which transmits the virus to its progeny.

Introduction

Sigma virus (SIGV) is a rhabdovirus that naturally infects fruit flies (*Drosophila* spp.). SIGV infection causes increased sensitivity to carbon dioxide (CO_2) gas, which is anesthetic for flies. Whereas uninfected flies recover rapidly from the effects of CO_2 exposure upon return to a normal atmosphere, flies infected with SIGV remain irreversibly paralyzed. This effect has been observed among both wild flies and laboratory strains of as many as 13 *Drosophila* species and in three of these (*D. melanogaster*, *D. affinis*, and *D. athabasca*) it has been shown to be the consequence of infection.

The discovery of SIGV originates from 1937 when a study by P. L'Héritier and G. Tessier described a CO_2-sensitive strain of *D. melanogaster*. While this gas is commonly used as an anesthetic in fly genetics, these flies were irreversibly paralyzed when exposed to a CO_2-rich atmosphere. The paralysis was specific to CO_2, and dependent on the gas concentration and temperature during exposure. For example, irreversible paralysis appears at 10 °C with CO_2 concentrations higher than 50% while CO_2 concentrations must reach 75% to induce irreversible paralysis at 16 °C.

Transmission of this characterstic appeared to be heritable but could not be linked to any chromosome. The agent was considered to be cytoplasmic and was named Sigma. Its infectivity was demonstrated by inoculation of resistant flies with sensitive-fly extracts. Inactivation by X-ray irradiation indicated the sensitive volume diameter to be 42 nm and filtration through a 180-nm membrane eliminated 99% of infectivity. In 1965, Sigma was finally described as a particle of 70×140 nm similar to vesicular stomatitis virus (VSV) or rabies virions. Thereafter, studies on SIGV focused on its hereditary transmission among flies. More recently, publications on SIGV have been centered on the population genetics of the SIGV–*Drosophila* linkage and descriptions of the defense mechanisms developed by *D. melanogaster*.

Classification

SIGV is currently classified as an unassigned member of the family *Rhabdoviridae*. The virion morphology, genome organization, and sequence relationships of several structural proteins are clearly consistent with its assignment as a rhabdovirus. However, it is not sufficiently closely related to other rhabdoviruses to be classified in any existing genus. It is closer to vesiculoviruses than to other rhabdoviruses according to phylogenetic studies (**Figure 1**) and biological properties (i.e., the CO_2 symptom induced by both vesiculoviruses and SIGV).

Virion and Genome Structure

The SIGV virion is a spiked and enveloped bullet-shaped particle of approximately 75×140–200 nm containing a helical nucleocapsid (**Figure 2**). The genome is a

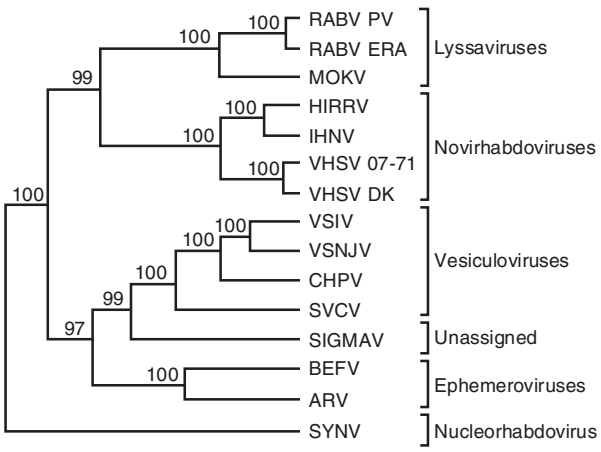

Figure 1 Phylogenetic tree of 15 rhabdovirus glycoproteins. The values adjacent to the branches indicate the boostrapping confidence limits. SIGV is not assigned to any genus of the *Rhabdoviridae* but the most conserved proteins (including the G protein) are most closely related to those of the vesiculoviruses. Reproduced from Björklund HV, Higman KH, and Kurath G (1996) The glycoprotein genes and gene junctions of the fish rhabdoviruses spring viremia of carp virus and hirame rhabdovirus: Analysis of relationships with other rhabdoviruses. *Virus Research* 42: 65–80, with permission from Elsevier.

negative-sense single-stranded RNA. It contains five genes arranged in the same order as in other rhabdoviruses (3′-*N*-*P*-*M*-*G*-*L*-5′) and encodes proteins with significant levels of sequence identity to the corresponding proteins of rhabdoviruses. For example, the P protein of SIGV is acidic and the distribution of charges is similar to other rhabdovirus P proteins. The charge and size of the M protein of SIGV are also similar to the M proteins of vesiculoviruses and the primary domains (basic domain, proline-rich domain, hydrophobic domain) are found in other rhabdovirus M proteins. The SIGV genome also contains an additional gene (*X*) between *P* and *M* genes (**Figure 3**). The *X* gene encodes a putative protein of 298 amino acids that is of unknown function, but which contains three conserved domains found in reverse transcriptases. Another unusual feature of the sigma genome is the 33 nt overlap of the *M* and *G* genes. The putative transcription initiation sequence CAACANG (+ sense) sequence is found at the beginning of the *P*, *X*, *M*, *G*, and *L* genes. The putative transcription termination/polyadenylation sequence $CAUG(A)_7$ (+ sense) terminates the *N*, *P*, *X*, *M*, and *G* genes. Phylogenetic analyses based on the N and G proteins indicate that SIGV clusters with vesiculoviruses (**Figure 1**).

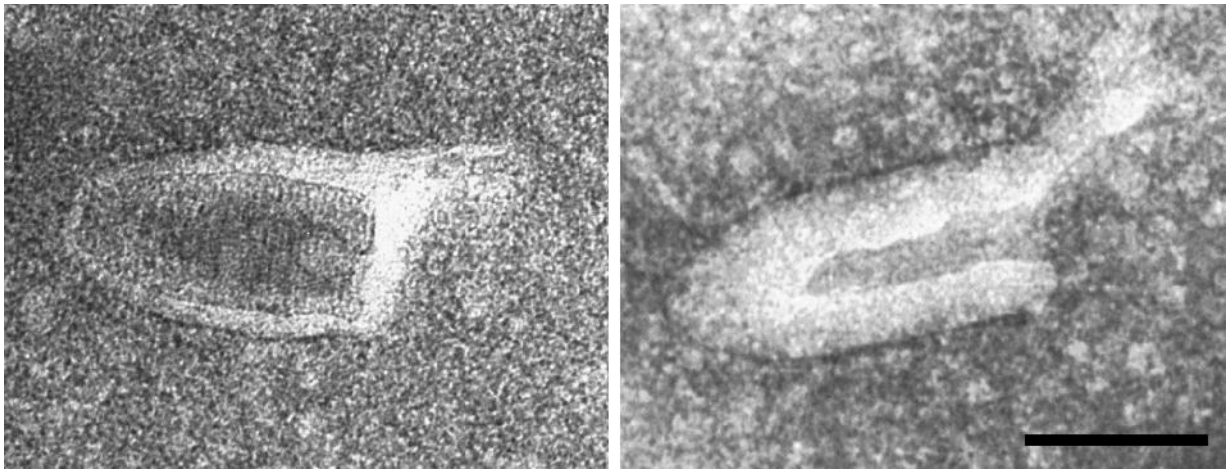

Figure 2 SIGV virions as observed by negative-contrast electron microscopy. The membrane fragment evident on the top right-hand side of the virions in each illustration is frequently but not always observed. Scale = 100 nm.

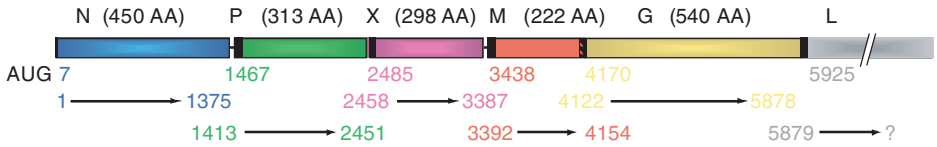

Figure 3 Genome organization of SIGV. The single-strand RNA genome encodes six proteins (N, P, X, M, G, and L) for which the size are indicated. The X protein is also named PP3 (protein product 3). The genome sequence has been obtained for all regions except the L gene which has only been partially sequenced. By comparison with other rhabdoviruses, the SIGV L gene is estimated to be approximately 6000 nt in length, resulting in a complete genome sequence of approximately 12 000 nt. The locations of mRNA transcripts and the position of putative initiation codons (AUG) are indicated. The arrows indicate the direction of transcription and the numbers indicate the transcription initiation and termination points. The M and G transcripts overlap from nucleotides 4122–4154.

CO_2 Sensitivity

The molecular basis of CO_2 sensitivity is unknown. However, the CO_2-induced paralysis of wings and legs correlates with viral invasion of thoracic ganglia that are involved in the nervous control of locomotion. Following abdominal inoculation of flies, several cycles of replication are necessary for SIGV to reach the thoracic ganglia and induce CO_2 sensitivity. Following injection of one infectious dose at 25 °C, an incubation period of 20 days is required for expression of the symptom and, as the virus dose is increased, the mean incubation period decreases. Moreover, a dose of virus that sensitizes flies to CO_2 in 10 days when injected into the abdomen, leads to CO_2-induced paralysis in only 3 days if injected into the thoracic ganglia.

The paralysis symptom is specific to CO_2 as other gases (e.g., N_2, H_2, CO, propane, and volatile acids) do not induce similar effects. This characteristic distinguishes SIGV from other viruses infecting *Drosophila* such as the entomobirnavirus drosophila X virus which induces sensitivity to both CO_2 and N_2 in what appears to be a general anoxia. There is evidence, however, that several vesiculoviruses, although not naturally infecting drosophila, induce CO_2-specific sensitivity in flies similar to that induced by SIGV. Each vesiculovirus tested to date, including vesicular stomatitis Indiana virus (VSIV), Cocal virus, pike fry rhabdovirus, and spring viremia of carp virus, is capable of replication in *D. melanogaster* and induces sensitivity to CO_2 but not to N_2 or propane. In contrast, the lyssavirus rabies virus (CVS strain) and two novirhabdoviruses of fish (infectious hematopoeitic nectosis virus and vesicular hemorrhagic septacaemia virus) do not replicate and do not induce CO_2 symptoms in *D. melanogaster*. The specificity of CO_2-induced paralysis in flies infected with SIGV or vesiculoviruses suggests that the underlying molecular mechanism responsible for the symptom is likely to be similar. Nevertheless, CO_2 symptoms vary for different vesiculoviruses. For example, Cocal virus induces CO_2-dependent paralysis when the virus titer in the nervous system reaches the maximum. Later in infection, although the virus titer in the entire fly remains constant, the titer decreases in the thoracic ganglia and CO_2 sensitivity disappears. It has also been observed that, following infection of flies with VSIV, a proportion of the exposed population displays a delayed CO_2 symptom while the remainder of the CO_2-sensitive flies are immediately paralyzed. The delayed sensitivity correlates with a more rapid invasion of the cephalic ganglia, than the thoracic ganglia and results in death 2–3 days after exposure, presumably due to paralysis of the mouthparts. Direct injection of SIGV into the cephalic ganglia also leads to this delayed sensitivity and lethality.

Host Range

SIGV has been reported to trigger CO_2 sensitivity in 15 of the 16 *Drosophila* species tested to date, the exception being *D. repleta*. However, some *D. melanogaster* genotypes are also resistant to SIGV replication, and so CO_2 sensitivity, and the observed resistance of *D. repleta* may not be valid for all genotypes.

One of the criteria used to demonstrate virus replication is the recovery of a virus yield that is in excess of the original infecting dose. This criterion is very stringent. Indeed, the virus yield from infected flies decreases soon after infection due to the entry of the nucleocapsids into the cytoplasm of infected cells, and there is a period of latency before replication generates new progeny virus. Therefore, a less-stringent criterion for SIGV replication is the observation of a higher virus yield than can be recovered during the latent period. Using these criteria, of 13 *Diptera* species (*Phormia terranovae*, *Ceratitis capitata*, *Musca domestica*, *Calliphora erythrocephala*, *Sarcophaga argyrostoma*, *Glossina mortisans*, *Aedes albopictus*, *Aedes aegypti*, *Aedes detritus*, *Anopheles stephensi*, *Toxorhynchites amboinensis*, *Culex pipiens*, *Culex quinquefasciatus*) that have been tested, only the fleshfly (*Phormia terranovae*) and the mosquito (*Aedes albopictus*) appeared incapable of supporting SIGV replication. As for *D. repleta*, there may be genotypic variation in the susceptibility of these insects and it is possible that susceptibility can be increased by SIGV strain adaptation. This is supported by the observation that SIGV can be adapted to replication in *A. albopictus* cell cultures by passage in the mosquito *Toxorynchites amboinensis*. The selected variants multiply and induce CO_2 sensitivity in *A. albopictus*. Adaptation of SIGV to replication in restrictive genotypes of *D. melanogaster* has also been observed. SIGV has not been observed to replicate in tests conducted in nine insect species representing five orders (*Blattaria*, *Orthoptera*, *Lepidoptera*, *Hymenoptera*, *Hemiptera*) other than *Diptera* or in cultured vertebrate cells.

Virus Transmission

SIGV is not transmitted between insects by casual contact and no vector of horizontal transmission has been identified. In nature, SIGV transmission appears to be exclusively vertical and, although 100% prevalence of infection can be achieved in laboratory strains, only a proportion of natural populations of flies are infected.

There is no evidence of integration of the SIGV genome into host chromosomes and the virus appears to remain exclusively in the cytoplasm. SIGV establishes a stable infection in oogonia, and between 10 and 40 viral genomes can be detected per oogonium according to the virus strain. Thereafter, there is an accumulation of

genomes as oocyte volume increases. This balance reflects an autoregulation of viral infection in which cellular proteins may play a role and allows virus transmission during cell division. The nature of the process also implies low cytopathogenicity of SIGV in oocytes. Furthermore, if viral genomes segregate stochastically following cell division, relatively rare events of completely asymmetrical distribution would lead to the presence of uninfected individuals in the progeny of an infected female.

In a lineage stabilized for SIGV infection, some females will not transmit the virus to 100% of their progeny and infected females are less fertile. This should lead to a rapid elimination of the virus if the males were not able to transmit the infection. The efficiency of viral transmission by males can be as high as 90% in the progeny of a cross between uninfected females and males infected with a recently isolated strain of wild virus. In *D. melanogaster*, the male progeny of such a cross does not transmit the virus to the next generation. However, the female progeny can transmit SIGV to the next generation and some of their daughters are the source of stabilized lineages. These transmission rules are the roots of the invasive character of the virus and allow the virus to maintain itself in nature.

In *D. affinis* and *D. athabasca*, SIGV transmission follows similar rules with the exception that the male progeny of an uninfected female crossed with an infected male can transmit the virus to the next generation.

Virus Replication Cycle

The replication cycle of SIGV has been studied *in vivo* following injection of a viral extract into the abdomen of flies. There is a rapid reduction in recoverable infectivity following inoculation such that after 1 h, only 1% of the infecting dose can be recovered and new viral production commences between 24 and 48 h post infection. Studies of the viral replication cycle have been conducted using both wild-type viruses and temperature-sensitive (*ts*) mutants. Heat–shock experiments have identified three groups of *ts* mutants corresponding to three phases in the replication cycle. The first group of mutants identified a transiently thermolabile complex comprising the viral genome and viral proteins. The half-life of thermosensitivity is 4 h with a maximum span of 9 h post infection. The molecular basis of thermoresistance has not been determined. However, similar studies in vesiculoviruses suggest that this phase could include the steps that precede replication of the viral genome such as the release of the ribonucleoprotein complex from the endosome and primary transcription and protein synthesis.

A second group of *ts* mutants is affected in a replication phase that has a half-life of 9 h, commencing 7 h post infection and terminating at 14 h post infection. This phase corresponds to genome replication since hereditary transmission of these mutants is interrupted at the restrictive temperature. Late functions are also altered, as have been observed in molecular studies of vesiculoviruses which have shown that the N, P, and L proteins are essential for genome replication and secondary transcription.

A third group of *ts* mutants is affected in the late phase of the viral cycle. At the restrictive temperature, these mutants can be hereditarily transmitted but no infectious particles are produced and CO_2-induced paralysis of the host is not observed. The proteins modified in these mutants could be the G, M, or X proteins. Since the N, P, and L proteins are involved in viral replication and the X protein is absent in vesiculoviruses, CO_2 sensitivity must be due to G, M, or both G and M proteins.

At 20 °C, the viral replication cycle can vary in length between 25 and 90 h post infection in different individuals with an average of 60 h. The cycle length varies according to temperature and is much faster at 25 °C, as is the metabolism of flies. The host genotype also influences the cycle length. In more permissive genotypes, the replication cycle is faster and in the most permissive genotypes, the longest cycle is only 48 h in duration.

Host Immunity

A reduced fertility that has been observed in female flies infected experimentally with SIGV should be a strong selective pressure in nature. Surprisingly, poor fertility is not evident in natural populations. A loss of fertility is observed in crosses between infected females from a natural population and uninfected males from laboratory strains. These results suggest that the viral infection cycle is controlled by the host genome. Indeed, seven such genes are known: *ref(1)H*, *ref(2)M*, *ref(2)P*, *ref(3)G*, *ref(3)O*, *ref(3)D,* and *ref(3)V*. Each is polymorphic with alleles segregating into two categories. Permissive alleles allow the viral infection cycle to proceed while restrictive alleles restrict virus cycling. The only exception is the *ref(3)V* gene for which the restrictive allele blocks hereditary transmission of SIGV from stably infected males.

The most intensively studied of the *ref* genes is *ref(2)P*. Restrictive *ref(2)P* alleles modify the rules for hereditary transmission of SIGV. The frequency of uninfected flies in the progeny of infected parents increases with the number of restrictive alleles in the genome of the female. Stabilized mothers that are homozygous for a restrictive allele do not display CO_2 sensitivity even though they remain capable of virus transmission. Their progeny are transmission defective but may be CO_2 sensitive, depending on the genotype. Moreover, when stabilized males are crossed with uninfected females, the proportion of progeny that is infected is twofold lower when the

mother is heterozygous for *ref(2)P* (permissive/restrictive) and zero when the mother is homozygous restrictive for *ref(2)P*. These restrictive alleles are often encountered in natural populations and do not appear to be counter-selected in uninfected drosophila. When the populations are infected with currently observed virus strains, which are sensitive to this defense system, *ref(2)P* restrictive alleles are favored until their frequency reaches 0.3. At this frequency, the sensitive strain of virus is eliminated. Thereafter, the lack of counter-selection of restrictive alleles maintains their frequency around 0.3, which protects the population from any new invasion by a sensitive virus.

Three functional domains have been identified in both the Ref(2)P protein and its mammalian homolog, p62/sequestosome-1. Two protein–protein interaction motifs are found: an amino-terminal PB1 (Phox and Bem 1) domain and a more central ZZ zinc finger. At the other end of both proteins there is a carboxy-terminal UBA (ubiquitin-binding area) domain. The Ref(2)P PB1 domain mediates the interaction with the drosophila atypical protein kinase C (DaPKC) and p62 binds mammalian aPKCs. The physiological function of Ref(2)P remains unknown even though it is essential for male fertility in some specific genotypes.

A comparison of susceptibility to the SIGV between flies that are homozygous for permissive alleles of *ref(2)P* and flies *ref(2)P*$^{-/-}$ has shown that permissive Ref(2)P protein is required for the virus to multiply at highest efficiency. For SIGV strains that are the most sensitive to *ref(2)P* alleles, a 16-fold higher dose is required for infection of a *ref(2)P*$^{-/-}$ genotype and a 10 000-fold higher dose is required for infection of a homozygous restrictive genotype than to infect homozygous permissive flies.

A comparison of the 15 sequenced alleles of *D. melanogaster ref(2)P*, among which three are restrictive, and the reference sequence of *D. simulans ref(2)P* indicate that the ancestral gene was permissive. Three mutations affecting the PB1 domain of the protein are necessary and sufficient to convert a permissive *ref(2)P* allele into a restrictive allele. Both permissive and restrictive alleles with sequence variations in the PB1 domain have been shown to form a monophyletic group that shows less internal variability than the group of ancestral permissive alleles. This suggests that the three variations in the PB1 domain that affect susceptibility to SIGV infection have emerged relatively recently. The high frequency of these variants (up to 50% of the observed alleles) indicates that their existence provides a selective advantage in drosophila populations.

The interaction between SIGV and the *ref(2)P* gene is highly specific. None of the other viruses that replicate in *D. melanogaster*, such as drosophila X virus and vesiculoviruses, is sensitive to restrictive *ref(2)P* alleles. A unique amino acid change in the PB1 domain is sufficient to suppress the restrictive character of an allele. In a viral population, genotypes with a capacity to replicate efficiently in a restrictive environment exist, even if the virus has never been exposed to restrictive alleles. For this reason, the elimination of sensitive viruses in a natural fly population by restrictive *ref(2)P* alleles is often associated with a new infection of the population by adapted viruses. Therefore, one could doubt that restrictive alleles provide a real defense system against SIGV but *ref(2)P* is not the only *ref* gene.

Each of the *ref* genes impacts independently on the viral replication cycle. For example, if a particular viral strain requires a tenfold higher dose to successfully infect flies that are restrictive at the *ref(2)P* locus, and a tenfold higher dose to infect flies restrictive at the *ref(2)M* locus, a 100-fold higher dose is required to overcome the flies that are restrictive for both *ref* genes. Adapted viruses can be isolated from a clone sensitive to *ref(2)P* restrictive alleles and studied for their sensitivity to *ref(2)M* restrictive alleles. As shown in **Figure 4**, the viral mutants

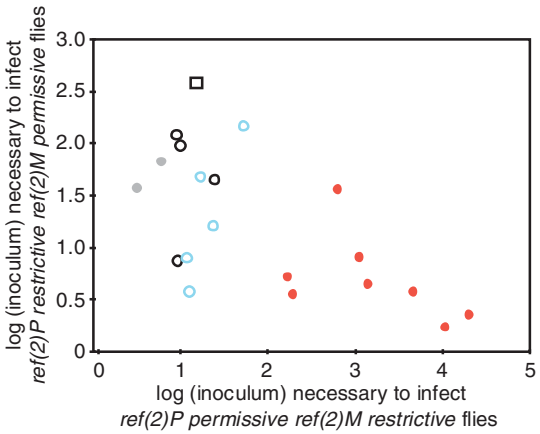

Figure 4 Virus clone distribution according to the inoculum size necessary to infect different fly genotypes. The reference *Drosophila melanogaster* strain was homozygous permissive for both *ref(2)P* and *ref(2)M*. The size of inoculum necessary to infect these flies was arbitrarily defined as 1.00. The *y*-axis values are the logarithm of the smallest inoculum capable of infecting flies homozygous for both a permissive *ref(2)M* allele and homozygous for a restrictive *ref(2)P* allele. The *x*-axis values are the logarithm of the smallest inoculum capable of infecting flies homozygous for both a permissive *ref(2)P* allele and a restrictive *ref(2)M* allele. The square represents the parental virus while circles represent viral mutants adapted to *ref(2)P* restrictive alleles. Open circles symbolize mutants that are not significantly different from the parental virus when assayed in *ref(2)M* restrictive flies. Blue circles depict the results observed for thermosensitive mutants, while gray and red circles show the observation made for mutants that are slightly adapted to both *ref* genes and mutants that are more sensitive to *ref(2)M* restrictive alleles than the parental clone, respectively. Among the mutants that are at least 20 times more adapted to *ref(2)P* than the parental clone, three are thermosensitive and thus would not survive in nature. The majority (seven out of eight) of the other 'adapted mutants' are more sensitive to *ref(2)M* restrictive alleles.

most adapted to *ref(2)P* restrictive alleles become more sensitive to restrictive alleles of *ref(2)M*. Increasing the frequency of *ref(2)M* restrictive alleles can also contribute to the elimination of viral mutants, only allowing viruses adapted to both *ref(2)P* and *ref(2)M* restrictive alleles to invade a fly population. It appears that the various *ref* genes cooperate to defend the fly population against the virus. For example, if the frequency of *ref(2)P* restrictive alleles was around 0.3, the frequency of *ref(2)M* restrictive alleles could rise while viruses sensitive to *ref(2)M* would disappear.

There are still SIGV strains in nature which are sensitive to *ref(2)P* restrictive alleles. In addition, a virus adapted to *ref(2)P* with an increased sensitivity to *ref(2)M* (i.e., equivalent to the red circles of **Figure 4**) is yet to be found in nature. Moreover, analysis of *ref(2)P* allele genealogy suggests that, if all the viruses present in a region were adapted to *ref(2)P* restrictive alleles, a new mutation in the PB1 domain of the protein would be selected to generate a new restrictive allele. Therefore, Ref(2)P remains as an active defensive mechanism against natural SIGV infections. The role of the other Ref proteins in host immunity remains unknown.

Concluding Remarks

In earlier studies, the detailed rules of vertical transmission of SIGVs in *D. melanogaster* populations illustrated how vector insects such as mosquitoes or sandflies can become the reservoirs of a virus. Currently, the two major interests in SIGV research are the description of the host–virus interactions in natural populations together with the development of an improved understanding of defensive mechanisms mediated by the *ref* genes. This immunity has certain similarities to innate immunity since its components are hereditary, but they differ because of the high specificity of protection and the memory effect that is generated in host populations. Strictly speaking, Ref(2)P may be part of the innate immune response through its interaction with DaPKC and a more extensive study could reveal that other *ref* genes also form part of a complex innate host immune system in flies.

Simian Alphaherpesviruses

J Hilliard, Georgia State University, Atlanta, GA, USA

© 2008 Elsevier Ltd. All rights reserved.

History

Members of the subfamily *Alphaherpesvirinae* in the family *Herpesviridae* have been identified in Old World monkeys and apes and in New World monkeys. It appears that nearly all host species have co-evolved with one or more alphaherpesviruses, and so it comes as no surprise that new agents in this group continue to be discovered. Indeed, the increased use of nonhuman primates in biomedical research has facilitated the discovery and characterization of such viruses. As assays improve, more virus isolates from nonhuman primates have been identified, and subsequently have been differentiated from closely related viruses by molecular and immunological means. The

benefit of enhanced techniques for virus differentiation is exemplified by the early reports in the 1970s that simian agent 8 (SA8; *Cercopithecine herpesvirus 2*) was not only found in vervets but also in baboons. It was not until nearly two decades later that the virus isolated from baboons in a captive colony was recognized to be herpesvirus papio 2 (HVP-2; *Cercopithecine herpesvirus 16*). Although improved technology enables differentiation of closely related herpesviruses, it remains a time-consuming task to find species-specific viruses, characterize the associated pathogeneses, and verify the natural hosts. Like human alphaherpesviruses, nonhuman primate alphaherpesviruses fall into the genera *Simplexvirus* and *Varicellovirus*.

Simplexviruses are readily isolated because they replicate rapidly in cell cultures from a variety of mammals. They produce a distinct cytopathology as quickly as 24–48 h following infection. Examples of this cytopathology and some of the differences among simplexviruses are shown in **Figure 1**. The property of rapid growth is one of the initial criteria for establishing that an isolate is an alphaherpesvirus. These viruses are most frequently isolated from mucosal sites or from necropsy samples, and occasionally from fomites. With sequence analysis readily available, they can be differentiated easily from close counterparts endemic in related species of Old and New World monkeys, apes, and humans. The zoonotic potential of these viruses is of particular interest, because at least one, B virus (*Cercopithecine herpesvirus 1*), can be rapidly lethal in humans when antiviral therapy is initiated too late.

Frequently, the identity of the natural host of a virus isolate has been established by the use of seroepidemiological assays. The natural host often shows 80–100% seroprevalence in the wild by the time the animals reach sexual maturity. Most data in this regard have been summarized from studies of vervets, baboons, and macaques in the wild, although there are excellent studies that have focused on apes and New World monkeys. The assays, however, upon which seroprevalence are based are not always uniform, and may utilize antigens that are not necessarily unique to the specific virus for which antibody is reactive, resulting in difficulty identifying the natural host of a particular virus. Nonetheless, the plethora of assays has afforded investigators the opportunity to establish candidates for the natural host, and, as assays improve, the identity of the natural host can be narrowed.

Owing to the close evolutionary relationships between monkeys, most notably within Old World groups and New World groups, the viruses that have co-evolved in each host group share significant similarities genotypically and phenotypically. Although genes are arranged mostly in a collinear layout in viruses from both groups of nonhuman primates, viruses from Old World and New World monkeys differ from each other more than viruses from within each monkey group. This point is best illustrated by studies evaluating immunological cross-reactivity among nonhuman primate alphaherpesviruses between groups and within groups. Within either of the Old World and New World groups, extensive genetic conservation renders classical serological assays using virus or infected cell lysates of relatively limited value in identifying the natural host, due to significant cross-reactivity of immunogenic epitopes. An assay for detection of HVP-2 will cross-react sufficiently strongly with mangabey or langur herpesviruses, such that differentiation of the antibody specificity will be nearly impossible using a virus- or infected

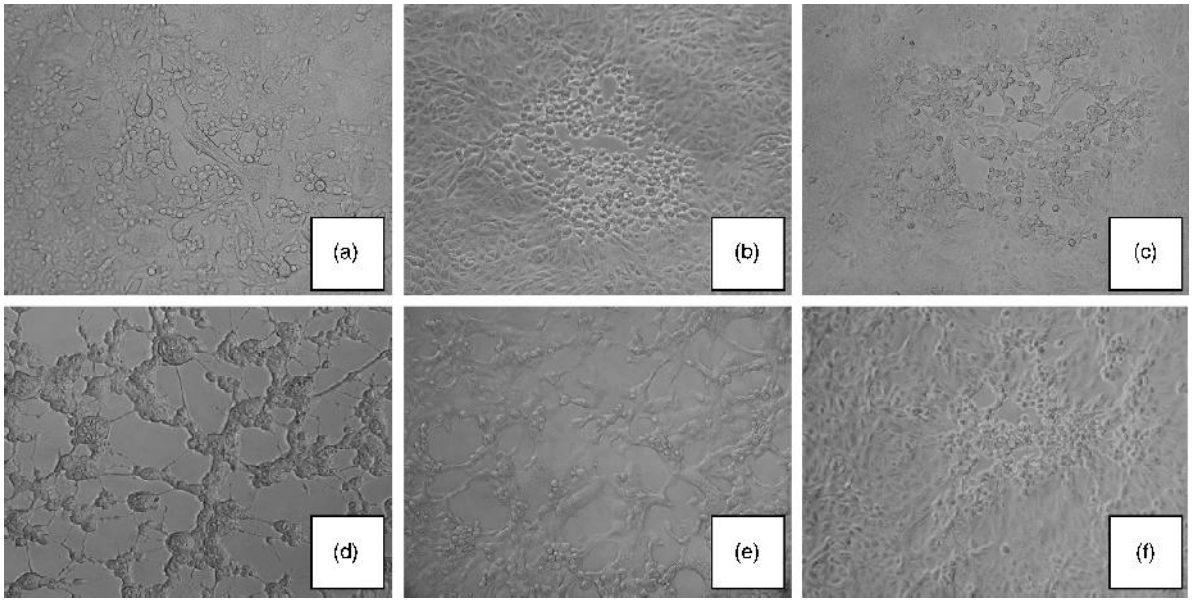

Figure 1 Vero cells in culture (ATCC-081) 24 h after infection with (a) B virus (E2490), (b) HSV-1 (KOS), (c) HVP-2 (SWF), (d) mangabey herpesvirus (EM-GS), (e) SA8 (Hull), or (f) langur herpesvirus (BZ).

cell-based immunoassay. With the advent of recombinant viral proteins, differentiation assays for human alphaherpesviruses have improved, but conservation of the major antigenic proteins can still cloud identification of endemic populations in nonhuman primates. The strategies that differentiate alphaherpesviruses in humans have not proved to be entirely successful when extrapolated to identifying alphaherpesviruses in nonhuman primates. The best example of this is the confusion caused by the finding that SA8 was endemic in baboons as well as vervets, which was still manifest decades after the first publication citing the identification of this agent in baboons. It is now appreciated that the viruses infecting vervets and baboons are distinct alphaherpesviruses, SA8 and HVP-2, respectively. Identification of the natural host of simian varicella virus (SVV) provides a similar example, since both macaques (Asian) and vervets (African) host similar, if not identical, varicelloviruses.

Classification and Evolution

The current list of nonhuman primate alphaherpesviruses is shown in **Table 1**. Nonhuman primate alphaherpesviruses belong to genus *Simplexvirus* (with human herpes simplex virus (HSV) types 1 (HSV-1) and 2 (HSV-2)), with the exception of SVV (*Cercopithecine herpesvirus 9*), which belongs to genus *Varicellovirus* (with human varicella-zoster virus, VZV). The marked genetic similarities between the nonhuman primate viruses and their counterparts in humans strongly support a co-evolutionary history.

The genomes of the Old World monkey simplexviruses have been shown to exist in four isomeric forms, like those of HSV (type E genome structure). The DNA sequences of B virus, SA8, mangabey herpesvirus, langur herpesvirus, and HVP-2 are similar in size (151–157 kbp) to those of their human counterparts, with somewhat greater G+C contents. The genetic contents of these viruses are very similar to that of HSV-1 and HSV-2, except that they lack the gene encoding the neurovirulence protein ICP34.5. The varicelloviruses have a type D genome structure, and the genetic content of SVV is very similar to that of VZV, differing in only a couple of genes at the left genome terminus.

In accord with the relationships among their hosts, simplexviruses of New World primates are more distantly related to those of Old World primates, and the genomes are smaller in size with relatively less complex isomeric organization. The evolutionary distances are apparent from the fact that antisera prepared against the major HSV proteins cross-react with homologous proteins from Old World, but not New World, simplexviruses. Thus far, no varicelloviruses have been found to be endemic in New World monkeys.

Virion Structure

Nonhuman primate alphaherpesviruses are similar in structure to the other members of the subfamily *Alphaherpesvirinae*. By electron microscopy, virus particles consist of capsids sheathed by a tegument and surrounded by an envelope. The icosahedral capsids are assembled in the infected cell nucleus and finally enveloped in the cytoplasm. Unenveloped capsids can be found in both the cytoplasm and nucleus, and are most abundant in the latter. Temporal studies of the kinetics of virus replication suggest that the envelope is acquired in a two-step process, similar to that of HSV. The envelope is rich in virus glycoproteins, which, as judged from antibodies induced during infection, are highly immunogenic. Sequencing and immunological cross-reactivity studies indicate that glycoprotein B is the most highly conserved glycoprotein.

Table 1 Nonhuman primate alphaherpesviruses

Host	*Common virus name*	*Official species name*
Old World		
Vervet (African green monkey)	Simian agent 8 (SA8)	*Cercopithecine herpesvirus 2*
Baboon	Herpesvirus papio 2 (HVP-2)	*Cercopithecine herpesvirus 16*
Macaque	B virus	*Cercopithecine herpesvirus 1*
Macaque	Simian varicella virus (SVV) (also known as Patas delta, Liverpool vervet and Medical Lake macaque herpesvirus)	*Cercopithecine herpesvirus 9*
Langur	Langur herpesvirus	Currently unnamed
Mangabey	Mangabey herpesvirus	Currently unnamed
New World		
Spider monkey	Spider monkey herpesvirus (also known as herpesvirus ateles)	*Ateline herpesvirus 1*
Marmoset	Marmoset herpesvirus (also known as herpesvirus saimiri and, in other platyrrhine monkeys, herpesvirus tamarinus)	*Saimiriine herpesvirus1*

Physical Properties and Epidemiology

Each of the nonhuman primate alphaherpesviruses has features in common with its human counterparts with respect to host range, replication kinetics, transmission, tissue tropism, pathogenecity, histopathology, and induced immune responses. The exception is B virus, which can infect humans, often resulting in a fatal zoonotic infection when left untreated. Each virus is predominantly found in one type of monkey, and recent experience indicates that antibody cross-reactivity with isolates from other species should be evaluated carefully in order to avoid deducing wrongly that a virus is endemic in multiple monkey types. As mentioned above, this is particularly apparent in the case of SA8 and HVP-2, but also features in case studies of alphaherpesviruses from Asian and African monkeys, as well as greater and lesser apes. Although apes are likely to have co-evolved with their own respective alphaherpesviruses, investigators have not yet found herpesviruses other than HSV-1 and HSV-2 in these animals.

Transmission of nonhuman primate alphaherpesviruses from animal to animal occurs as a result of biting, scratching, and splashing activities that contaminate susceptible mucosal epithelial cells. Seroprevalence of virus-induced antibodies increases with the onset of sexual maturity, but infected infants have also been identified, albeit infrequently. Infection is associated with few or no apparent symptoms, whether the virus is latent or replicating actively. Periodic reactivations from latency have been associated with virus shedding from mucus membranes, and this is the time period during which transmission is greatest. Except for B virus, none of the nonhuman primate alphaherpesviruses appears to be transmissible to humans under natural circumstances. Evidence for transmission of human viruses to apes has been substantiated in certain circumstances, as mentioned above, but nonhuman primates are not usually found to be infected with human alphaherpesviruses. When transmission of Old World simplex- or varicelloviruses to New World primates occurs, infection is readily apparent with high morbidity and frequent mortality.

Virus Replication

Nonhuman primate alphaherpesviruses appear to follow the same pattern of biosynthetic activities leading to virus replication and assembly as do their human counterparts, with some exceptions noted. The nonhuman primate simplexviruses replicate in a manner similar to HSV, with a replication cycle of approximately 18 h. Cytopathic effects in cultured cells are also similar, with the exceptions of B virus and mangabey herpesvirus, which induce cell fusion between infected cells and also with neighboring uninfected cells. **Figure 1** shows representative cytopathic effects of B virus versus other alphaherpesviruses in nonhuman primate cells. SVV replicates with kinetics similar to VZV over an interval of 48–72 h in cell culture and, like VZV, remains mostly cell associated.

Following adsorption of a nonhuman primate alphaherpesvirus to a susceptible cell, de-enveloped capsids are released into the cytoplasm and proceed to the nuclear membrane by mechanisms that are poorly understood, but which probably involve the cell's cytoskeleton components. Microarray studies have revealed that host gene remodeling in B virus-infected cells begins within the first hour post infection, and within 3 h post infection the events are clearly distinguishable from those transpiring in HSV-infected cells. Nonetheless, the outcome at the level of the infected cell in culture is the same for both human and nonhuman primate alphaherpesviruses – productive virus replication. The temporal cascade of protein synthesis is conserved, with immediate early, early, and late expression. The major difference between human and nonhuman primate alphaherpesviruses is that the US11 protein is produced as an immediate early protein in the nonhuman primate viruses and as an early protein in HSV-1 and HSV-2. This protein in nonhuman primate viruses prevents phosphorylation of protein kinase R, which in turn prevents phosphorylation of eIF-2α, thus blocking apoptosis in the infected cell and enabling virus replication.

Immune Response to Infection

Nonhuman primates infected by their respective alphaherpesviruses induce humoral antibodies generally within 7–14 days following the onset of acute replication. Antibody titers, however, are not apparent in all animals within this period. Titers can also wax and wane depending on the intervals between reactivated infections. Nonetheless, intermittent virus shedding makes reliance on virus isolation or polymerase chain reaction (PCR) impractical; thus, detection of antibodies is used as the current indicator of whether an animal is infected. Antibodies induced in Old and New World monkeys are cross-reactive with the alphaherpesviruses infecting animals within each group, but there is no apparent cross-reactivity between the two groups. There is little evidence that Old World monkeys can be infected by New World monkey viruses, but New World monkeys generally succumb to viruses from Old World monkeys or humans. Cross-species housing is generally avoided.

The antibodies most commonly produced are against the major glycoprotein (glycoprotein B). There is no clear-cut evolution of the humoral immune response, but the antibodies most observed include those reactive with glycoprotein B, glycoprotein C, glycoprotein D,

glycoprotein G, and the major capsid protein. Having said this, antibody profiles from different animals are quite distinct, as in the case of human antibody profiles induced against HSV.

Future Perspectives

Identification and characterization of simplex- and varicelloviruses from nonhuman primates afford the opportunity to learn more about the origins, evolutionary processes, and pathogenic properties of these viruses. Thus, study of a particular member provides insights on the virus as an individual species and as a representative of a lineage of related agents. Perhaps even more important is the development of understanding on how to approach novel viruses, whether newly discovered or emerging. Knowledge of these viruses in relation to their natural hosts often cannot be extrapolated to their effects in foreign hosts, and the responses of a non-natural host can influence pathogenesis in unexpected ways. This is illustrated by B virus infection of humans, the most dramatic example of cross-species transmission among the herpesviruses. Current attention focused worldwide on emerging viruses and viruses that invade foreign hosts places an emphasis on primate alphaherpesviruses that will teach investigators for decades to come.

Introduction

The *Gammaherpesvirinae* is a large subfamily of the family *Herpesviridae*. Although gammaherpesviruses usually cause limited disease upon primary infection of their natural hosts, several are relevant tumor viruses of the hematopoietic system and form an important chapter of viral oncology. The first clearly identified human herpesvirus, Epstein–Barr virus (EBV; species *Human herpesvirus 4*), is the prototype of genus *Lymphocryptovirus* (whose members are referred to as lymphocryptoviruses or γ1-herpesviruses) and the cause of infectious mononucleosis. Homologs of EBV had been recognized for decades in various Old World primates, and have been found recently in several species of American monkeys. They may serve to develop models for pathogenesis or treatment of human lymphoproliferative diseases and cancers that are caused by EBV, such as B-cell lymphomas and other lymphoproliferative syndromes, nasopharyngeal carcinomas, and, possibly, gastric cancer.

The second genus of gammaherpesviruses, *Rhadinovirus* (whose members are referred to as rhadinoviruses or γ2-herpesviruses), is distinct biologically and molecularly. The prototypic member of this group, herpesvirus saimiri (HVS; species *Saimiriine herpesvirus 2*), and herpesvirus ateles (HVA; species *Ateline herpesvirus 2* and ateline herpesvirus 3) were detected as T-lymphotropic viruses in neotropical primates and raised primary interest from the fact that they cause fulminant T-cell lymphomas in numerous primate species as well as in rabbits. The related animal pathogens alcelaphine herpesvirus 1 and ovine herpesvirus 2 cause malignant catarrhal fever, a T lymphoproliferative disease of ruminants. Although no exact correlates of these T-cell tumors exist in human pathology, HVS strains of subgroup C are capable of transforming human and simian T lymphocytes to continuous growth in cell culture. This provided for the first time a reliable means of immortalizing human T lymphocytes in cell culture, a useful tool for T-cell immunology. These viruses have been used as expression

vectors for gene transfer in T lymphocytes and have facilitated study of the mechanisms of episomal persistence in the T-cell system. Further interest in the rhadinoviruses arose when the first human member of this genus was recognized. This virus was found to be strongly associated with all forms of Kaposi's sarcoma (KS), as well as with multicentric Castleman's disease and primary effusion lymphoma (PEL). Since DNA from this virus is regularly found in all KS forms, specifically in the spindle cells of KS, it was also termed KS-associated herpesvirus (KSHV; species *Human herpesvirus 8*). Viral membrane-associated oncoproteins Stp and Tip, which act on T-lymphocyte signaling, were defined in HVS, though it is far less clear which of several candidate genes encode the relevant oncoproteins of KSHV.

For many years, research on lymphotropic simian herpesviruses focused on the tumorigenic T-lymphotropic rhadinoviruses, especially HVS. Then the discovery of KSHV prompted research on B-lymphotropic agents and led to the description of rhesus rhadinovirus (RRV; species *Cercopithecine herpesvirus 17*) and several closely related rhadinoviruses in various Old World primates, although these are only loosely associated with pathogenicity or tumor induction. New World primate EBV-like viruses were discovered recently, and an increasing number of DNA sequences from additional, new gammaherpesviruses are being amplified from diverse host species using degenerate polymerase chain reaction (PCR) techniques that target strongly conserved herpesvirus genes, such as that encoding DNA polymerase. A provisional compilation of the better defined primate gammaherpesviruses is represented in **Table 1**, and more extensive information is available in the website of the International Committee on Taxonomy of Viruses (ICTV).

Herpesvirus Saimiri and Herpesvirus Ateles

This section focuses on the basic biology, gene content, and viral mechanisms of oncogenic transformation of HVS and HVA, and their possible applications as T-cell vectors and in cell-based immunotherapy. These gammaherpesviruses must not be confused with two alphaherpesviruses isolated from the same host species, designated as species *Saimiriine herpesvirus 1* and *Ateline herpesvirus 1*, respectively.

History, Host Range, Transmission, and Pathology

HVS was originally isolated by Melendez and others from captive monkeys of various species, but it soon became clear that this virus is found regularly only in squirrel monkeys (*Saimiri sciureus*), whose natural habitat is South American rainforests. Squirrel monkeys are usually infected via saliva within the first two years of life. The virus does not cause disease or tumors, and establishes lifelong persistence. In other New World primate species such as tamarins (*Saguinus* spp.), common marmosets (*Callithrix jacchus*), or owl monkeys (*Aotus trivirgatus*), infection with HVS causes acute peripheral T-cell lymphoma within less than 2 months after experimental intramuscular or intravenous infection. Intramuscular injection of purified virion DNA can also cause disease in susceptible primates.

HVS strains are classified into three subgroups (A, B, and C) depending on pathogenic properties and on sequence divergence in the left-terminal nonrepetitive region of the genome (**Figure 1**). The major representative strains are the prototypic A11 for subgroup A; B S295C and B-SMHI for subgroup B; and C488 and C484 for subgroup C.

Viruses of HVS subgroups B and C are considered to be the least and most oncogenic, respectively. Tamarins are susceptible to viruses of all subgroups, whereas subgroup B viruses are not able to cause disease in adult common marmosets. Strain C488 causes acute peripheral T-cell lymphoma within only a few weeks in common marmosets or cottontop tamarins (*S. oedipus*). A similar fulminant disease is induced in Old World rhesus and cynomolgus monkeys (*Macaca mulatta* and *M. fascicularis*, respectively) by large intravenous doses of C488. Similar to the situation in New World primates, the disease in cynomolgus monkeys is designated as a pleomorphic, peripheral T-cell lymphoma or a pleomorphic, T-lymphoproliferative disorder. A high-titer infection in New Zealand white rabbits results in tumor induction, but pathogenicity has not been reported in rodents. HVS can be isolated from the peripheral blood cells of persistently infected squirrel monkeys or diseased tamarins, presumably from infected T cells, by co-cultivation with permissive owl monkey kidney (OMK) cells. HVS replicates productively in, and induces cell lysis of, OMK cells and some primary mesenchymal cultures established from marmosets, and less efficient replication is possible in Vero (African green monkey) cells.

HVA can be isolated at a high frequency from spider monkeys (*Ateles* spp.). Strain 810 from *A. geoffroyii* is a member of species *Ateline herpesvirus 2*, whereas strain 73 and related strains (87, 93, and 94) from *A. paniscus* are isolates of ateline herpesvirus 3. HVA replicates in OMK cells, but remains mostly cell-associated with syncytia formation. As a result, supernatants of such cultures have low, unstable virus titers.

Like HVS, HVA is not pathogenic in its natural host, but causes acute T-cell lymphomas in various New World primate species, including cottontop tamarins and owl monkeys. The pathological changes are similar to those observed after HVS infection. In addition, HVA transforms

Table 1 Primate gammaherpesviruses

Species	*Common name(s) and abbreviation(s)*	*Host*	*Associated pathogenicity*
Genus *Rhadinovirus*			
Human herpesvirus 8	Kaposi's sarcoma-associated herpesvirus (KSHV)	Human (*Homo sapiens*)	Kaposi's sarcoma, multicentric Castleman's disease, primary effusion lymphoma
NA[a]	Chimpanzee rhadinovirus	Chimpanzee (*Pan troglodytes*)	Unknown
NA	Gorilla rhadinovirus	Gorilla (*Gorilla gorilla*)	Unknown
Cercopithecine herpesvirus 17	Rhesus rhadinovirus (RRV), *Macaca mulatta* rhadinovirus	Rhesus macaque (*M. mullata*)	B-cell hyperplasia?
NA	Retroperitoneal fibromatosis-associated herpesvirus (RFHV, RFHVMn, RFHVMm)	Southern pig-tailed macaque (*M. nemestrina*), rhesus macaque (*M. mullatta*)	Retroperitoneal fibromatosis?
NA	*Macaca nemestrina* rhadinovirus 2 (MnRRV)	Southern pig-tailed macaque (*M. nemestrina*)	Unknown
Saimiriine herpesvirus 2[b]	Herpesvirus saimiri (HVS)	Squirrel monkey (*Saimiri sciureus*)	T-cell lymphoma in other neotropical monkey species
Ateline herpesvirus 2	Herpesvirus ateles (HVA)	Spider monkey (*Ateles paniscus*)	T-cell lymphoma in other neotropical monkey species
NA	Herpesvirus ateles strain 73 (HVA), ateline herpesvirus 3	Spider monkey (*A. paniscus*)	T-cell lymphoma in other neotropical monkey species
Genus *Lymphocryptovirus*			
Human herpesvirus 4[b]	Epstein–Barr virus (EBV)	Human (*Homo sapiens*)	B-cell lymphoma, nasopharyngeal lymphoma, Hodgkin's disease
Pongine herpesvirus 1	Herpesvirus pan, chimpanzee lymphocryptovirus	Chimpanzee (*Pan* sp.)	Unknown
Pongine herpesvirus 2	Orangutan herpesvirus	Orangutan (*Pongo* sp.)	Unknown
Pongine herpesvirus 3	Gorilla herpesvirus	Gorilla (*Gorilla* sp.)	Unknown
Cercopithecine herpesvirus 12	Baboon herpesvirus, herpesvirus papio	Baboon (*Papio* sp.)	Spontaneous B-cell lymphoma (and in immunosuppressed animals)
Cercopithecine herpesvirus 14	African green monkey EBV-like virus	African green monkey (*Chlorocebus aethiops*)	Unknown
Cercopithecine herpesvirus 15	Rhesus EBV-like herpesvirus, rhesus lymphocryptovirus	Rhesus macaque (*M. mullatta*)	Spontaneous B-cell lymphoma (and in immunosuppressed animals)
NA	Cynomolgus EBV-like virus, *Macaca fascicularis* gammaherpesvirus (herpesvirus MF1, A4, TsB-B6, Si-IIA-EBV)	Cynomolgus monkey (*M. fascicularis*)	Spontaneous B-cell lymphoma (and in immunosuppressed animals)
Callitrichine herpesvirus 3	Marmoset lymphocryptovirus	Common marmoset (*Callithrix jacchus*)	Spontaneous B-cell lymphoma
NA	Gold-handed tamarin lymphocryptovirus (SmiLHV1)	Gold-handed tamarin (*Saguinus midas*)	Unknown
NA	Squirrel monkey lymphocryptovirus (SscLHV1)	Squirrel monkey (*S. sciureus*)	Unknown
NA	White-faced saki lymphocryptovirus (PpiLHV1)	White-faced saki (*Pithecia pithecia*)	Unknown

[a]NA, species not assigned by ICTV.
[b]Type species of the genus.

T cells of certain New World monkey species (such as cottontop tamarin) in culture, yielding cytotoxic T-cell lines. Human T cells are not susceptible to transformation with various HVA strains, but could be transformed by a recombinant HVS C strain in which the HVS oncogenes were replaced by the HVA oncogene Tio.

Transformed T-cell lines have been derived from HVA-infected tamarins and cultivated continuously for several years. Whereas in most cases virus particles were found initially, virus production was frequently lost after prolonged culture. The episomal DNA is heavily methylated in such nonproductive cell lines, and rearrangements or

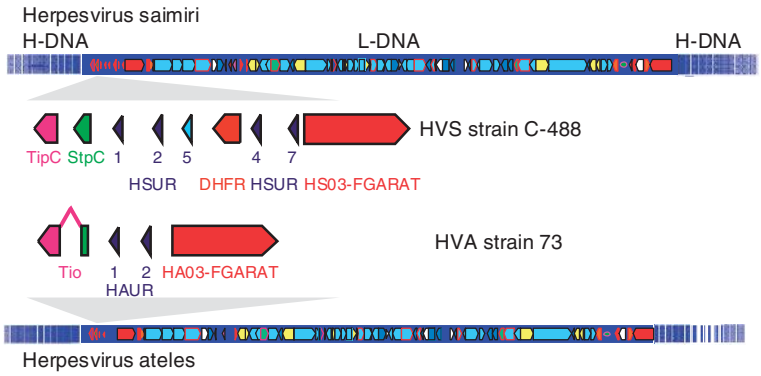

Figure 1 Gene arrangements at the left genome end of HVS and HVA. The oncoproteins Stp, Tip, or Tio are encoded at the variable left terminal region of the coding L-DNA. Stp, saimiri transformation-associated protein of the respective subgroup A, B, or C; Tio, two-in-one-protein of HVA; Tip, tyrosine kinase-interacting protein of HVS subgroup C; HSUR or HAUR, HVS or HVA-encoded URNA; HS03-/HA03-FGARAT, formylglycineamide ribotide amidotransferase ORF3.

large deletions are evident in the viral genomes. Marmoset and tamarin T cells can be transformed by HVS to stable T-cell lines *in vitro* and are designated as semipermissive, since virus particles are released, although to lower titers than from OMK cells.

Genome Properties, Replication, and Gene Content

The term 'rhadino' viruses was coined from the ancient Greek word ραδινοσ for fragile, because the viral genomic DNA breaks upon isopyknic centrifugation in CsCl gradients into two classes of highly differing densities. The L DNA (low density, low G + C content) contains the viral protein-coding genes, and the repetitive H DNA (high density, high G + C content) from the genome termini is noncoding. The intact viral (M) genome has intermediate density. Two strains of HVS, strain A11 and the highly oncogenic subgroup C strain C488, have been sequenced. The A11 H DNA consists of multiple tandem repeats of 1444 bp (70.8% G + C), and the unique L DNA comprises 112 930 bp (34.5% G + C). The size of the M DNA genome is variable owing to different numbers of H DNA repeats attached to both ends of the linear virion genome. In strain C488, the L DNA comprises 113 027 bp, and it is flanked by arrays of two distinct repeat unit types of 1318 and 1458 bp, the shorter representing the longer with 140 bp deleted. The packaged M genome of C488 is approximately 155 kbp in size, with a range of 130–160 kbp owing to variable numbers of terminal H DNA repeats. The HVS L DNA contains at least 76–77 protein-coding open reading frames (ORFs) and encodes 5–7 U RNAs (termed HSURs) (**Figure 1**).

HVA strain 73 has a similar genome structure to HVS, with a slightly shorter L DNA of 108 409 bp (36.6% G + C), and H DNA consisting of multiple tandem repeats of 1582 bp (77.1% G + C). The HVA L DNA contains 73 ORFs and only two genes for U RNA-like transcripts (termed HAURs). HVA does not encode ORF12, vIL17, vCD59, or vFLIP homologs, but the genes encoding superantigen (SAG), cyclin, and G-protein-coupled receptor (GPCR) are conserved. Thus, HVA may be an ancient variant of HVS that has either collected a smaller set of cell-homologous genes or has secondarily lost several genes.

In all gammaherpesviruses, the genes that are conserved among the herpesvirus subfamilies are arranged in blocks. Flanking or interspersed among the blocks are other genes, most of which do not occur in the other subfamilies. Among these are transforming oncogenes and viral homologs of cellular genes, which are described below. Most genes are well conserved between different HVS strains, but there is pronounced sequence variation near the left end of the HVS L DNA and in the region of the R transactivator gene (*orf50*) and the adjacent glycoprotein gene (*orf51*), a region that is also highly variable among other rhadinoviruses.

The replication mechanism of rhadinoviruses has not been investigated in much detail, and is generally considered to follow that of other herpesviruses. The lytic origin of DNA replication (OriLyt) in HVS strain A11 has been mapped to an untranslated region upstream of the thymidylate synthase gene. A putative latent origin of DNA replication (OriP) in the left-terminal region of the L DNA in strain C484 was reported to mediate episomal maintenance, but is not conserved between different HVS strains and is not required for viral replication or episomal persistence. Thus, although HVS persists in transformed human T cells as stable nonintegrated episomes at high copy number, OriP and the viral factors involved remain unidentified. Histone modification of the HVS C488 episome in human T cells has been analyzed, and bears similarities to that of KSHV episomes in B cells.

Infection of tissue culture cells by HVS is asynchronous, and hence the assignment of HVS genes to the immediate early (IE) phase of infection is based mostly

on experiments using cycloheximide to inhibit protein synthesis. The IE57 post-transcriptional regulator encoded by *orf57* appears to be the sole regulatory viral IE gene. It codes for a nuclear phosphoprotein of 52 kDa with structural and functional homology to herpes simplex virus ICP27 and EBV BMLF1. IE57 stimulates the expression of unspliced, and represses the expression of spliced, transcripts, has been shown to redistribute nuclear components of the splicing machinery, and is involved in nuclear RNA export. A strong viral transactivator function was mapped to the delayed early gene *orf50*, the homolog of the EBV R transactivator gene. Owing to differential splicing and promoter usage, this gene codes for a full-length protein (ORF50A) and a smaller, C-terminal variant (ORF50B). The transactivation domain resides in the C-terminal region of these proteins and binds to the TATA-binding protein in the basal transcription complex. Although IE57 is highly conserved between subgroups A and C, the *orf50* region is divergent. Neither HVS nor HVA encodes a homolog of bZip/Zta of EBV or KSHV.

The HVS ORF73 protein of strains A11 and C488 localizes to the host cell nucleus, and, like the latent nuclear antigen (LANA) of KSHV, can associate with host cell chromosomal DNA. The A11 ORF73 protein can associate with cellular p32 and binds to GSK-3β. Although not detectable by northern blotting of RNA from C488-transformed human T cells, *orf73* transcripts are detectable by reverse transcription-polymerase chain reaction (RT-PCR). The C488 ORF73 protein can downregulate the *orf50A* and *orf50B* promoters, and this prevents ORF50-mediated activation of viral replication gene promoters. This suggests that the HVS ORF73 protein, and its homologs in the other rhadinoviruses, can block initiation of the lytic replication cascade, thereby controlling the transition between latency and lytic replication.

Sequestered Cellular Genes

Rhadinoviruses such as HVS and KSHV contain several intronless genes that are homologous to cellular genes; in this context, a role for reverse transcription during putative capture of these genes might be speculated upon. A few of these cellular gene homologs are unique to specific viruses, and some are common to several rhadinoviruses (and to lymphocryptoviruses, including EBV). This suggests that successful uptake of cellular genes is a rather infrequent event during herpesvirus evolution. Most of these cellular homologs can be categorized into two major groups: (1) genes related to cellular growth control or nucleotide metabolism, and (2) genes that modulate innate or adaptive immune functions, including apoptosis. For example, HVS *orf72* codes for a functional viral cyclin D, and homologs related to nucleotide metabolism include a dihydrofolate reductase (DHFR; *orf2*) and a functional thymidylate synthase (TS; *orf70*). Both *orf3* and *orf75* encode large tegument proteins that share similarity with formylglycineamide ribotide amidotransferase (FGARAT). It is thought that these enzymes may possibly augment the free nucleotide pools and could thus facilitate DNA synthesis and virus replication.

Oncogenic Signaling and Transformation

The Stp Oncoproteins

The HVS oncogenes required for induction of T-cell leukemia and T-cell transformation *in vitro* reside in the variable region at the left end of the L DNA (**Figure 1**). Subgroup A and B strains have a single gene termed *stpA* or *stpB* (saimiri transformation-associated protein of subgroup A or B strains), and subgroup C strains carry *stpC* (*stp* of subgroup C strains) and *tip* (tyrosine kinase-interacting protein). The proteins StpA and StpB share limited sequence homology with StpC, but are structurally unrelated to Tip. Although *stpA* and *stpC/tip* are not required for viral replication, deletion of either *stpA, stpC*, or *tip* abolishes transformation by HVS *in vitro* and pathogenicity *in vivo*. *stpA*- or *stpC*-transfected rodent fibroblasts form foci *in vitro* and induced tumors in nude mice. *stpA*-transgenic mice develop polyclonal peripheral T-cell lymphomas, and an *stpC* transgene induces epithelial tumors.

stpC and *tip* are transcribed into a single bicistronic mRNA from a common promoter directed toward the left end of the L DNA, with *tip* situated downstream from *stpC*. Transcription of *stpC/tip* is regulated similarly to IE genes in human T cells, and no obvious viral factors seem to be involved. The *stpC/tip* promoter carries euchromatic histone modifications in C488-transformed human T cells.

The 102-residue StpC phosphoprotein has an N terminus of 17 mostly charged residues, and the C terminus contains a hydrophobic region that probably serves as an anchor to perinuclear membranes. In between are 18 collagen tripeptide repeats of the form $(GPX)_n$, which may mediate multimerization of the protein. StpA and the less efficiently transforming StpB bind to, and are phosphorylated by, the nonreceptor tyrosine kinase Src. StpC interacts with the small G-protein Ras and stimulates mitogen-activated protein (MAP) kinase activity. Both StpA and StpC interact with tumor necrosis factor receptor-associated factors (TRAFs), leading to nuclear factor kappa B (NFκB) activation.

The Tip Oncoprotein

The subgroup C-specific 40 kDa Tip phosphoprotein has been shown to co-precipitate with the T-cell-specific nonreceptor Src family tyrosine kinase p56/Lck in C488-transformed T cells. Tip-transgenic mice develop T-cell proliferations. Tip has an N-terminal glutamate-rich

region, duplicated in some strains, followed by one or two serine-rich regions, a bipartite kinase-interacting domain, and a C-terminal hydrophobic domain that anchors the molecule at the inside of the plasma membrane. The kinase-interacting domain consists of nine residues with homology to the C-terminal regulatory regions of various Src kinases (CSKH), and a proline-rich SH3-domain-binding sequence (SH3B). Several tyrosine residues, three of which are conserved between all strains investigated, are substrates for Lck. Tyrosine residue 127 (Y127) is the major tyrosine phosphorylation site of Tip (strain C488), but this modification does not enhance Lck binding in T cells. Recombinant viruses expressing mutations in Tip show that the strong Lck binding mediated by cooperation of the SH3B and CSKH motifs is essential for transformation of human T cells by C488, whereas Tip Y127 is required for transformation in the absence of exogenous interleukin-2, suggesting its involvement in cytokine signaling pathways.

Tip binding to Lck modulates the kinase activity and could result in an altered substrate specificity, contributing to the abrogation of ZAP70 phosphorylation. This dysregulation may further link Tip-bound Lck to alternative downstream effectors. In addition, the implication of Tip Y114 with constitutively active signal transducers and activators of transcription (STATs), especially STAT3, and the role of STATs in growth regulation and oncogenesis in multiple cell types, suggest a central role for Tip-induced STAT activity in viral T-cell transformation. However, recombinant HVS C488 expressing Tip with a tyrosine-to-phenylalanine mutation at residue 114 was able to transform primary human T lymphocytes in the absence of STAT1 or STAT3 activation. Tip is further associated with lipid rafts, and this is essential for the T-cell receptor (TCR) and CD4 downregulation but not for inhibition of TCR signal transduction and activation of STAT3 transcription factor. The activation of Lck and the inhibition of T-cell signaling by Tip may represent two different aspects of the same function, since the activation of Lck by Tip might trigger negative feedback mechanisms, such as apoptosis, in stably transfected Jurkat cells expressing high levels of Tip.

The Tio Oncoprotein

A spliced gene with two exons is located at the junction between H DNA and the left-terminal L DNA in HVA strain 73. The encoded protein shares local similarity with StpC and Tip of HVS subgroup C strains, and was therefore termed 'two in one' (Tio). Tio is expressed in HVA-transformed simian T cells, and is bound to, and phosphorylated by, the Src family tyrosine kinases Lck or Src. Phosphorylation of Tio at Y136 is required for successful transformation of human T cells. These cells are also transformed by recombinant HVS C488 in which *stpC* and *tip* has been replaced by a *tio* cDNA transcribed from a heterologous promoter. Furthermore, Tio induces NFκB signaling via direct interaction with TRAF6.

Growth Transformation of Human T Cells by Rhadinoviruses

Human T-cell growth transformation by HVS subgroup C strains has provided a reproducible technique for generating T-cell lines, and has opened up a new research direction linking T-cell biology, signal transduction pathways, and viral transforming functions. Infection of cord or peripheral blood mononuclear cells, thymocytes, or established human T-cell clones by C488 results in T-cell lines that grow continuously without restimulation by antigen or mitogen and do not require the presence of feeder or antigen-presenting cells. Many HVS subgroup C strains are able to transform human T cells, though to a varying extent; C488 is often preferred, as it achieves dependable growth transformation. Recombinant HVS C488 in which *stpC* and *tip* have been replaced by HVA *tio* can offer increased efficiency of human T-cell transformation along with a decreased requirement for IL-2. HVS C488 carrying mutations in Tip is being investigated for an expanding range of T-cell phenotypes.

The resulting polyclonal T-cell lines display the irregular morphology of T blasts. They carry nonintegrated HVS genomes in high copy numbers, have a normal karyotype, and are not tumorigenic in nude or severe combined immune-deficient (SCID) mice. The phenotype of HVS-transformed T cells is remarkably stable for many months in culture. It corresponds to that of mature, activated CD4+ CD8– or CD4– CD8+ T cells, usually with αβ-type (less frequently γδ-type) T-cell receptors. Transformed lines derived from established T-cell clones show the phenotype and human leukocyte antigen-restricted of the parental T cells. Cellular responses after CD3, CD4, or IL-2 receptor stimulation or antigen contact can be measured by signal transduction parameters, by proliferation, or, most reliably, by interferon-γ production. Transformation of cytotoxic T lymphocytes (CTLs) is rather inefficient, but may be increased by optimized protocols for prestimulation and culture of CTLs.

Transformation by HVS C488 has, in many cases, been the only way to cultivate and amplify T cells from patients with primary human immune deficiencies, including genetic T-cell defects involving the CD3γ chain, IL-2Rγ chain, CD95/Fas, IL-12R, major histocompatibility complex class II, Wiskott–Aldrich syndrome, or CD18/LFA-1. HVS-transformed human CD4+ T cells provide a productive system for T-lymphotropic viruses such as human herpesvirus 6 and human immunodeficiency virus (HIV) types 1 and 2, including primary clinical and macrophage-tropic HIV isolates.

Although most HVS-transformed New World monkey T lymphocytes produce infectious viral particles, HVS-transformed human T-cell lines maintain an intact viral genome but do not shed infectious virus. Production of infectious particles is also not induced by specific or nonspecific stimulation of the cells, using phorbol esters, nucleoside analogues, or other drugs that can reactivate viruses such as EBV or KSHV. Many macaque T-cell lines have been shown to shed very low amounts of virus particles, in contrast to their human counterparts, and the infusion of HVS-transformed autologous T cells into donor macaques did not cause disease. The reinfused T cells persisted for extended periods and the animals were protected against challenge with HVS C488. This is a relevant observation, since macaques are a common model for the situation in humans, and HVS-transformed simian T lymphocytes are similar to their human counterparts in many characteristics, including retained antigen specificity and presentation.

Alterations

StpC and Tip are the only viral proteins that have been demonstrated regularly in HVS-transformed human T cells, and yet their expression alone or together in a lentiviral background is not sufficient to transform primate T cells. The HSURs are expressed abundantly in a similar way to the small, noncoding RNAs (EBERs) of EBV, but deletion of all the HSUR genes does not influence virus replication or T-cell transformation. Viral transcription other than that of the bicistronic *stpC/tip* genes is rarely detected in human T cells; it is restricted to *ie14/vsag*, and few others at extremely low abundance (*orf57*/IE57, *orf50*/RTA, *orf70*/TS, *orf71*/vFLIP, *orf72*/vCyclin, and *orf73*/LANA). Some of these increased after stimulation with phorbol ester. Many other viral genes, such as the weakly transcribed *orf71* and *orf72*, have been shown by deletion analysis not to be required for T-cell transformation.

Compared to parental, untransformed T cells, a few cellular and biochemical alterations have been detected consistently in HVS-transformed T-cell lines: CD2 and its ligand CD58 are both expressed at high densities on the cell surface and there is hyper-responsiveness to CD2 ligation. Since withdrawal by limiting dilution halts the growth of HVS-infected human T cells, IL-2 induction by CD2–CD58 contact likely contributes to the transformed phenotype of HVS-transformed human T cells. Furthermore, subcloning of HVS-transformed cells is not possible. The Src family protein tyrosine kinase $p53/56^{Lyn}$ is usually expressed in B cells. Lyn is also found in HVS-transformed T-cell lines, similar to HTLV-1-immortalized T cells, but is not activated by HVS Tip. HVS-transformed T cells secrete high amounts of the Th1 cytokine interferon gamma (IFN-γ), and Th2-skewed T cells or Th2 clones shift toward a Th1 or Th0 profile. Many transformed clones also secrete large amounts of chemokines, such as MIP-1α and MIP-1β, and CCL1/I-309, which may protect HVS-transformed T cells from apoptosis via CCR8. IL-26, a new IL-10 cytokine family member, was discovered due to its over-expression in HVS-transformed T cells. IL-26 may influence T-cell interaction with epithelial cells *in vivo* but seemingly does not contribute to HVS-mediated T-cell transformation.

Gene Transfer

HVS vectors are attractive for gene transfer into T cells, since the functional phenotype of transformed T lymphocytes is maintained and the T cells can be simultaneously expanded by transformation. They may even be considered for therapeutic redirection of human T-cell antigen specificity, as tools for experimental cancer therapy applications. However, replication-deficient vector variants are necessary, and a number of biosafety aspects remain to be clarified. Remarkably, ganciclovir administration does not prevent pathogenesis by HVS expressing a TK suicide gene, and tumor induction is even more rapid than with a wild-type HVS control.

Genetic alteration of HVS-transformed cells can be achieved by transduction with retroviral or lentiviral vectors, or by using recombinant HVS. Efficient infection and occasionally limited productive replication of HVS have been observed in various human cell types, including human bone marrow stroma cells, primary fibroblasts, and hematopoietic precursors. Although foreign genes were first inserted into the genome of HVS more than two decades ago, the reconstitution of virus from overlapping cosmids and engineering of bacterial artificial chromosomes has greatly facilitated mutational analysis of the HVS genome and expression cloning in HVS. This includes attenuated, nononcogenic vectors deleted in the transformation-associated left-terminal region of L DNA that harbors the HVS oncogenes. Episomally persisting herpesvirus vectors, based either on replication defective viruses or on amplicons, are currently regarded as a promising alternative that can avoid side effects of integration, which is now a major concern in the field of gene transfer.

Rhesus Rhadinovirus and Related Old World Primate Rhadinoviruses

Natural Occurrence and Pathology

The discovery of KSHV as the first human rhadinovirus in 1994 greatly stimulated the search for rhadinoviruses in other Old World primates. Serological studies using KSHV-derived antigens indicated that a related herpesvirus may exist in rhesus monkeys. This led to the isolation

of RRV by co-cultivation of lymphocytes from seropositive rhesus monkeys with rhesus fibroblasts by Desrosiers and colleagues in 1997. RRV seems to be very widespread in captive monkeys and, in contrast to KSHV, can be propagated efficiently in cell culture. Although there exists no clear disease association for RRV in infected healthy macaques, there is one report concerning rhesus macaques that were immunosuppressed by previous infection with simian immunodeficiency virus (SIV). In this case, RRV infection resulted in a multifocal lymphoproliferative disease resembling multicentric Castleman's disease. However, this had not been noticed previously in numerous studies of SIV-infected macaques of unknown, but presumably mostly positive, RRV infection status.

Using degenerate PCR of the DNA polymerase gene, DNA fragments of rhadinovirus origin have been identified in various Old World primates, including African green monkey, chimpanzee, gorilla, and mandrill. Phylogenetic analysis of short sequences has revealed that Old World primate rhadinoviruses probably segregate into two groups: one that is more closely related to KSHV and another that is more closely related to RRV.

Genome Structure and Replication

Analysis of the genome sequences of two independent strains has revealed that RRV is indeed more closely related to KSHV than to the prototypic rhadinovirus HVS. The RRV genome organization is essentially collinear with that of KSHV. It has (at least) 79 genes, 67 of which are homologous to genes found in both KSHV and HVS. Of the remaining 12 genes, 8 are similar to KSHV genes (see below). Interestingly, *orf2*/DHFR is in the same position as in HVS, and different from that in KSHV. The RRV OriLyt is located in the same region as in HVS and KSHV, between *orf69* and *orf71*/vFLIP. The functions of viral transactivators and regulatory proteins resemble those of KSHV. The gene content of RRV is similar to that of KSHV, but contains only one *vMIP* gene and lacks *K3* and *K5*. The genes encoding CCPH and vIL-6 are conserved in RRV, and eight genes are present with homology to the family of viral interferon regulatory factors (*vIRF-1* through *vIRF-8*). Several large DNA viruses have been shown to encode micro-RNAs (miRNAs), including EBV and the rhadinoviruses RRV and KSHV, and miRNA genes are evolutionary conserved in at least the lymphocryptoviruses. However, the role of miRNA and RNA interference in the viral context is controversial. Given the specificity of RNA interference, it remains to be determined whether this can have a role in herpesviral transformation of foreign hosts. An interesting speculation is that herpesviral miRNAs may act as specificity factors that initiate heterochromatin assembly of the latent viral genome.

Rhadinoviruses from Retroperitoneal Fibrosis

In an approach using a degenerate PCR technique, Rose and co-workers identified fragments of a herpesvirus DNA polymerase gene in tissue specimens from retroperitoneal fibromatosis (RF) from macaque species, *M. nemestrina* (six cases) and *M. mulatta* (one case). RF is a rare disease occurring in immunesuppressed macaques that consists of aggressively proliferating fibrous tissue with a high degree of vascularization; thus, it somewhat resembles KS. Earlier transmission studies indicated that an infectious agent may be involved in RF pathogenesis. Sequence comparisons indicate that the DNA polymerase and adjacent genes of these two potentially novel rhadinoviruses, tentatively termed RFHVMm and RFHVMn, are related more closely to KSHV than RRV. Attempts to isolate the viruses on cultured cells have so far been unsuccessful. The possible coexistence of two different rhadinoviruses in the same host animal is also indicated, since in one study all RF-diseased macaques harbored RRV DNA (and all were coinfected with simian retrovirus 2 and/or SIV). In these animals, RFHV DNA was present at significantly higher copy numbers in the RF tumors.

Lymphocryptoviruses of Old and New World Primates

Gammaherpesviruses closely related to EBV have been recognized in several species of Old World primates from the mid-1970s. The genome of rhesus lymphocryptovirus (abbreviated to rhesus LCV; species *Cercopithecine herpesvirus 15*) has been sequenced. Until recently, the paradigm was that the lymphocryptoviruses are restricted to Old World primates, including humans. However, a virus related to EBV was isolated from common marmosets, both from healthy animals and animals with spontaneous B-cell lymphomas. Related lymphocryptoviruses have also been detected in several other New World primate species (**Table 1**). The new lymphocryptovirus (marmoset LCV; species *Callitrichine herpesvirus 3*) has an EBV-like genome structure, and determination of the genome sequence has shown that several Old World primate lymphocryptovirus-specific genes are absent. Specifically, homologs of EBV BCRF1/vIL10, BARF1/CSF-1R, BARF0, the EBERs, and several other genes of unknown function have not been detected, and marked divergences exist in LMP-1, LMP-2, EBNA-LP, EBNA-2, and the EBNA-3 family. Also, the organization of the putative marmoset LCV OriP-region is clearly distinct from that in Old World primate lymphocryptoviruses.

In vitro transformation of B cells by human and simian Old World primate lymphocryptoviruses seems to be mostly restricted to the natural host or closely related

species. However, experimental T-cell tumors can be induced in rabbits following infection by cynomolgus LCV or baboon LCV.

Conclusion and Perspective

Viruses of the gammaherpesvirus genera *Lymphocryptovirus* and *Rhadinovirus* can be found in New World and Old World primates, including humans. Although several members of both genera are closely associated with viral oncogenesis, the simian viruses do not generally provide a straightforward model for multifaceted human diseases. The direct transforming action of viral oncogenes, as well as a chronic inflammatory reaction that may be affected by KSHV-encoded or KSHV-induced cytokines or angiogenic factors, may contribute to the genesis of KS. The KSHV-related simian rhadinoviruses do not provide a corresponding animal model as yet. Historically, interest in the rhadinoviruses has focused on the long-established prototype, HVS. Although a comparable virus-associated, acute, peripheral, pleomorphic T-cell lymphoma is not known yet in humans, this disease, which is induced reproducibly by HVS within weeks, can serve as an experimental model for general tumor development. The ability of certain HVS strains to transform human T lymphocytes to stable proliferation in culture provides a valuable tool for laboratory studies of T-cell immunology, including inherited and acquired immunodeficiency. In addition to their use as an immunological and biochemical T-cell model, HVS-transformed T cells can provide a source for the purification of specifically overexpressed cytokines or chemokines from culture supernatants. A detailed analysis of differential gene expression will lead to identification of signaling pathways that lead to lymphocyte transformation by herpesviral oncoproteins. Those involving STAT, nuclear factor of activated T cells (NFAT), and NFκB may be particularly important, perhaps providing hints to the roles of the respective pathways in human (nonviral) T-cell malignancy. Furthermore, rhadinovirus-transformed T-cell lines can be valuable tools in screening for specific drugs that target these pathways.

The side effects of retroviral integration have shown the requirement for efficient nonintegrating vectors. Recombinant rhadinoviruses can deliver foreign genes into primary human mesenchymal cells and T lymphocytes; this may prepare the ground for future therapeutic applications of persisting rhadinoviral vectors in adoptive immunotherapy. Safety considerations will prevent the use of unconditionally transforming rhadinovirus vectors, and require the development of novel rhadinovirus-based T-lymphotropic episomes, including conditional/attenuated or amplicon vector systems. Analysis of viral genome episomal modification in host T cells and the detection of genomic insulating regions can provide markers for the selection of regions suitable for the insertion of transgenes into the viral backbone.

Glossary

Dysplasia Abnormal growth of tissues, organs, or cells.
Endemic Prevalent in a particular group of animals or people.
Epitope The part of a macromolecule that is recognized by the immune system.
Hypergammaglobulinemia Increased blood levels of gamma globulin (IgG).
Hyperplasia An abnormal increase in the number of cells in an organ or a tissue with consequent enlargement.
MHC-I (major histocompatibility complex I) T-cell epitopes are presented on the surface of an antigen-presenting cell, where they are bound to MHC molecules. T-cell epitopes presented by MHC class I molecules are typically peptides between 8 and 11 amino acids in length, while MHC class II molecules present longer peptides, and nonclassical MHC molecules.

Taxonomy and Discovery

Simian immunodeficiency viruses (SIVs) are members of the genus *Lentivirus* and the family *Retroviridae*. The genus *Lentivirus* includes viruses that infect ungulates (maedi-visna virus of sheep; caprine arthritis-encephalitis virus, CAEV), horses (equine infectious anemia virus, EIAV), cows (bovine immunodeficiency virus, BIV), wild and domesticated cats (feline immunodeficiency virus, FIV), nonhuman primates (NHPs; SIV), and humans (human immunodeficiency virus, HIV). All retroviruses are spherical, 80–100 nm in diameter, and have a diploid, single-stranded RNA genome and viral enzymes inside a viral protein case, or core, which is enveloped by a host cell membrane studded with viral glycoproteins. The diploid genome of single-stranded RNA is linked noncovalently near the 5′ end of the molecules. The 5′ end of the viral RNA is capped and the 3′ end is polyadenylated. DNA synthesis by the viral encoded reverse transcriptase (RT) is primed by host tRNA that is base-paired to the viral RNA. The double-stranded DNA provirus is integrated into the host chromosomes by a viral encoded integrase and the remaining events in transcription, translation, and assembly are host cell dependent. Depending on the cell type infected, particles assemble and bud through the plasma membrane or into membrane-lined intracytoplasmic vesicles. The morphological feature that distinguishes lentiviruses from other retroviruses is the cone or rod shape of the viral core protein in a mature virion.

SIV_{mac} was the first member of the group to be identified following isolation of a retrovirus from a captive rhesus macaque housed at a US primate center. Apparently, the virus was introduced into captive macaque populations in the US during experiments into the transmission of kuru and leprosy, at which time material derived from tissue of SIV-infected African monkeys was deliberately introduced into Asian macaques. SIV has been eliminated from captive populations of macaques in the US through a rigorous testing program. Fortunately, serology provides an effective and economical tool for screening for infection. Extended quarantine periods and regular serologic testing programs are rigorously applied to maintain the SIV-free status of captive macaque colonies.

Nomenclature and Classification of Primate Lentiviruses

Primate lentiviruses are classified as originating in NHPs (SIVs) or humans (HIVs). SIVs are given specific names based on the NHP species from which they are isolated, for example, SIV_{cpz} was isolated from chimpanzees and SIV_{deb} from De Brazza's monkeys.

Recently, a hierarchical nomenclature has been developed to describe the high level of genetic diversity found among the many HIV isolates. HIV is first divided into two

broad types, designated HIV-1 and HIV-2. Both HIV types are subdivided into groups consisting of phylogenetically similar viruses that resulted from different nonhuman-primate–human SIV transmission events (**Figures 1** and **2**). Within a group, phylogenetic clusters of viruses are termed subtypes. There is a movement toward a unified, standard nomenclature to describe genetic diversity within and among SIVs in which a three-letter abbreviation of the vernacular name of the NHP species is used (**Figure 3**). For example, the SIV from chimpanzees is termed SIV_{cpz} and subspecies designation is provided a three-letter abbreviation – thus $SIV_{cpz.Ptt}$ is derived from *Pan troglodytes troglodytes*. SIVs of African green monkeys (SIV_{agm}) are divided into four subtypes, each named for the African green monkey subspecies from which it was isolated (**Figure 3**).

Genome Organization

Like all retroviruses, lentivirus genomes contain long terminal repeats (LTRs) at each end and genes encoding three virion structural components: core (*gag*), polymerase (*pol*), and envelope (*env*). In addition, all primate lentivirus genomes also contain five accessory genes: *vif*, *vpr*, *rev*, *tat*, and *nef*. The genomes of a subset of primate lentiviruses

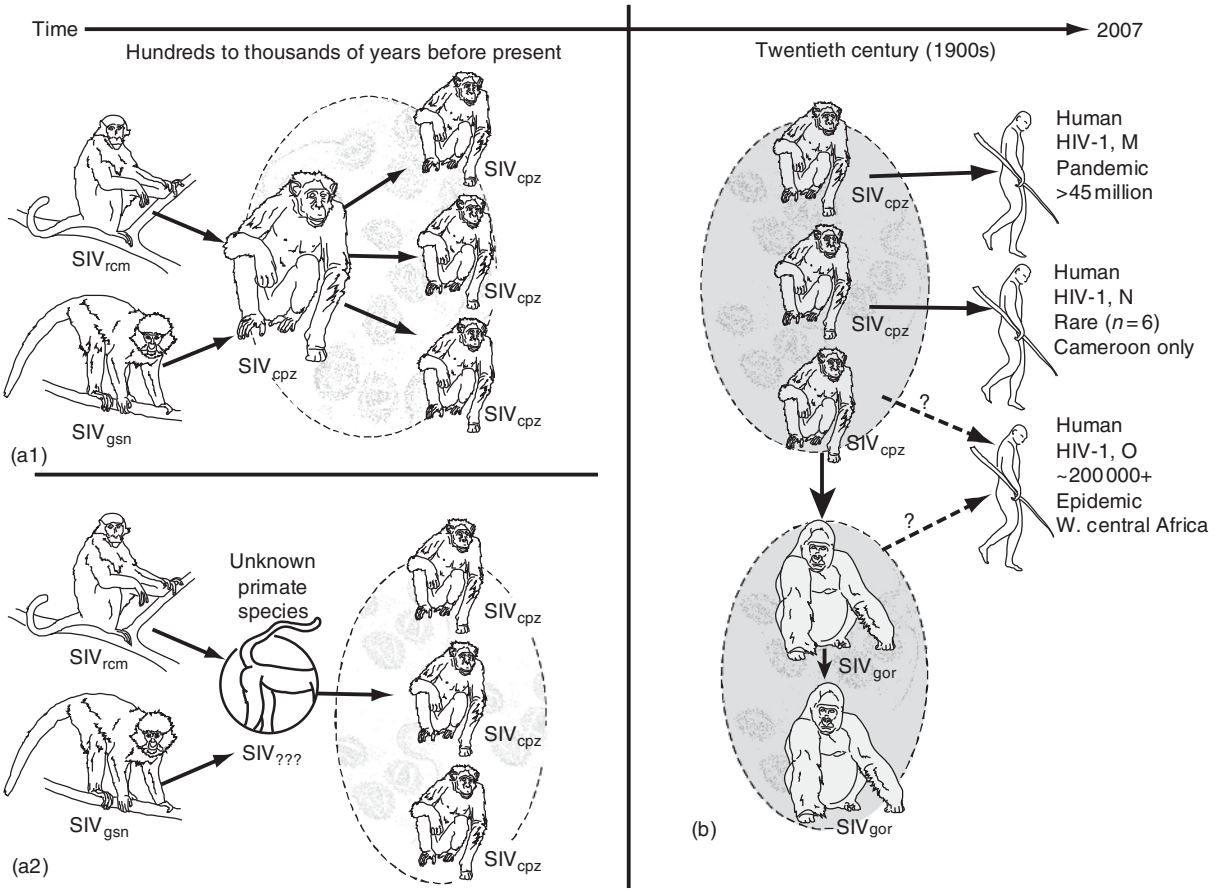

Figure 1 Origin of HIV-1 inferred from phylogenetic analyses of SIV and HIV-1 genomes. (a) The earliest event is transmission of SIVs from African monkeys (red-capped mangabey (RCM) infected with SIV (SIV_{rcm}) and greater spot nose monkey (GSN) infected with SIV (SIV_{gsn})) to chimpanzees followed by virus recombination that resulted in SIV_{cpz}. Two scenarios are consistent with the data: (a1) SIV_{rcm} and SIV_{gsn} initially infected a chimpanzee; or (a2) SIV_{rcm} and SIV_{gsn} first infected an unknown primate species where virus recombination occurred – in either case, a recombinant SIV was transmitted among chimpanzees producing SIV_{cpz}. (b) Three separate transmissions of SIVs to humans occurred from distinct populations of chimpanzee (SIV_{cpz}) or gorilla (SIV_{gor}) in the 1900s producing three HIV-1 groups, M (main), N, and O (outlier). Recent, but limited, phylogenetic data show that HIV-1 group O is most closely related to SIV_{gor}. The most likely scenario suggested by the data is that chimpanzees transmitted SIV_{cpz} to gorillas which resulted in SIV_{gor}; it is unknown whether HIV-1 group O was transmitted to humans from gorillas or from an as yet unidentified chimpanzee reservoir infected with SIV_{cpz} more closely related to HIV-1 O. Only HIV-1 groups M and O have established efficient human-to-human transmission. Group M HIV-1 is pandemic, infecting over 45 million persons; group O HIV-1 is epidemic having infected an estimated several thousands of persons in Africa. In contrast, only six individuals from Cameroon are known to be infected with HIV-1 group N. Dotted circles indicate distinct populations of a primate species; shading indicates SIV isolated from individuals of this species; solid arrows show inferred transmissions of SIV; dashed arrows indicate where SIV transmission is hypothesized, but there are insufficient data to confirm.

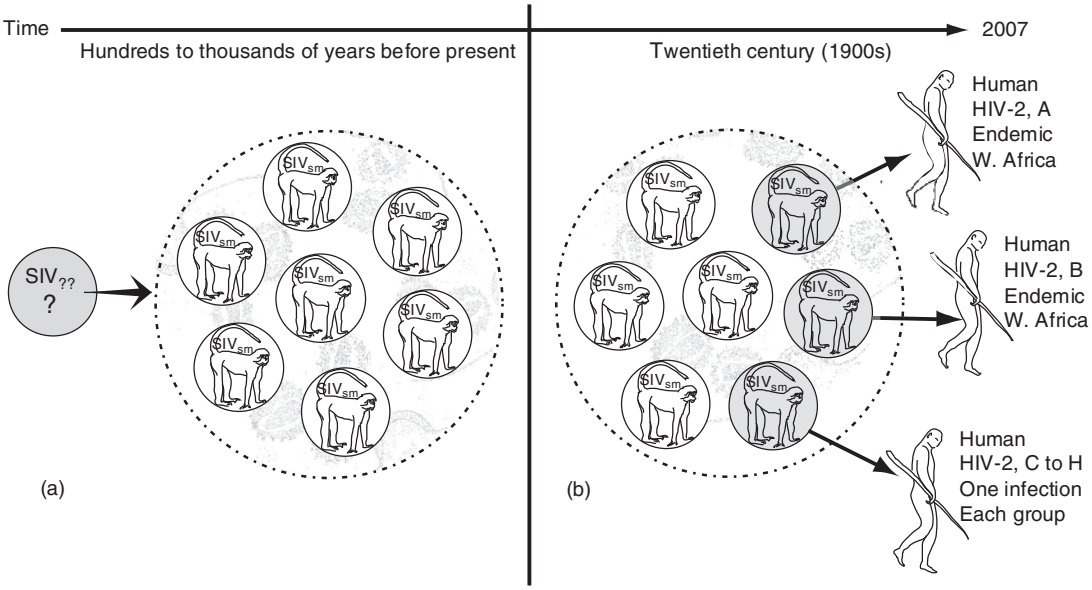

Figure 2 Origin of HIV-2 inferred from phylogenetic analyses of SIV and HIV-2 genomes. (a) SIV probably infected sooty mangabeys (SMs) thousands of years ago. Multiple separate transmissions of SIV_{sm} from distinct populations of SMs to humans occurred during the 1900s giving rise to eight HIV-2 groups, A–H (b). Only HIV-2 groups A and B have resulted in efficient human transmission and established epidemics; a single person is known to be infected with each of the HIV-2 groups C–H. Dotted circles indicate distinct populations of SMs; shading indicates SIV_{sm} isolated from individual SM in a population; arrows show inferred transmissions of SIVs.

have one of two unique genes: *vpr* or *vpu*. Three types of genomic structure are observed for primate lentiviruses (**Figure 4**). Group A includes SIVs only from African NHPs; these SIVs cause no disease in the host species from which the SIV was isolated: SIV_{agm}, SIV_{syk}, SIV_{lhoest}, $SIV_{mnd\text{-}1}$, SIV_{sun}, and SIV_{col} (A, **Figure 4**). SIVs in group A all have the basic primate lentivirus genome structure, which contains only five accessory genes. Group B includes HIV-2 and SIVs most closely related to HIV-2 (SIV_{sm}, SIV_{mac}, SIV_{rcm}, and $SIV_{mnd\text{-}2}$); each group B virus has a *vpx* gene which is absent in the Group A viruses (B, **Figure 4**). Group C viruses include HIV-1, SIV_{cpz}, and other SIVs with a *vpu* gene, but lacking *vpx* (SIV_{gsn}, SIV_{mon}, and SIV_{mus}; C, **Figure 4**).

As retroviruses, all lentiviruses also have two complete RNA genomes in a single virion. Therefore, when a host cell is infected with two or more genetically different primate lentiviruses, two different genomic viral RNAs can be packaged into the same virion, generating recombinant viral genomes in the next viral replication cycle. *vpx* shares sequence similarity with *vpr* and is thought to have originated by recombination among SIV genomes. Thus, viral recombination has been a dominant force in the evolution of primate lentiviruses as suggested by the diagrams of primate lentivirus genomes in **Figure 4**. As SIVs are isolated from more primate species and their full genome sequences compared, it was found that some primates harbored SIV with apparently 'mosaic' genomes which included portions of structural genes derived from SIVs of different primate species. Thus, recombination among SIVs has resulted in novel viruses; for example, the current SIV_{cpz} evolved from a recombinant between two SIVs – SIV_{rcm} from red-capped mangabeys and SIV_{gsn} from greater spot nose monkeys (**Figure 1**).

Evolution

All primate lentiviruses are more closely related to each other than to lentiviruses from nonprimates. This genetic similarity suggests primate lentiviruses co-evolved with their host species and that primates have not been infected by lentiviruses from other mammals, such as ungulates or felines. SIVs have been isolated from many wild African NHP species, but no SIVs have been found to infect any wild Asian or New World NHPs. This suggests that lentiviruses became established in primates sometime after the divergence of Old and New World primate species (~35–40 million years ago). Although they lack an endemic SIV, Asian macaques are susceptible to experimental infection with a variety of SIV isolates and develop acquired immune deficiency syndrome (AIDS), similar to HIV-infected humans. The estimated origin of the macaque genus is ~6 million years ago and emigration of macaques from Africa to Eurasia began ~5 million years ago. Thus, it is probable that lentiviruses were not widespread among African primates 5 million years ago.

Lentiviral replication generates high genetic diversity in two ways: mutation caused by the highly error-prone retroviral polymerase (RT) and recombination between

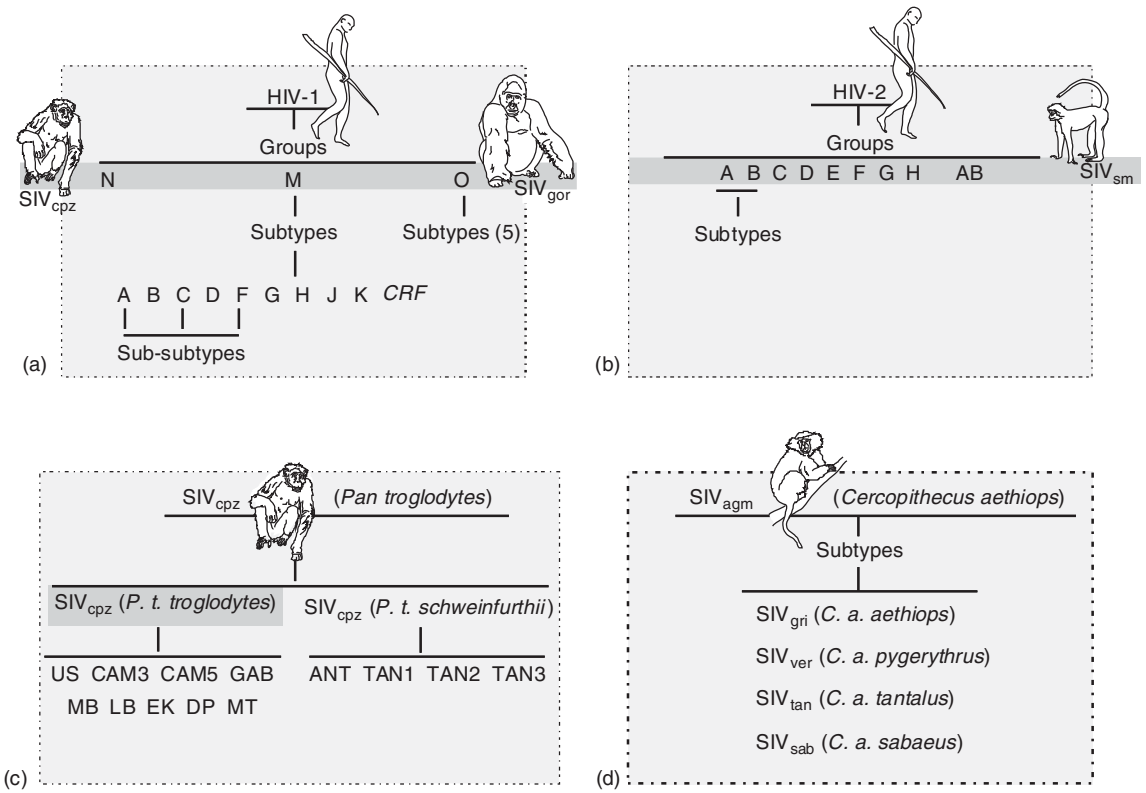

Figure 3 Classification and phylogenetic relationships of primate lentiviruses. (a) HIV-1 lineage. HIV-1 is divided into three groups: M (main), N (non-M/non-O or 'new'), and O (outlier); based on phylogenetic clustering with SIVs, each group represents a separate chimpanzee- or gorilla-to-human transmission event (see also **Figure 1**). Subtype diversification occurred in humans after each cross-species transmission; CRF indicates inter-subtype recombinants. Clusters of diversity within a subtype are called sub-subtypes. The shaded bar indicates the SIVs which gave rise to the HIV-1 groups. (b) HIV-2 lineage. HIV-2 is divided into eight groups (A–H); based on phylogenetic clustering with SIVs, each group represents a separate sooty mangabey-to-human transmission event (see also **Figure 2**); AB indicates recombinant virus. The shaded bar indicates SIV_{sm} giving rise to the HIV-2 groups. (c) SIV_{cpz} lineage. SIV_{cpz} is designated as one subtype although SIV_{cpz}'s have been isolated from two subspecies of chimpanzees, *Pan troglodytes troglodytes* and *Pan troglodytes schweinfurthii*; multiple SIV_{cpz}'s from each of these two subspecies have been isolated and sequenced (abbreviations are listed). SIV_{cpz} from *P. t. troglodytes* (shaded bar) is most closely related to HIV-1. (d) SIV_{agm} lineage. There are four subtypes of SIV_{agm}, one for each of the four subspecies of African green monkey, *Cercopithecus aethiops*: *C. a. aethiops* (grivet), *C. a. pygerythrus* (vervet), *C. a. tantalus* (tantalus), and *C. a. sabaeus* (sabaeus).

two different viral genomic RNA molecules packaged in a virion. The majority of African NHP species have genetically distinct SIVs. The isolation of more than one distinct SIV from a primate species provides evidence for regular interspecies SIV transmission (**Figures 1** and **3**). A notable example is isolation of two SIVs from mandrills (SIV_{mnd-1} and SIV_{mnd-2}; **Figure 4**) that are as genetically different from each other as are HIV-1 and HIV-2.

Thus, genetic diversity of primate lentiviruses has evolved in two ways: (1) within a single host species, and (2) by transmission of SIV from one primate host species to another (cross-species transmission). Cross-species SIV transmission has occurred in both wild and captive primates. The most likely modes of SIV transmission between wild primate species are thought to be fighting among different primates or hunting and eating of one primate species by another; for example, wild chimpanzees are known to kill and eat a variety of monkeys that share the same geographic range. When a cross-species SIV transmission event occurs in an individual already SIV infected, there is the opportunity for viral recombination and, thus, the generation of SIV variants with novel phenotypes, including increased pathogenicity. Such a dual SIV infection is proposed to have been the origin of SIV_{cpz} (**Figure 1**). Dual (or multiple) SIV infection of individuals can also occur when a primate species has genetically distinct SIV variants in one or different populations of animals. Thus, intraspecific SIV recombination increases the genetic diversity within an SIV lineage (**Figure 3**).

Virology

The life cycle of SIV is similar to all retroviruses; once uncoated from the capsid, the RNA genome is reverse-transcribed into a full-length DNA genome that

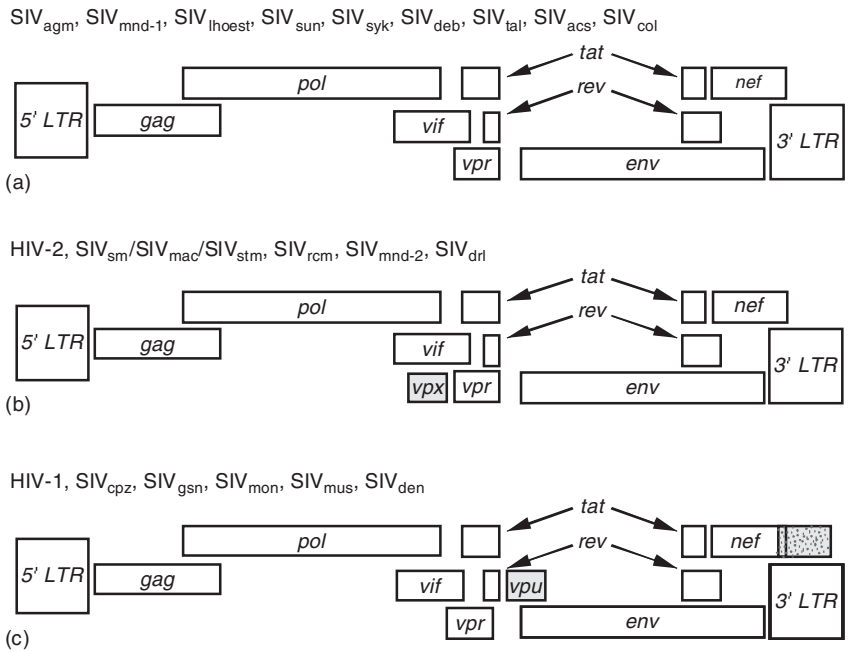

Figure 4 Genomic structure of primate lentiviruses. Viral genes are represented by rectangles with names inside and arrows show genes with two separate coding regions. Group A includes SIVs only from African NHPs (agm, African green monkey; mnd, mandrill; lhoest, l'Hoest monkey; sun, sun-tailed monkey; syk, Sykes monkey; deb, de Brazza's monkey; tal, talapoin; acs, *ascanius*; col, colobus). Group B includes HIV-2 and SIVs most closely related to HIV-2; each group B virus has a *vpx* gene (shaded box), that is absent in the Group A viruses (sm, sooty mangabey; mac, macaque; stm, stump-tailed macaque; rcm, red-capped mangabey; mnd, mandrill; drl, drill). Group C viruses include HIV-1, SIV_{cpz}, and other SIVs with a *vpu* gene, but lacking *vpx* (cpz, chimpanzee; gsn, greater spot nose monkey; mon, mona monkey; mus, mustached guenon; den, Dent's mona monkey). For HIV-1 and SIV_{cpz} genomes only, the *nef* gene (stippled) does not overlap the *env* gene.

is transported to the nucleus and integrated into host chromosomes. Once integrated, the provirus produces a variety of RNA species that can be spliced to produce all the proteins required for virion assembly and egress. In T cells the immature virions bud from the plasma membrane into the extracellular space, but in macrophages virions often bud into intracellular vesicles that can eventually fuse with the plasma membrane of the cell releasing the progeny virions.

SIV can be propagated in many human T-cell and macrophage cell lines derived from tumors, mitogen-stimulated peripheral blood mononuclear cells (PBMCs), monocyte-derived macrophages, etc., although the range of permissive cell types varies from isolate to isolate. In PBMC cultures and many cell lines, viral infection results in obvious cytopathic effects including ballooning degeneration and syncytia formation due to fusion of cell membranes. Syncytium formation is mediated by the envelope glycoprotein and allows direct cell-to-cell spread of the infection.

The CD4 molecule is the primary cellular receptor for SIV. As with HIV, infection is primarily mediated by CD4 but interaction with CD4 alone is not sufficient to allow viral entry into the cell. A number of chemokine receptors are required co-receptors for SIV and HIV infection. The SIV envelope glycoprotein (gp120) binds to CD4 resulting in a conformational shift in the glycoprotein that exposes a co-receptor binding site. This secondary binding site interacts with a chemokine receptor on the cell surface, and fusion of cell and virion membranes results. Although various SIV strains can use a variety of chemokine receptors (CCR5, BOB, Bonzo) as a co-receptor *in vitro*, CCR5 is the most important co-receptor for SIV *in vivo* as it widely expressed by target cells (T cells, macrophages, dendritic cells (DCs)) in the body. Chimeric viruses have been constructed using SIV as a backbone for inserting HIV genes. In HIV infection, differential co-receptor usage by HIV variants has been implicated as a determinant in virulence and pathogenesis. Some of the SIV/SHIV (SHIV) viruses have been constructed using the *env* from HIV variants known to preferentially use CxCR4 or CCR5 as co-receptors. Although differential co-receptor usage can be demonstrated by the chimeric viruses *in vitro*, the extent to which altered replication capacity independent of co-receptor usage contributes to observed differences in pathogenesis has been difficult to determine.

Host cellular factors have recently been identified that confer resistance or susceptibility to productive SIV infection. In host cells resistant to another species' lentivirus, the host protein APOBEC3G is incorporated into the virion during particle formation. During reverse transcription, virion-incorporated APOBEC3G deaminates

the minus strand of viral DNA and inactivates/degrades the viral genome. In permissive cells, the *vif* gene permits SIV to replicate by targeting APOBEC3G for degradation in the proteosome and preventing its incorporation into the virion. However, the activity of *vif* is species specific. Thus human APOBEC3G is inhibited by HIV-1 Vif but not by SIV_{agm} Vif, and AGM APOBEC3G is inhibited by SIV_{agm} Vif, but not by HIV-1 Vif. TRIM5alpha, a member of the poorly understood tripartite motif (TRIM) family of proteins, is another host-restriction factor. TRIM5alpha restricts HIV replication in rhesus macaques, by interacting with the virion capsid and blocking the uncoating of HIV-1 after entry but before reverse transcription.

Transmission and Dissemination

When experimentally inoculated onto intact mucosal surfaces, SIV rapidly infects local DCs, macrophages, and T cells. Although the number of SIV-infected cells is generally higher in the lamina propria adjacent to regions of epithelial damage, SIV-infected DCs and T cells can be found within the intact epithelium of the genital tract, indicating that the virus can cross the intact genital mucosa. Within 24 h of infection, SIV-infected cells can be detected in the lymph nodes that drain a mucosal inoculation site. Initially, there is limited viral replication in local tissues prior to widely disseminated infection in peripheral lymphoid tissues, but by 1 week, post inoculation (PI), viral replication is explosive with dramatic increases in viral RNA levels in all lymphoid tissues. At 10–14 days PI, the peak of viral replication and plasma vRNA levels occurs, and adaptive immune responses develop. By day 28–56 PI, plasma vRNA levels decline to moderate levels, where they remain for a variable period of time. Eventually viral replication increases, CD4+ T-cell levels decline further and AIDS develops. Examples of plasma viral levels in rhesus macaques inoculated with two pathogenic SIV variants are provided in **Figure 5**.

Disease Pathogenesis

While the endemic SIV infections of African monkeys and apes seem to be minimally pathogenic, SIV infections of Asian macaques cause simian AIDS. This disease results from the profound destruction of CD4+ T cells in lymphoid organs throughout the body. To an even greater degree than HIV infection of people, SIV replicates to very high levels in the infected host with as many as 10^9 vRNA copies per ml of plasma during peak infection. This high replicative capacity coupled with the error-prone viral RT produces viral quasi-species of tremendous genetic diversity in infected individuals. This viral quasi-species makes the virus very adaptable to changing conditions in the host as antiviral immune responses develop or successive waves of target cells are destroyed. As in HIV infection, the level of SIV RNA in plasma is an excellent indicator of clinical prognosis in Asian macaques.

The central feature of AIDS is the destruction of CD4+ T cells and the crippling effect this has on the host's ability to control opportunistic, or latent, infections. The majority of the CD4+ T cells in the body reside in the gastrointestinal (GI) tract and other mucosal sites, and these cells are activated memory and $CCR5^+$ T cells. Thus the GI tract is a major site for the destruction of CD4+ T cells. As viral replication occurs, the level of immune activation and lymphocyte proliferation dramatically

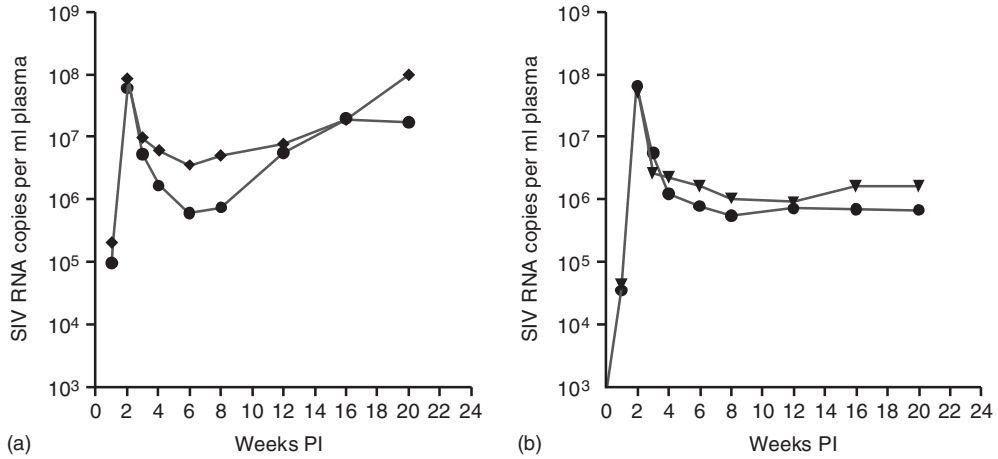

Figure 5 Plasma SIV RNA levels in rhesus macaques following intravenous inoculation of pathogenic SIV. (a) Plasma vRNA levels in two macaques inoculated with SIVmac251. (b) Plasma vRNA levels in 2 macaques inoculated with SIVmac239. Note in all four animals there was a peak in plasma vRNA at 2 weeks PI followed by a variable period of declining or stable plasma vRNA. While setpoint vRNA levels remained stable in both SIVmac239 inoculated animals over the period of observation, plasma vRNA had begun increasing by 24 weeks PI in both SIVmac251-infected animals, suggesting that these animals would soon develop clinical AIDS.

increases as the host attempts to mount an immune response. Many of the transcriptional signals involved in the host's innate and adaptive immune responses are controlled by nuclear factor-kappa B (NF-κB) transcriptional factors. NF-κB is also a key promoter for SIV replication as the viral LTR contains binding sites for NF-κB transcription factors. Thus the host immune response to SIV generates activated T cells with high levels of critical molecules (dNTPs, transcriptional factors) and, paradoxically, these are the cellular targets needed for optimal viral replication.

In addition to the effects of CD4+ T-cell depletion on the host defenses, SIV can directly produce disease. Thus SIV crosses the blood–brain barrier, infecting resident and transient cells of the macrophage lineage, which can result in viral encephalitis. In addition, the high levels of viral antigen and strong antibody responses can produce immune complex glomerulonephritis, while SIV infection of bone marrow macrophages is presumed to be the cause of the anemia and other hematologic abnormalities that SIV infection produces. The above features are also common in HIV infection, but SIV infection of macrophages can produce histiocytic inflammation with syncytial cell formation in the lung, lymphoid tissues, and GI tract.

The above discussion describes the pathogenesis of AIDS in SIV-infected Asian macaques, but in the African primates that are natural hosts of SIV there is little clinical effect of infection. A key difference lies in the response of natural hosts and Asian macaques to SIV infection. Thus SIV-infected African primates mount a complete adaptive immune response but there is little inflammation and no chronic immune activation associated with these immune responses despite continuous high-level viral replication. In marked contrast, SIV infection of macaques, as with HIV infection of humans, produces chronic immune activation and inflammation that is associated with depletion of central memory T-cell pools and loss of effector memory T cells. Thus despite levels of viral replication that are similar to Asian macaques, SIV infection rarely produces AIDS in natural hosts indicating that inflammation and immune activation are necessary for AIDS pathogenesis.

Specific strains of SIV have altered pathogenesis with a number of molecular clones and biologic isolates being attenuated for replication in Asian macaques. Although these variants do not produce disease in the typical time course of viruses with higher replicative capacity, some eventually produce disease in adults or infant macaques, while other attenuated SIV variants (SIVmac1A11) have failed to produce disease in infected macaques after more than 15 years of observation. In addition, some strains of SIV have specific tropism for monocyte/macrophages that are mediated by post-entry events. Infections with these macrophage-tropic SIV strains are more commonly associated with SIV-induced meningoencephalitis than other SIV strains.

Immune Response to SIV Infection

As SIV infection is lifelong, the host immune response cannot clear the infection but, in some cases, it can exert considerable control on the level to which SIV replicates. Before day 5 after mucosal SIV inoculation, there is little evidence of innate immune responses with only modest increases in type 1 interferon levels and interferon-stimulated gene levels at the site of inoculation. At days 6–7 PI, there is a dramatic and simultaneous increase in innate antiviral immune responses in all lymphoid tissues that coincides with the dramatic explosion of viral replication in these tissues. By days 10–14 PI, SIV-specific CD8+ T-cell responses are present in blood and in the mucosal sites of inoculation, with strong antiviral T-cell responses widespread by day 28 PI. This rapid increase in antiviral effector T cells occurs as viral replication and plasma vRNA levels decline from a peak at 14 days PI. The temporal relationship between the decline in plasma viremia and the appearance of antiviral T cells has been interpreted to be evidence that CD8+ T cells are critical in the control of HIV replication. Further evidence for the control of SIV replication by CD8+ lymphocytes has been obtained by using monoclonal antibodies to the α-chain of the CD8 complex to transiently deplete T cells and natural killer (NK) cells. In chronically infected animals, plasma vRNA levels dramatically increase during the period of CD8+ lymphocyte depletion and then rapidly fall as the lymphocyte population is replenished. Finally, as in HIV infection, detailed studies of well-characterized MHC-I-restricted T-cell epitopes in infected macaques have shown that as the host T-cell response targets a specific peptide sequence, viral variants with proteins that contain a variant of the targeted epitope become increasingly common. The effect of these mutated epitopes on viral replication is variable. In some cases, these variants are relatively unfit and the virus gains little advantage; however, in other cases, these immune escape variants are relatively fit and viral replication increases dramatically as the escape variants appear in the viral population. Finally, as in humans, specific MHC-I alleles of macaques (i.e., Mamu-A*01) are associated with particularly strong CD8+ T-cell responses, enhanced immune control of viral replication, and increased disease-free survival times after infection. Taken together, these observations argue that CD8+ T-cell responses can play a significant role in controlling viral replication. B-cell responses also have a role in controlling HIV and SIV replication. Thus it has been shown that passive transfer of high-titer SIV-specific gammaglobulin or neutralizing anti-HIV antibodies inhibits SIV and SHIV replication and retards the pace of disease progression. Further, if macaques are prevented from developing anti-SIV IgG antibodies by B-cell depletion prior to infection with highly pathogenic SIV, they rapidly develop uncontrolled viral replication, and

progress to AIDS in a few months PI, while most SIV-infected macaques make strong antibody responses and develop AIDS at 10–24 months PI.

Clinical Features, Pathology, and Histopathology of SIV Infection in Asian Macaques

End-stage disease in SIV infection is indistinguishable from human AIDS and can be divided into four broad categories: (1) opportunistic infections, (2) SIV-mediated inflammatory diseases, (3) neoplastic diseases, and (4) diseases of unknown etiology. The clinical course of SIV varies with the strain involved but rhesus macaques infected with common pathogenic SIV strains develop AIDS within 6–24 months PI. In the first few weeks of infection, all animals initially develop lymphocytosis consisting largely of CD8+ T cells, which resolves in 4–6 weeks. Lymphadenopathy and splenomegaly are apparent by 2–4 weeks PI and these conditions remain manifest until a very late stage of the disease when lymphoid collapse can occur. As in HIV infection, hypergammaglobulinemia due to polyclonal B-cell activation is often a feature of the disease. Anemia can also be a feature of the clinical disease. Weight loss and diarrhea are very common in SIV-infected animals and can be the result of opportunistic infections (*Mycobacterium avium* complex, cytomegalovirus, adenovirus, *Cryptosporidium* sp., *Ameoba* sp., *Balantidium coli*) or an unknown etiology. Often these enteric conditions do not respond to antibiotic therapy. Lymphomas are the only neoplastic condition of significance in SIV-infected macaques. In fact, a B-cell lymphoma arising in a 19-year-old sooty mangabey infected with SIV may represent the best candidate for the case of an SIV-related fatal disease in a naturally infected African primate.

Lymphoid tissues, including the mucosal-associated lymphoid tissues of the GI, reproductive, and respiratory tracts, are the targets of SIV infection, and a range of histopathologic changes occur in these tissues from follicular hyperplasia to dysplasia, followed by follicular collapse and expansion of the paracortex, ultimately ending in lymphoid depletion, collapse, and fibrosis. These changes occur independent of any opportunistic infections. The same pattern of histologic changes occurs in lymphoid tissues of HIV-1-infected humans and these histologic changes accurately reflect the clinical stage of the infection in both SIV and HIV.

SIV Infections as Animal Models of AIDS

The HIV-1 pandemic continues unabated and developing effective vaccines and therapies is the greatest current public health need. Samples from HIV-infected individuals have provided key insights into AIDS pathogenesis. However, direct experimental testing of specific hypothesis arising from these studies cannot be undertaken in humans for ethical reasons and HIV-1 infection of chimpanzees does not produce AIDS. Thus, SIV infection of Asian macaques is the most widely accepted animal model of HIV pathogenesis. The biology of the macaque immune system, and the key organ systems (gut, lymphoid tissue, and reproductive tract) involved in AIDS pathogenesis and HIV transmission are very similar to humans, and SIV and HIV are closely related phylogenetically. Thus, SIV infection of macaques closely mimics the pathogenesis, virology, immunology, and pathology of HIV infection in the human. The model has been used to show that infection with a molecular clone of SIV is sufficient to cause AIDS, that the GI tract is a major site of $CD4^+$ T-cell depletion, and that some vaccine strategies elicit immune responses that can provide considerable control of viral replication. The macaque monkey model of AIDS has been used to define the molecular determinants of viral pathogenesis, the basis for nonpathogenic infections in natural hosts. These animal models have been particularly valuable for defining the mechanisms of HIV transmission and events in acute infection that are very difficult to study in humans.

Sexual HIV transmission can occur through oral, anal, or vaginal intercourse. Allowing SIV-discordant macaques to mate normally would seem to be most similar to sexual HIV infection. However, sexual SIV transmission occurs at a low or variable rate after natural mating, and, in addition, there is significant biting behavior during mating and thus significant potential for blood-borne SIV transmission. When SIV-discordant juvenile rhesus macaques were housed in groups, SIV transmission most commonly occurred when uninfected, dominant animals bit their SIV-infected, subdominant cagemates as part of social interactions. Thus, once deposited in the mouth of an uninfected macaque SIV-infected blood-transmitted infection therefore biting during mating would confound transmission studies.

A more controlled experimental approach to reliably transmit SIV across the genital mucosa is to intravaginally inoculate female macaques with a known quantity of well-characterized SIV stock. Most studies have used suspensions of cell-free SIV virions, but infection can be transmitted by intravaginal inoculation with SIV-infected cells. In order to reliably transmit SIV to monkeys by a single intravaginal inoculation, relatively high doses of cell-free virus (2–3 log 10 more virus) are used compared to intravenous inoculation. In addition, exogenous progestins have been used to ensure reliable intravaginal SIV transmission, as these hormones thin up the genital mucosa, lower the barrier to transmission, and enhance SIV transmission. Finally, intravaginally inoculating

animals with relatively low doses of virus, approximately the same dose needed for IV transmission, repeatedly over the course for several months eventually produced infection in all exposed animals, although the number of exposures needed to acquire infection is variable; this strategy probably best models the level of virus exposure that occurs during HIV sexual transmission.

HIV transmission by sexual, intravenous, and perinatal routes is often associated with the acquisition of a limited distribution of genetic variant. In many instances, the transmitted variant represents a minor variant in the donor's virus population. Given the extent of genetic diversity between HIV isolates, these findings have been interpreted to suggest that HIV transmission may involve selective entry or selective amplification of specific viral variants. However, the inherent limitations of all studies using human samples include small sample sizes and uncertainty as to the genetic identity and the extent of genetic diversity of the virus population in the donor at the time of transmission. Thus, the mechanisms that underlie the sexual transmission of HIV variants are unclear, and are difficult to assess because of the difficulties in establishing the precise time of infection. The SIV macaque model for HIV transmission is particularly valuable for evaluating the role of viral selection during transmission. The model allows access to information that is usually unattainable in human studies, such as: the genotypic and phenotypic properties of the infecting virus; knowledge of the exact time of virus exposure; and the characteristics of viral variants in the infected host immediately after transmission. Both IV and IVAG SIV inoculation transmit genetically diverse populations of SIV env V1–V2 variants to macaques. However, compared to the complex SIV populations in the IV inoculated animals, most IVAG inoculated animals are infected with SIV populations that have relatively low genetic diversity in the env gene. The finding that genetically diverse SIV populations are transmitted to some IVAG inoculated monkeys is consistent with the observation that a more genetically diverse population of viral variants is sexually transmitted from HIV-infected men to women. The model has also been used to show that recombination can occur readily *in vivo* after mucosal SIV exposure and thus viral recombination contributes to the generation of viral genetic diversity and enhancement of viral fitness in the peracute stages of infection. The model has also been used to show that the mucosal barrier of the female genital tract greatly limits the infection of cervicovaginal tissues after intravaginal SIV inoculation, and thus the initial founder populations of infected cells are small. Despite limited foothold, SIV rapidly disseminates to distal sites, and continuous seeding from an infection in the genital tract is likely critical for the later establishment of a productive disseminated systemic infection.

Perinatal HIV transmission can occur at any time during gestation, delivery, or breast-feeding. Allowing female macaques infected with virulent SIV before or during pregnancy is most similar to perinatal HIV infection, because SIV/SHIV transmission can occur any time during gestation, delivery, or breast-feeding. However, mother–infant SIV transmission occurs at a low or variable rate and the timing of virus transmission is unknown. Alternatively, female macaques can be infected with SIV after delivery and the infant allowed to breast-feed normally. This model best mimics natural HIV breast milk transmission by eliminating fetal exposure to virus and transplacental transfer of maternal virus-specific antibodies to the infant. Thus, this approach controls more variables and transmission rates are high; however, a major limitation is that the time at which breast-feeding infants become SIV infected varies substantially (i.e., a few weeks to several months). Finally, direct oral inoculation of infant macaques with SIV or SHIV can be performed without infecting their dams. This approach controls most of the important variables related to the viral inoculum (dose, number, timing, and duration of virus exposure), maternal host immune response (level and quality of anti-HIV-specific maternal/passively transferred antibodies), and infant rearing (by uninfected dams or in a primate nursery). This system has been used to show that after oral inoculation of infant rhesus macaques with virulent SIVmac251, virus disseminates to distal lymphoid tissues faster than after oral inoculation of juvenile macaques or vaginal inoculation of adult macaques with the same virus.

In addition to helping define critical steps in AIDS pathogenesis, these SIV mucosal transmission models are ideal for testing vaccines and microbicide strategies designed to prevent HIV transmission. The demonstrated utility of the SIV model for vaccine testing contrasts sharply with the inability of models using macaques infected with CxCR4 SHIVs (SHIV 89.6P) to meaningfully segregate HIV-1 vaccine candidates by relative efficacy. Thus the SIVs will continue to be the most valuable model of HIV infection and a critical tool in AIDS research.

Simian Immunodeficiency Virus: General Features

M E Laird and R C Desrosiers, New England Primate Research Center, Southborough, MA, USA

© 2008 Elsevier Ltd. All rights reserved.

History

Simian immunodeficiency virus (SIV) was first isolated in 1984 from captive rhesus macaques (*Macaca mulatta*) at the New England Primate Research Center (NEPRC). This virus was originally called STLV-III because it displayed similar morphology, growth characteristics, and antigenic properties to the newly described immunosuppressive virus HTLV-III of humans. When HTLV-III was renamed human immunodeficiency virus (HIV), the name STLV-III was also changed to SIV. Retrospective studies have shown that SIV was introduced to the NEPRC when a group of rhesus macaques with immuosuppressive disease was delivered from another primate center 15 years prior to the initial SIV isolation. The original cohort of rhesus monkeys was most likely accidentally infected with SIV from wild-caught sooty mangabey monkeys at the same institution. SIV has been subsequently isolated from other captive macaque species (*M. fascicularis*, *M. nemestrina, and M. arctoides*) that were dying of immunosuppression-associated diseases, and from many species of feral asymptomatic African nonhuman primates (**Table 1**).

Taxonomy and Classification

SIVs belong to the genus *Lentivirus* of the family *Retroviridae*. Related lentiviruses have been isolated from sheep, goats, horses, cattle, cats, and humans. Based on host species and genetic analysis, 14 discrete evolutionary groupings of primate lentiviruses are now recognized (**Figure 1**). Even within a single grouping, discrete subgroupings are defined based on host subspecies, geography, and genetic distance. Within a specific subgroup whose host range covers an extensive geographical area, discrete genetic sub-subgroups are further defined that correlate with monkey subspecies and precise natural geographic habitat.

The lentiviruses have a common morphogenesis and morphology that distinguish them from other retrovirus subgroups. Lentivirus particles are 80–100 nm in diameter and consist of an RNA genome and viral enzymes enclosed in viral protein core that is encased by a cell-derived membrane spiked with viral envelope glycoproteins. In lymphocytes, immature lentiviruses bud from the plasma membrane without a preformed nucleoid; mature particles contain a characteristic conical or rod-shaped nucleoid. Classification of lentiviruses by morphology alone is consistent with classification by phylogenetic analysis of polymerase (*pol*) gene sequences. The *pol* gene exhibits the greatest degree of sequence conservation and viruses classified as lentiviruses have *pol* gene sequences more closely related to one another than to other retroviruses.

Lentiviruses also share similarities in certain biological properties and genome organization. All lentiviruses have a propensity to replicate in macrophages and produce long-term, persistent infections in susceptible hosts.

Table 1 Detailed listing of primate lentiviruses[a]

Virus designation	*Primate Lentivirus grouping*	*Species (common)*	*Species (formal)*	*Subspecies isolates*
HIV-1	HIV–1/SIVcpz	Humans	*Homo sapiens*	
SIVcpz	HIV–1/SIVcpz	Chimpanzees	*Pan troglodytes*	*P. t. troglodytes* *P. t. schweinfurthi*
SIVsm	SIVmac/SIVsm/HIV-2	Sooty mangabeys	*Cercocebus atys*	
SIVmac	SIVmac/SIVsm/HIV-2	Macaques	*Macaca mulatta*	*M. arctoides* *M. nemestrina* *M. fascicularis*
HIV-2	SIVmac/SIVsm/HIV-2	Humans	*Homo sapiens*	
SIVagm	SIVagm	African green monkeys	*Chlorocebus aethiops*	*C. a. grivet* *C. a. tantalus* *C. a. sabeus* *C. a. alboqularis* *C. a. nictitans*
SIVsyk	SIVsyk	Sykes' monkeys	*Cercopithecus mitis*	
SIVgsn	SIVgsn/SIVmon/SIVmus	greater spot-nosed monkey	*Cercopithicus mitis*	
SIVmon	SIVgsn/SIVmon/SIVmus	mona monkey	*Cercopithicus mona*	
SIVmus	SIVgsn/SIVmon/SIVmus	mustached monkey	*Cercopithicus cephus*	
SIVlhoesti	SIVsun/SIVlhoesti	L'hoest monkey	*Cercopithicus lhoesti*	*C. l. lhoesti*
SIVsun	SIVsun/SIVlhoesti	Sun-tailed monkey	*Cercopithicus lhoesti*	*C. l. solatus*
SIVdeb	SIVdeb	DeBrazza monkey	*Cercopithicus neglectus*	
SIVden	SIVdeb	Dent's mona monkey	*Cercopithicus mona denti*	*C. m. denti*
SIVrcm	SIVrcm	Red-capped mangabey	*Cercocebus torguatus*	*C. t. torguatus*
SIVmnd	SIVmnd 1	Mandrill	*Mandrillus sphinx*	
SIVmnd	SIVmnd 2	Mandrill	*Mandrillus sphinx*	
SIVdrl	SIVmnd 2	Drill	*Mandrillus leucophaeus*	
SIVcol	SIVcol	Querza colobus	*Colobus querza*	
SIVolc	SIVolc	Olive colobus	*ProColobus badius*	
SIVwrc	SIVwrc	Western red colobus	*Pilocolobus badius*	
SIVtal	SIVtal	Angolia-talapoin monkey	*Miopithicus talapoin*	
SIVtal	SIVtal	Gabon talapoin monkey	*Miopithicus ogouensis*	

[a]Partial pol sequences have also been obtained from a black mangabey (*Loplcocebus aterrimus*) and from a Schmidt's guenon (*Cercopithicus ascanius schmidti*). In addition to the primate lentiviruses listed, serologic surveys for the detection of antibodies to SIV have suggested SIV infection of a variety of other species.

SIVs use CD4 as the first of two receptors used sequentially for viral entry into cells. The chronic disease induced by SIV includes immunodeficiency, undoubtedly because of the targeting of CD4+ lymphocytes for infection through the use of CD4 as the primary receptor. In addition to the *gag*, *pol*, and *env* genes that are found in all simpler retroviruses, lentiviruses have a number of auxiliary genes (**Figure 2** and **Tables 2** and **3**).

The SIVs are named according to the primate species of origin, for example, SIVmac from macaques or SIVsmm from sooty mangabey monkeys. Widespread availability of DNA sequencing has allowed an in-depth understanding of phylogenetic relationships among SIVs. However, to date, only 39 of the 69 recognized species of nonhuman primates that inhabit sub-Saharan Africa have been surveyed; additional distinct SIV groupings will likely be identified.

Geographic Distribution and Host Range

Many different species of African nonhuman primates are known to be infected with SIV in their natural habitats. However, few studies have investigated the distribution or extent of natural SIV infection. There has recently been an effort to overcome this shortfall of information by identifying and assessing the extent of SIV infection in wild primate populations. In 2002, Peeters *et al.*, collected and screened 788 blood samples from wild-caught monkeys for the prevalence of SIV infection in 13 different monkey species in Cameroon. The study examined the rates of SIV infection in monkeys hunted for bushmeat and those captured as pets as possible routes of zoonotic transmission. It was reported that 18.4% of bushmeat samples and 11.6% of pets tested positive for SIV infection. These results identified four species of monkeys not previously known to harbor SIV (*Cercocebus agilis*, *Lophocebus albigena*, *C. pogonias*, and *Papio anubis*) and likely underestimate the extent of SIV prevalence as not all native primate species were screened.

The origins of both HIV-2 and HIV-1 in humans are believed to have occurred through cross-species transmission events from SIV-infected simians relatively recently in history. SIVsmm is closely related to HIV-2 with the same genome organization and both viruses group together phylogenetically apart from the other 13 groups

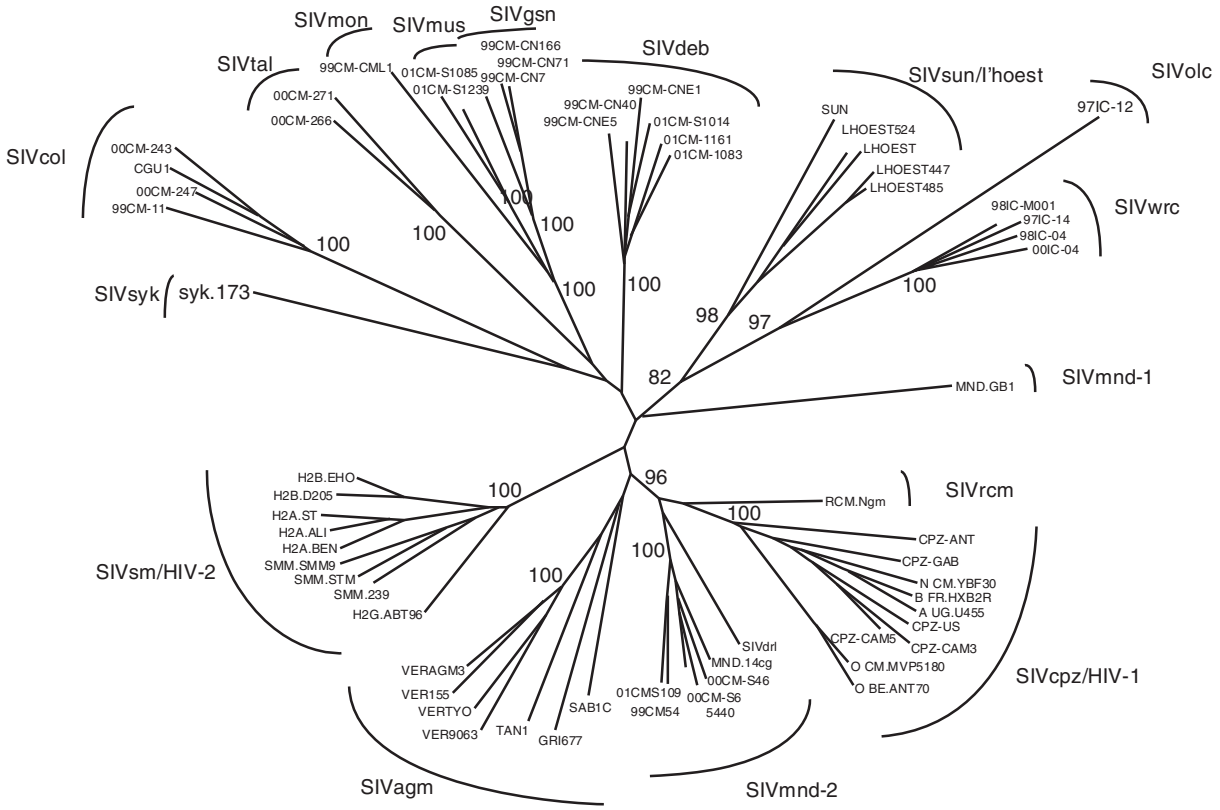

Figure 1 Phylogeny of primate lentiviruses. The 14 groupings of primate lentiviruses are shown. Please see **Table 1** for species abbreviations. Adapted from Courgnaud V, Formenty P, Koffi CA, *et al*. (2003) Partial molecular characterization of two simian immunodeficiency viruses (SIV) from African colobids: SIVwrc from Western Red Colobus (*Piliocolobus badius*) and SIVolc from Olive Colobus (*Procolobus verus*). *Journal of Virology* 77(1): 744–748, with permission from American Society for Microbiology.

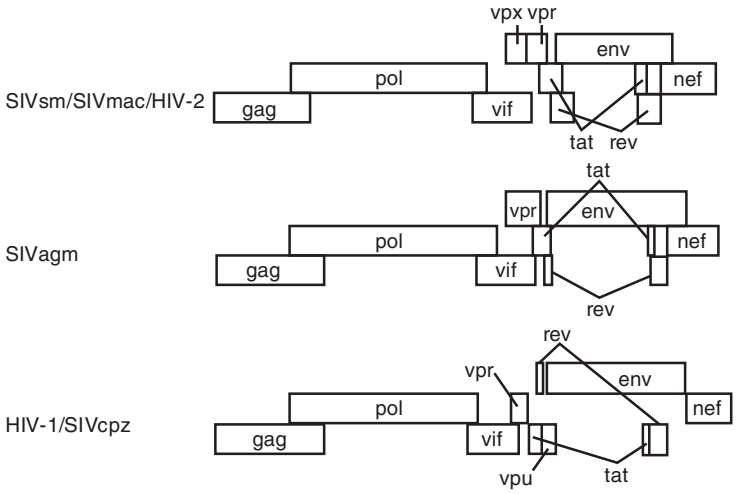

Figure 2 Genome organizations of representative primate lentiviruses.

of primate lentiviruses. The sooty mangabey monkey is native to the coastal forest regions of western Africa, where HIV-2 emerged and is now endemic in the human population. Thus, strong circumstantial evidence involving both viral sequences and geographic distribution link the monkey SIVsmm and HIV-2 in western Africa. In 2006, Keele and co-workers examined the wild chimpanzee (*Pan troglodytes troglodytes*) populations of Cameroon to determine the extent of natural SIVcpz infection and to investigate which infected populations may be responsible

Table 2 Presence of auxiliary genes in SIV species

	SIVsm/SIVmac/HIV- 2	*SIVagm*	*SIVsyk*	*SIVsun/SIVl'hoesti*	*HIV-1/SIVcpz*	*SIVgsn/SIVmon/SIVmus*	*SIVrcm*
vif	+	+	+	+	+	+	+
vpu					+	+	
vpr	+	+	+	+	+	+	+
vpx	+						+
tat	+	+	+	+	+	+	+
rev	+	+	+	+	+	+	+
nef	+	+	+	+	+	+	+

Different SIV species may vary with respect to the auxiliary genes that they carry. The presence or absence of these auxiliary genes do not always associate with phylogenetic clustering. For example, SIVmnd2 has a *vpx* gene, but SIVmnd1 does not. SIVden from a pet Dent's Mona monkey (*Cercopithecus mona denti*) has a *vpu* gene, although it clusters more closely to the SIV from DeBrazza monkeys, SIVdeb. SIVdeb has a *vpr* gene, but no *vpx* or *vpu* genes.

Table 3 Auxiliary gene function in SIV

Auxiliary gene product	*Essential for replication?*	*Early gene product?*	*Function*
tat	Yes	Yes	Potent activator of viral gene expression; enhances LTR-driven transcription
rev	Yes	Yes	Required for efficient transport of unspliced and singly spliced viral RNAs into the cytoplasm
nef	No	Yes	Functional activities include CD4 downregulation, MHC downregulation, infectivity enhancement and lymphocyte activation
vif	Yes/no[a]	No	Blocks restricting activity of innate cellular proteins, APOBEC-3G and APOBEC-3F
vpr	No	No	Involved in G_2/M phase cell-cycle arrest; mediates apoptosis of CD4+ T cells
vpx	No	No	Facilitates nuclear import of the preintegration complex in nondividing cells

[a]SIV strains containing a deletion in *vif* (SIVΔvif) can be grown in a *vif*-complementing cell line; when inoculated into animals no virus or PCR-amplifiable sequences could be recovered from PBMCs; however, monkeys still developed lowlevel antibody titers suggesting highly attenuated infection.

for the cross-species transmission events that initially introduced HIV-1 into the human population. By measuring the presence of anti-HIV cross-reactive antibodies and the ability to amplify viral gene sequences it was determined that SIV infection was widespread but uneven among the chimpanzee populations, with the prevalence of infection ranging from 23% to 35% in some isolated groups to a 4–5% infection rate in others, while still others had a complete absence of SIV infection. Sequence and phylogenetic analyses of the newly identified wild SIVcpz strains supported that distinct geographical chimpanzee groups acted as the sources of HIV-1 groups M and N in the human population.

Although SIVs naturally infect a variety of African nonhuman primates, a single example of natural infection of Asian Old World monkeys is yet to be reported. SIVsmm and SIVagm, when used to infect macaque monkeys (Asian Old World primates), can persist and cause an AIDS-like disease. Accidental introduction of SIVsmm into macaque monkeys in captive United States colonies occurred and was spread unknowingly into other macaques for more than a decade before it was identified and eliminated. At least one clear case of laboratory-acquired infection of a human with SIVmac has been documented.

Virus Propagation and Receptor Use

SIVs can be propagated in mitogen-stimulated primary peripheral blood mononuclear cells (PBMCs), in monocytes/macrophages from the primate host, and in many cultured cell lines including human tumor-derived CD4+ T-lymphocyte cell lines. The types of cells that can be infected by different strains of SIV correlate with the receptor(s) that are expressed on the cell surface. Some acutely pathogenic strains are unusual in their ability to replicate in lymphocytes of resting PBMC cultures without prior stimulation. In PBMC cultures and many cell lines, viral infection results in the fusion of cellular membranes producing large syncytial cells. Syncytium formation, which is mediated by *env*, allows the virus to spread directly from cell to cell in addition to direct infection. Several isolates also grow well in cultured macrophages derived from lung, blood, or bone marrow.

As with HIV-1, the SIVs use both CD4 and a chemokine receptor for viral entry. The SIVsmm/SIVmac/HIV-2 and SIVagm groups of viruses are known to use CCR5 as their principal co-receptor. However, a variety of other chemokine receptors, CCR2b, CCR3, STRL33 (Bonzo), GPR15 (Bob), and GPR1, also can be used as the co-receptor,

depending on the individual virus isolate. A larger percentage of isolates from the SIVsmm/SIVmac/HIV-2 group of viruses show less dependence on CD4 for entry than do HIV-1 variants. Isolates of SIVsmm/SIVmac appear to use CXCR4 as the principal co-receptor much less frequently than HIV-1 isolates. SIVs from red-capped mangabeys (*Cercocebus torquatus torquatus*) predominantly use CCR2b as the principal co-receptor.

Genetics

SIV, like other retroviruses, replicates its genome through a proviral DNA intermediate. From the 5′ cap to the 3′ polyadenylation site, the SIV genome is approximately 9.6 kbp in length. The viral particle contains a diploid genome of single-stranded RNA that is linked noncovalently near the 5′ end of the molecules. The 5′ end of the viral genome is capped and the 3′ end is polyadenylated. DNA synthesis by the viral-encoded reverse transcriptase is primed by host tRNA that is base-paired to viral RNA. The double-stranded proviral DNA is integrated into the host cell chromosome by a viral-encoded integrase and further replication events of transcription, translation, and particle assembly depend on cellular components. Particles then assemble at and bud through the plasma membrane. Because of this replication strategy, cloned DNA representing the entire proviral genome can yield infectious virus.

All retroviruses contain certain standard features in their genomic organization (**Figure 2**). Sequences regulating DNA synthesis, integration, transcription, and other functions are contained in the long terminal repeat (LTR) region at each end of the provirus. Open reading frames (ORFs) encoding the major structural and nonstructural proteins lie between the LTRs. Genes are encoded in any of three possible ORFs; overlaps between ORFs are common. All retroviruses contain three standard genes called *gag* (group-specific antigen), which encodes the core proteins; *pol* (polymerase), which encodes the viral reverse transcriptase, protease, and integrase; and *env* (envelope), which encodes the envelope glycoproteins.

Env is essential for virus replication. The envelope glycoproteins are responsible for binding the receptor and co-receptor on the cell surface and mediating viral entry. The *env* products are the main targets of antibodies that can neutralize infection. In addition, determinants of cell and tissue tropism often map to the *env* gene. Derivatives in which the SIVmac *env* has been replaced by envelope of HIV-1 are replication competent in macaque cells and are capable of infecting rhesus monkeys. These recombinant viruses are known as simian–human immunodeficiency viruses (SHIVs). Serial passage of several SHIV strains has resulted in second-generation SHIVs that are consistently pathogenic in macaques.

In addition to *gag*, *pol*, and *env*, all lentiviruses, including SIV, encode additional accessory genes not found in other simple retroviruses (**Tables 2** and **3**). Both SIV and HIV encode *tat* (transactivator protein), *rev* (regulator of gene expression), *vif* (viral infectivity factor), *nef* (originally termed negative factor), and *vpr* (viral protein 'r'). SIVagm and SIVsmm/HIV-2/SIVmac encode an additional gene, *vpx* (viral protein 'x'), thought to be a duplicated homolog of *vpr*. The ORF for *vpu*, found in HIV-1/SIVcpz and SIVgsn/SIVmon/SIVmus/SIVden, is not contained in HIV-2 or in other SIVs. These auxiliary genes likely contribute to the complex life cycle of lentiviruses, including persistent viral replication and immune evasion.

Some of the accessory proteins found in SIV can be deleted without abrogating the ability of the virus to replicate *in vivo* and *in vitro*, specifically *nef*, *vpr*, and *vpx*. However, the presence and the conservation of these genes in several different subgroups of lentiviruses suggest that they contribute to the virus' ability to replicate and persist *in vivo*. Cloned proviral DNAs containing deletions in these auxiliary ORFs have been used to study the contributions to replication and functional activity of the auxiliary genes in the context of experimental animal infection. Auxiliary gene functional data are summarized in **Table 3**.

Evolution

Comparison of genetic sequences among human and simian immunodeficiency suggests that there are at least 14 discrete groups of primate lentiviruses in existence: HIV-1/SIVcpz; SIVmnd-2; SIVagm; SIVsmm/HIV-2; SIVsyk; SIVcol; SIVtal; SIVmon/SIVmus/SIVgsn; SIVdeb/den; SIVsun/l'hoest; SIVolc; SIVwrc; SIVmnd-1; and SIVrcm (**Figure 1**). It is thought that HIV-1 and HIV-2 evolved from simian viruses that entered the human population through cross-species transmission events relatively recently in human history. Cross-species transmission among nonhuman primates occurring in nature may have generated further pathogenic variants; however, it is likely that most of the primate immunodeficiency viruses have long been present in the natural host but not recognized until recently. The SIVs and HIVs are more closely related to each other than to any other nonprimate retrovirus, suggesting that they are inherently primate viruses, not derived from nonprimate viruses that were introduced via other cross-species transmission events.

Serologic Relationships and Genetic Diversity

The *pol* gene generally contains the greatest degree of sequence conservation and therefore is most often used

for the comparison of lentiviruses from different groups or subgroups to assess relatedness. *Pol* sequences from one subgroup of SIV (e.g., SIVsmm) will generally contain only a 55–60% amino acid identity when compared to another SIV subgroup (e.g., SIVagm). When different lentivirus groups are compared (e.g., EIAV with SIV) the amino acid identity in *pol* is often 35% or less, and the sequence homology found in other genes is even less. Antiserum to the Gag protein is generally cross-reactive to different strains within a group, whereas antiserum to the envelope is not and can be used to distinguish between isolates within a group.

Epidemiology

SIV has been found in many species of nonhuman primates throughout sub-Saharan Africa, but in most cases infection does not seem to cause an AIDS-like disease in the natural host. There are only a few examples of immunodeficiency in monkey species naturally infected with SIV. In contrast, though infection does not appear in nature, SIV infection of Asian macaques in captivity induces an AIDS-like disease similar to that observed in HIV-infected humans.

Transmission

There is little information regarding natural modes of SIV transmission. A study of wild grivet monkeys in Awash National Park in Ethiopia analyzed SIVagm serologic status as compared to age, sex, and risk. Infection was found overwhelmingly in females of reproductive age and was nearly absent among younger female animals. In the male population, infection was only observed in monkeys that were fully adult. These data support a predominantly sexual mode of transmission among the grivet population. SIV transmission through contact with infected blood from aggressive contacts (e.g., bite and scratch wounds) may also be a prominent mode by which SIV may be spread. In addition, maternal–infant transmission of SIV has been observed in captive animals.

Experimental infection of laboratory animals has most commonly been performed by direct needle inoculation. However, mucosal exposure is being used more frequently, especially in vaccine studies, as a model for the most common routes of HIV infection.

Features of Infection

While SIV infection of the natural host is usually not associated with any disease progression, SIV infection of macaques induces both acute and chronic disease symptoms that are similar to that which HIV-1 causes in human patients. SIV infection of rhesus macaques is generally thought to be the closest model of AIDS in humans.

The main sites of pathogenic SIV replication shortly after infection have been localized to the gastrointestinal (GI) tract, thymus, spleen, and other lymphoid tissues. SIV has been detected at early time points within periarteriolar lymphoid sheaths in the spleen, paracortex of lymph nodes, and medulla of the thymus. SIV infection of rhesus monkeys results in a dramatic and selective depletion of CD4+ T cells in the GI tract within days of infection, before depletion is evident in the peripheral lymphoid tissues. Coincident with the loss of CD4+ T cells in the GI tract is the productive infection of large quantities of mononuclear cells at this site. It is now clear that SIV replicates principally in the CD4+ CCR5+ cells of the memory T-cell phenotype. These cells predominate in the gut and other mucosal sites and are found at much lower levels in peripheral lymphoid tissues. Therefore, the GI tract appears to be a major site of SIV replication and CD4+ memory T-cell depletion early in the course of infection. Within the thymus, marked depletion of thymic progenitor cells has been observed 21 days post infection with pathogenic SIV; this cell depletion is followed by increased cell proliferation in the thymus and a marked increase in thymocyte progenitors. SIV can also be found in the central nervous system (CNS) at early time points following infection. The cells that are targeted in the brain, either early in infection or in late-stage SIV-induced encephalitis, are primarily cells of the monocyte/macrophage lineage.

Viral loads in infected animals decrease with the onset of immune responses, and this decrease correlates with CD8+ T-cell lymphocytosis and the rise of SIV-specific antibodies. Following immune system activation, animals enter an asymptomatic period of infection of variable duration. Viral replication persists during this period, inducing immune abnormalities, including gradual declines in CD4+ T-cell count, CD4/CD8 ratio, and the ability to respond to mitogens. Infected animals can also exhibit chronic diarrhea and wasting resulting in up to a 60% loss of the original body weight. Over the course of disease, dramatic changes, including hyperplasia and/or atrophy, take place in most of the lymphoid tissues. Terminal stages of SIV infection are characterized by a range of diseases that can be grouped into four broad categories: SIV-related inflammatory disease, opportunistic infections associated with SIV-induced immunosuppression, neoplastic diseases, and diseases of unknown pathogenesis. The tropism of SIV strains for monocytes/macrophages correlates with dramatic inflammatory and degenerative changes seen in the CNS, lung, digestive tract, and other organs that are separate from the pathogenesis of opportunistic infections. The characteristics and frequency of inflammatory lesions in SIV-infected macaques closely resembles those seen in HIV-infected

patients. SIV-induced encephalitis is frequent, although the appearance of brain lesions is dependent on the infecting SIV strain. At necropsy, 30–50% of SIVmac-infected animals have characteristic multinucleate giant cell encephalitis that closely resembles that seen in HIV-associated encephalitis. The opportunistic infections seen in infected monkeys are also similar to those observed in HIV-infected individuals and include *Pneumocystis carinii*, *Mycobacterium avium*, *Crytposporidia* sp., *Toxoplasma gondii*, rhesus Epstein–Barr virus (rhesus lymphocryptovirus), cytomegalovirus, polyomavirus (SV40), and adenovirus. Neoplastic diseases during SIV infection are primarily limited to lymphomas, the frequency of which varies from study to study. Lymphoma induction in SIV-infected macaques has additionally been associated with the co-infection of rhesus Epstein–Barr virus. Diseases of unknown pathogenesis include generalized lymphoproliferative syndrome, arteritis, and arteriopathy.

Acutely pathogenic strains exist, such as SIVsmPBj14, which can be acutely lethal in infected macaques. SIVsm PBj14 infection causes death in infected monkeys within 14 days. These animals have very high viral loads, severe GI disease, cytokine disregulation, lymphoproliferative disease, and organ system failure. The increased pathogenicity of this virus has been attributed to the creation of an ITAM motif by a tyrosine at residue 17 of the nef protein. This change allows the virus to induce lymphocyte activation and replicate to high titers in PBMC cultures without prior stimulation. However, the disease induced by the majority of SIV infections is typically chronic and manifests itself over the course of 1–3 years post infection.

Several independent research groups have constructed recombinant forms of SIVmac with HIV-1 *env*, *tat*, *rev,* and, in some cases, *nef* and/or *vpu* genes renamed 'SHIV' (for simian–human immunodeficiency virus) that have been passaged in macaques to establish pathogenic virus strains. Although most of the HIV-1 envelopes that were used to construct these SHIVs were dual-tropic, in that they can use either CCR5 or CXCR4 as a co-receptor, the large majority of SHIV viruses appear to target primarily CXCR4-expressing cells when used to infect rhesus macaques. The pathogenic SHIVs consistently, rapidly, and irreversibly deplete CD4+ T cells from the periphery and can be acutely lethal.

Immune Response and Persistence

SIV-infected macaques typically produce high levels of antiviral antibodies and high-frequency cytotoxic T-lymphocyte (CTL) responses to the infecting virus. These immune responses persist for the lifetime of the infected host in both natural and experimental infection. SIV deletion mutants that are progressively more attenuated based on viral load measurements generate progressively weaker anti-SIV antibody responses. Anti-SIV CTL responses have been demonstrated as being major histocompatibility complex (MHC) restricted. Detailed investigation of CTL responses has been impeded by a lack of information regarding MHC types in different monkey species. However, a considerable amount of new information regarding MHC alleles and their cognate peptides is emerging for rhesus macaques.

The importance of CD8+ lymphocytes in limiting the extent of SIV or SHIV replication has been definitively shown using CD8+ T-cell depletion. Extensive depletion of CD8+ cells was accomplished by intravenous administration of large doses of anti-CD8 monoclonal antibodies. When CD8+ T cells were depleted during primary infection, viral replication continued unabated after the usual peak of viral loads, 10–14 days post infection; this was in stark contrast to undepleted animals, in which intact immune responses typically act to decrease viral loads after 14 days post infection. During chronic infection, elimination of CD8+ lymphocytes through depletion resulted in a rapid and dramatic increase in viremia, which was again suppressed upon removal of anti-CD8 antibody and the return of the SIV-specific CD8+ lymphocytes. Depletion of CD8+ T cells in animals infected with SHIV viruses has facilitated the appearance of the more highly pathogenic, passaged variants.

In macaques developing SIV-induced disease from wild-type strains of SIV, viral-specific, proliferative responses of CD4+ T cells are typically weak or absent all together. However, infection by attenuated SIV mutants containing a deletion of the *nef* gene produces strong, SIV-specific, CD4+ helper cell proliferative responses. This situation recalls that of HIV infection in humans, in which HIV-specific CD4+ proliferative responses in progressing patients are usually weak or absent, but are often very strong in nonprogressors that are able to control their infection. It seems that as CD4+ helper T cells try to respond to SIV at sites of infection, they arrive in the location where they are the ideal target cells for the invading virus. In pathogenic infections, the virus wins the battle between it and the responding CD4+ T cells.

All lentiviruses persist in the infected host through chronic active viral replication. Over the course of the months and years of chronic infection, macaques infected with SIV are producing and turning over millions of viral particles and infected cells every day. Although active replication persists throughout the course of infection, there are some cells that are most likely infected in a quiescent or latent fashion. The extent of chronic active replication may also differ depending on the infecting virus strain and the host. Consistent with prolonged antigen expression and chronic replication is the long-term persistence of a high level of circulating antibody and viral-specific CTLs. Nonpathogenic SIV derivatives also continue to replicate at low levels over long periods, as

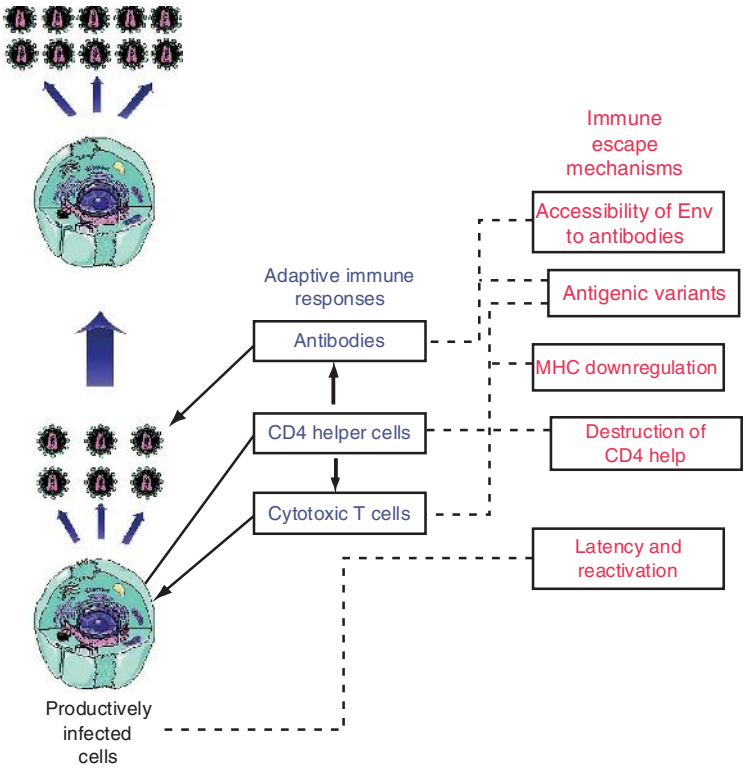

Figure 3 Simian immunodeficiency virus uses a variety of strategies to avoid recognition and clearance by both the humoral and cellular arms of the immune system.

demonstrated by accumulated sequence changes in these viral genomes and persistent antibody titers.

The dilemma of all lentiviruses is how to replicate persistently in the face of an apparently strong immune response. The levels of antiviral antibody and the frequency of CTLs in the infected individual have been measured and appear to be consistently high. Several strategies are used by SIV and other lentiviruses to allow persistent replication and evade the immune response. These are summarized in **Figure 3**.

Prevention and Control

Extensive testing and removal programs have essentially eliminated SIV from captive macaque colonies. However, continued vigilance is required to minimize the chance that breeding colonies may again become accidentally exposed to the virus. Animals can be easily and conveniently tested serologically for infection. Cases of SIV infection in humans are extremely rare and laboratory personnel that work with SIV follow the same precautions when working with SIV as working with HIV-1. Disposable gloves and surgical gowns are used, all work with live virus is performed in a biosafety hood, procedures creating aerosols are avoided, and any use of glass or needles in conjunction with live virus is minimized.

Future Perspectives

The development of a safe, effective, affordable vaccine for HIV/AIDS is one of the greatest challenges of our time. SIV will inevitably play an important role in instructing what is needed for protective immunity and how best to make a vaccine. Because SIVs are the closest known relatives of HIVs, the induction of AIDS in macaques by infectious molecular clones of SIV represents the best existing animal model for AIDS. SHIV infections are also extensively used in vaccine development because it allows for the analysis of HIV-1 envelope-containing vaccine products in an established system. Vaccine studies in animal models are vitally important as they provide useful information in several different ways. Head-to-head comparisons of different vaccine approaches can be performed to investigate which approach is more effective, at least within defined experimental conditions. Further, more in-depth analyses of specific vaccine approaches may also provide fundamental insights into what is needed to establish persistent, protective immunity to SIV and/or HIV infection. The worldwide crisis of HIV infection and AIDS has brought attention to the SIV system as a source of information that will shed light on the human condition. SIV as an animal model can contribute to further understanding of the most critical issues for future progress, including better understanding of pathogenesis,

improvements in therapy and, most importantly, the development of a safe, effective, and affordable vaccine.

Glossary

APOBEC Human protein superfamily that interferes with the HIV/SIV replication. This family of proteins has cytidine deaminase activity and has been suggested to play an important role in innate antiviral immunity.
Catarrhines Relating to or being any of a division of primates (*Catarrhina*) comprising the Old World monkeys, great apes, and hominids that have nostrils close together and directed downward, 32 teeth, and a tail, when present, which is never prehensile.
Chemokine receptors Family of approximately 20 different G-protein-coupled receptors that have seven transmembrane segment polypeptides, and which cause cell activation. Each receptor subtype is capable of binding multiple chemokines within the same family.
Endemic (1) Natural to or characteristic of a specific place; native; indigenous. (2) A disease which persists in a given population or locality.
Giant cell disease Pathologic condition specific for nonhuman primates with severe immunodeficiency characterized by infiltration with syncytial cells in multiple tissues.
Guenon An Old World monkey native to sub-Saharan Africa; possesses a round head with beard, and 'whiskers' at side of face; slender, with long hind legs and tail; some species with colorful coats.
Sympatric Of two or more population or taxa, inhabiting the same geographic area.

Introduction

More than 40 different types of simian immunodeficiency viruses (SIVs) naturally infect different species of monkeys and apes. Two of these, SIVcpz, which naturally infects chimpanzees, and SIVsmm, which naturally infects sooty mangabeys (SMs), are the ancestors of HIV-1 and HIV-2, respectively. Inadvertent cross-species transmission of SIVsmm from naturally infected SMs to different species of macaques resulted in severe immunodeficiency and subsequent development of the animal models for AIDS. Unlike HIV/SIV infection of humans and macaques, which normally progresses to AIDS, natural SIV infection is generally nonpathogenic in African nonhuman primates (NHPs). The mechanisms behind this lack of disease progression are currently under investigation.

History

The history of SIVs began two decades prior to virus discovery, when two outbreaks of opportunistic infections and lymphoma occurred in rhesus macaques (RMs) (1968) and in stump-tailed macaques (1973) at the California National Primate Research Center (CNPRC). SIVmac was discovered in 1985, during another outbreak of lymphomas in RMs at the New England Primate Research Center from monkeys transferred from CNPRC. However, occurrence of SIV infection in macaques was perplexing since tests carried out on RMs in Asia failed to reveal any evidence of SIV circulation in the wild. In 1986, at the Tulane National Primate Research Center, attempts to transmit leprosy from SMs to RMs resulted in a new AIDS outbreak in RMs, establishing the link between pathogenic SIVs in macaques and an African monkey species. During the following 20 years, more than 40 SIVs were identified in different African NHP species.

SIVsmm is also the ancestor of HIV-2. At least eight cross-species transmissions in West Africa resulted in the emergence of the eight HIV-2 groups (AH). In 1989, the discovery of SIVcpz in chimpanzees from Gabon identified the ancestor of HIV-1. At least three cross-species transmissions were at the origin of HIV-1 groups M, N, and O. Groups M and N resulted from cross-species transmission of SIVcpz from *Pan troglodytes troglodytes* in West-Central Africa. Group O is more closely related to the recently discovered SIVgor from *Gorilla gorilla*.

The arguments to support cross-species transmission from NHPs as the origin of HIVs are: (1) similarities in viral genome organization; (2) phylogenetic relatedness; (3) prevalence in the natural host; (4) geographic coincidence; and (5) plausible routes of transmission. All these criteria are fulfilled by both SIVsmm/HIV-2 and SIVcpz+SIVgor/HIV-1. Therefore, the discovery of SIVs in African species identified the origin of HIVs. However, the events behind HIV emergence are still under debate. Some authors consider that human exposure to SIVs through bush meat consumption is the original source of AIDS ('cut-hunter theory'). Others believe that simian exposure is necessary but insufficient for HIV emergence as a human pathogen, which requires adaptation to the new human host. Reuse of needles and syringes or transfusions may have played a role in triggering SIV adaptation to humans. It is probable that deforestation, political unrest, increase in urbanization and travel in the second half of the twentieth century also acted as cofactors of HIV emergence. Altogether, the action of these factors explain why HIVs only emerged in the second half of the twentieth century while people in sub-Saharan Africa were exposed to SIVs for millennia.

Virology

Currently, there are 47 fully sequenced SIV genomes from 21 NHP species. Partial genomic sequences are available for 13 additional SIVs, and serological evidence only of SIV infection has been obtained for seven primates (**Table 1**). Asian species of Old World monkeys (colobine and macaques), as well as some African species (such as baboons) do not carry a species-specific SIV, suggesting that the last common ancestor of the catarrhines (Old World monkeys and apes) was not SIV-infected 25 million years ago and that SIV emerged after species radiation, from a nonprimate source.

Classification and Taxonomy

In most instances, the infected NHP species represents the reservoir of that virus type, which is designated by a three-letter abbreviation of the vernacular name of the host (**Table 1**). When related NHP subspecies are infected, the subspecies name is included in virus designation. Thus, for chimpanzee subspecies infected by SIVs, the two SIVcpz are identified as SIVcpz.Ptt (from *Pan troglodytes troglodytes*) and SIVcpz.Pts (from *P. t. schwenfurthii*). For individual isolates, nomenclature includes SIV type and the country of origin: SIVrcmGB1 is a red-capped magabey virus isolated from Gabon. The year of sample can also be included: SIVsmmSL92 is an SM virus isolated from Sierra Leone in 1992. This feature is useful in tracking the origin and evolution of viruses.

Phylogenetic Relationships

SIVs have a starburst phylogenetic pattern, suggesting the evolution from a single ancestor, and a high genetic divergence, forming six SIV lineages with genetic distances of up to 40% in Pol proteins (**Table 2** and **Figure 1**). Each SIV lineage is represented by two or more strains. The l'hoesti lineage is unique in being formed by SIVs circulating in distantly related species. The relationship between SIV lineages and newly characterized SIVs is complicated by sequence diversity and recombination that results in different clustering patterns when different genomic regions are analyzed.

To better understand SIV phylogenetic relationships, a brief presentation of primate species radiation follows. African NHPs belong to two different groups: Old World monkeys and anthropoid primates (apes). Two ape genera are endemic in Africa: *Pan* (formed by the four subspecies of chimpanzees and bonobo) and *Gorilla*. The Old World monkeys (family *Cercopithecidae*) are divided into two subfamilies (*Cercopithecinae* and *Colobinae*), separated 11 million years ago (**Figure 1**). *Cercopithecinae*

Table 1 African apes and monkeys infected with SIV

Species/ subspecies	*Virus type*	*Geographic location*[a]	*Seroprevalence*	*Pathogenicity*	*Cross-species transmission*
Common chimp (*Pan troglodytes troglodytes*)	SIVcpz.Ptt	Central Africa (Cameroon, Gabon, Congo)	<10%	Not reported	Humans, HIV-1 groups M and N*P. t. velerosus*
Eastern chimp (*Pan troglodytes schweinfurthii*)	SIVcpz.Pts	East Africa (Tanzania, Democratic Republic of Congo-DRC)	<10%	Thrombocytopenia	Not reported
Pan troglodytes velerosus	SIVcpz.Ptt[b]	Zoo in Cameroon		Not reported	
Gorilla gorilla	SIVgor	West-Central Africa (Cameroon)	?	Not reported	Humans, HIV-1 group O
Sooty mangabey (*Cercocebus atys*)	SIVsmm	West Africa (Sierra Leone, Liberia, Ivory Coast)	20–58%	AIDS	Humans, HIV-2 Experimentally to *M. mulatta* (SIVmac), *M. nemestrina* (SIVptm), *M. fascicularis* and *M. arctoides* (SIVstm): AIDS. Accidentally to *L. aterrimus* (AIDS)
Red-capped mangabey (*Cercocebus torquatus*)	SIVrcm	West-Central Africa (Gabon, Cameroon, Nigeria)	10–20%	Not reported	Agile mangabey Experimentally, to *Macaca mulatta* and *M. fascicularis* (no AIDS)
Agile mangabey (*Cercocebus agilis*)	SIVagi	West-Central Africa (Cameroon)	0–10%	Not reported	Not reported
White-crowned mangabey (*Cercocebus lunulatus*)	SIVagm.ver[b]	Zoo in Tanzania		Not reported	
Gray-crested mangabey (*Lophocebus albigena*)	?	Central Africa	?	?	?
Black mangabey (*Lophocebus aterrimus*)	SIVbkm	Central Africa (DRC)	Not known	Not reported	Not reported
Mandrill (*Mandrillus sphinx*)	SIVmnd-1	Central Africa (Gabon)	50%	AIDS in captivity	Not reported
	SIVmnd-2	West-Central Africa (Cameroon, Gabon)	50%	AIDS in captivity	Experimentally, to *M. mulatta* (transient infection)
Drill (*Mandrillus leucophaeus*)	SIVdrl	West-Central Africa (Nigeria, Cameroon, Gabon, Bioko)	Not known	Not reported	Not reported
Yellow baboon (*Papio cynocephalus*)	SIVagm.ver[c]	Tanzania	Not known	Not reported	Not reported
Chacma baboon (*Papio ursinus*)	SIVagm.ver[c]	South Africa	Not known	Not reported	Not reported
Allen's monkey (*Allenopithecus nigroviridis*)	?	Central Africa	?	?	?
Talapoin (*Miopithecus talapoin, M. ougouensis*)	SIVtal	Central Africa (Gabon, Angola, Cameroon)	11%	Not reported	Transient infection in Rh upon experimental transmission

Table 2 SIV clusters based upon phylogenetic relationships

Cluster	*Species*	*SIV strain*	*Comments*
1	Arboreal guenons (*Cercopithecus*)	SIVsyk, SIVblu, SIVgsn, SIVdeb, SIVmon, SIVden, SIVmus, SIVasc, SIVtal, SIVery	Ancestral source of SIVcpz/SIVgor/HIV-1 (SIVgsn, SIVmon, SIVmus, and SIVden harbor a *vpu* gene); lineage formed by all arboreal guenons; partial sequences from SIVbkm from the black mangabey cluster in this lineage
2	Sooty mangabey	SIVsmm	Ancestral virus of SIVmac/HIV-2; SMs from Ivory Coast harbor SIVsmm strains related to the epidemic HIV-2 groups A and B; those from Sierra Leone are the sources of HIV-2 groups C-H
3	African Green Monkey	SIVagm (SIVagm.ver, SIVagm.tan, SIVrcm. gri, SIVagm.sab)	Four different SIV subtypes described for each species in the genus *Chlorocebus*, suggesting host-dependent evolution; SIVagm.sab is a recombinant between an SIVagm ancestor and a SIVrcm-like virus
4	L'Hoest supergroup, mandrill	SIVlhoest, SIVsun, SIVmnd-1, SIVpre	Host-dependent evolution for monkeys in the C.l'hoesti supergroup; cross-species transmission from solatus guenon to mandrills
5	Red-capped Mangabeys	SIVrcm, SIVagi	Originally considered recombinants, now appear to be 'pure' viruses; SIVagi is cross-species transmitted from RCMs
6	Mantled colobus	SIVcol	First virus isolated from *Colbinae*; other viruses from Western colobus species do not cluster with SIVcol

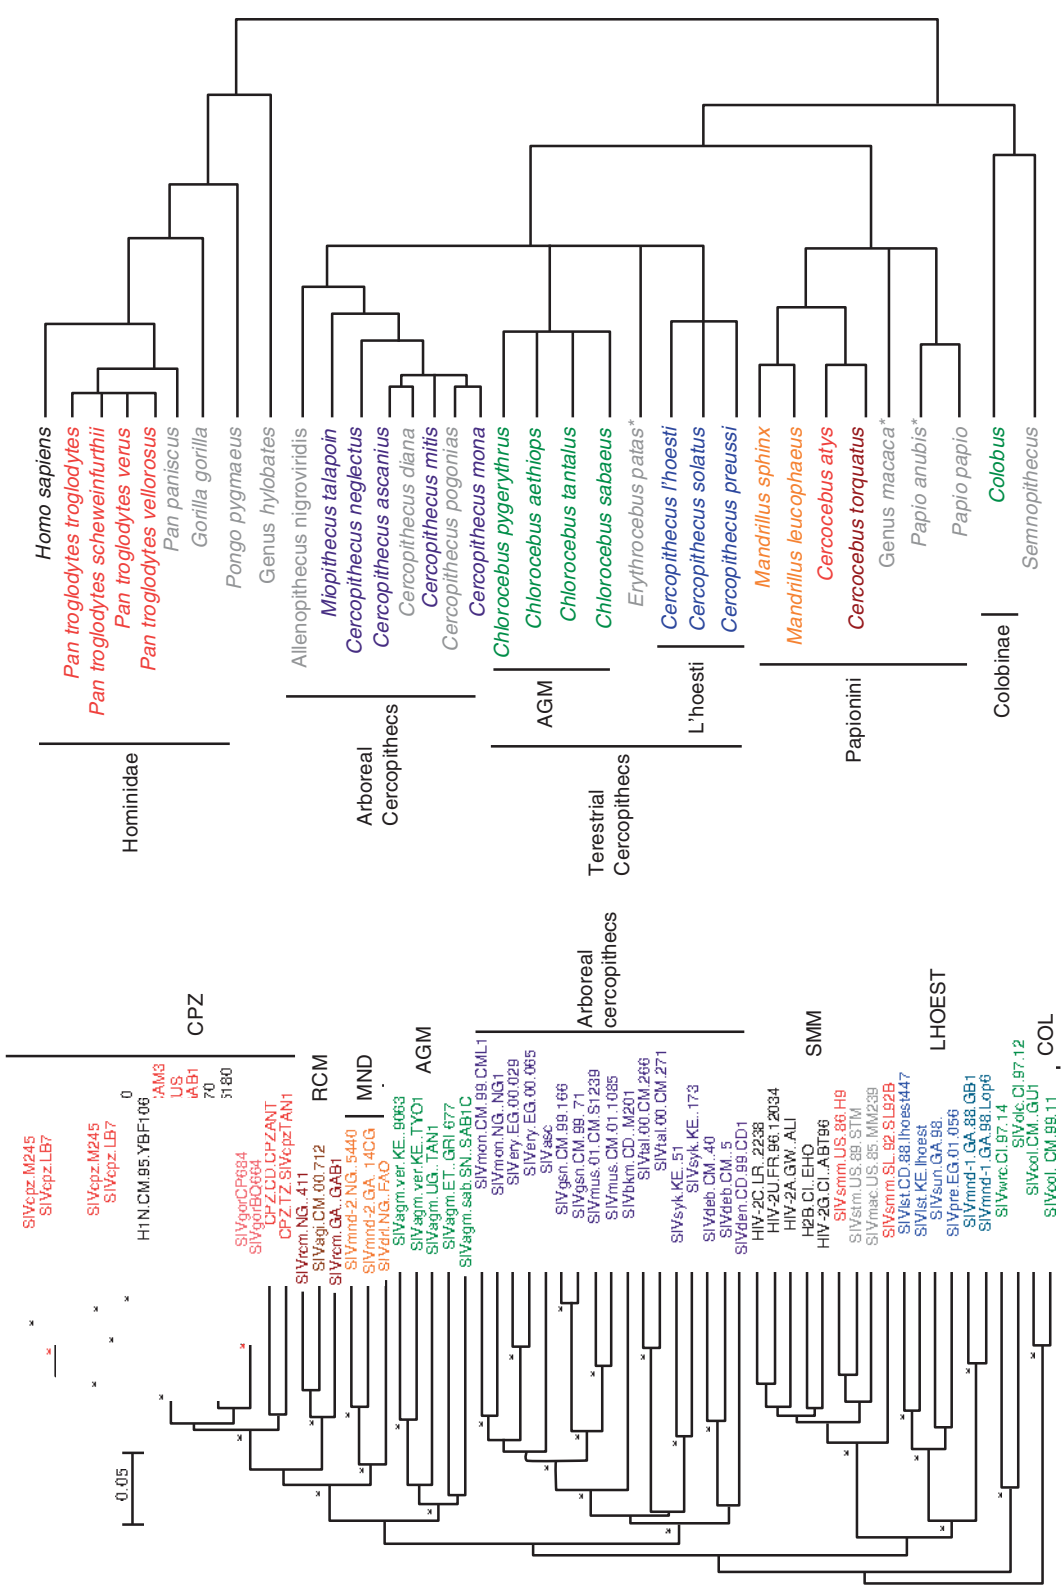

Figure 1 Comparison between SIV phylogeny (a) and primate phylogeny (b). Neighbor-joining tree constructed from available SIV sequences (a); primate phylogeny is a schematic using relationships cited in the text (b). While general alignment of host vs. virus can be observed, cross-species transmissions and viral recombination events make this correlation less than absolute. Asterisks indicate significant bootstrap values. Adapted from VandeWoude S and Apetrei C (2006) Going wild: Lessons from T-lymphotropic naturally occurring lentiviruses. *Reviews in Clinical Microbiology Reviews* 19: 728–762, with permission from American Society for Microbiology.

are divided into two tribes: Papionini (mangabeys (*Cercocebus* and *Lophocebus*), baboons (*Papio*), mandrills and drills (*Mandrillus*), gelada (*Theropithecus*), and the Asian genus, *Macaca*) and Cercopithecini (25 species in 3 arboreal genera: *Allenopithecus*, *Miopithecus*, and *Cercopithecus*, and three terrestrial genera: *Erythrocebus*, *Chlorocebus*, and *Cercopithecus lhoesti* supergroup).

The approximate equidistance among the major SIV lineages does not always match the relationships among their hosts (**Figure 1**). Thus, terrestrial monkeys form a single clade indicating that the evolutionary transition between arboreality and terrestriality has occurred only once among the extinct lineages. However, each of the terrestrial genera are infected with specific viral lineages. Arboreal guenons are infected with a cluster of viruses sharing biological properties and structural features. Papionini monkeys are infected with related viruses, though a higher proportion of recombinant viruses can be observed in these monkeys.

Genome Organization and Composition

SIVs have a complex genomic structure with three structural genes – *gag* (group antigen gene), *pol* (polymerase), and *env* (envelope) – and several accessory genes whose number varies in different SIVs. The accessory genes *vif* (virus infectivity factor), *tat* (transcriptional *trans*-activator), and *rev* are facilitators of viral transcription and activation; *tat* and *rev* each consists of two exons; *nef* induces CD4 and class I downregulation. Three accessory genes are specific for primate lentiviruses: *vpr*, *vpx*, and *vpu*. All primate lentiviruses harbor *vif*, *rev*, *tat*, *vpr*, and *nef*. The presence of *vpx* and *vpu* is variable and defines three patterns of genomic organization (**Figure 2**): (1) SIVsyk, SIVasc, SIVdeb, SIVblu, SIVtal, SIVagm, SIVmnd-1, SIVlhoest, SIVsun, and SIVcol contain no *vpx* or *vpu*; (2) Papionini viruses, SIVsmm, SIVmac, SIVstm, SIVrcm, SIVmnd-2, SIVdrl together with HIV-2 harbor a *vpx* gene, acquired following a nonhomologous recombination and duplication of the *vpr*; and (3) SIVcpz, SIVgor, SIVgsn, SIVmus, SIVmon, SIVden together with HIV-1 encode a *vpu* gene. *vpu* first appeared in cercopithecines, which appear to be the reservoir for viruses in the SIVcpz/HIV-1 lineage. SIVblu, SIVolc, SIVwrc, SIVbkm, SIVery, and SIVagi have not yet been completely sequenced; therefore, their classifications are pending.

SIV Recombination

Virus substrain recombination is a hallmark of SIVs and represents an important intrinsic mechanism other than rapidly accumulating point mutations for developing strains adapted to evade host defense mechanisms or for cross-species transmission. The most critical recombination of SIVs appears to be that involving SIVgsn/mon/mus and SIVrcm which resulted in the origin of the chimpanzee SIVcpz. Subsequent cross-species transmission from chimpanzees to humans is the root cause of the HIV/AIDS

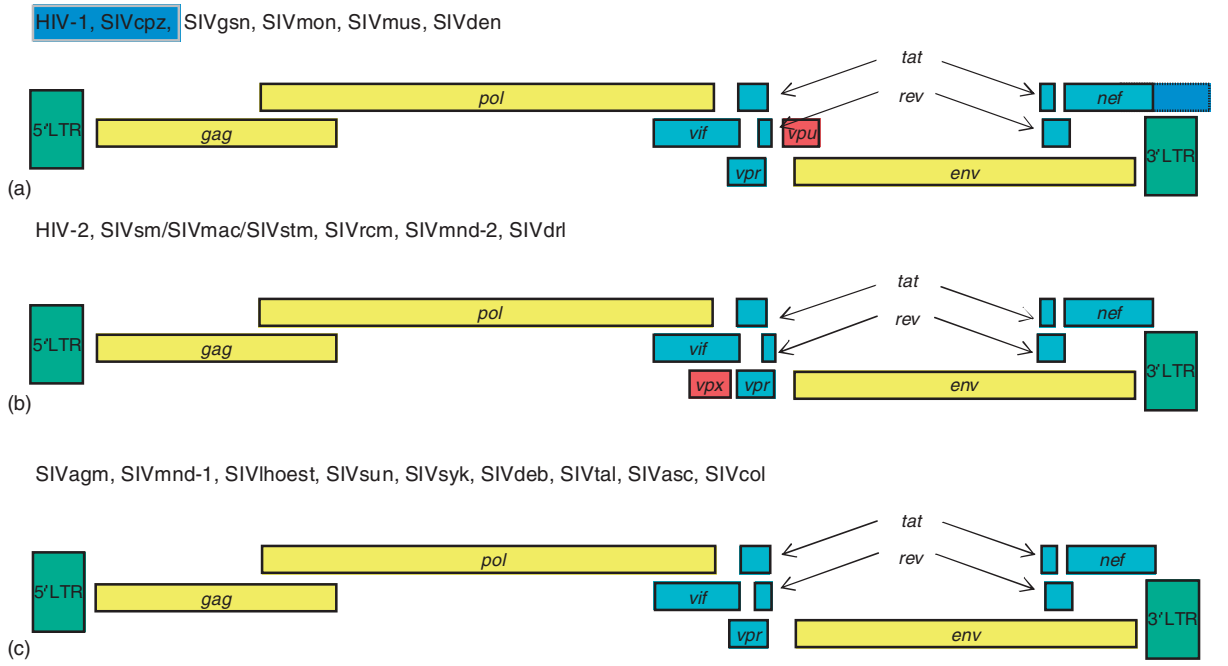

Figure 2 Genomic organization of the SIV strains belonging to different genomic types. SIV classification based on genomic structures is not superimposable on phylogenetic relationships. For references, see **Table 1**. Adapted from VandeWoude S and Apetrei C (2006) Going wild: Lessons from T-lymphotropic naturally occurring lentiviruses. *Reviews in Clinical Microbiolology Reviews* 19: 728–762, with permission from American Society for Microbiology.

pandemic. Other recombinant SIVs include SIVagm.sab (containing SIVrcm-like fragments) and SIVmnd-2/SIVdrl (mosaic between SIVrcm and SIVmnd-1).

Host Range

Typically, SIVs are restricted to their host species (species-specific). However, cross-species transmissions can occur as rare events, the most notable of which were those of SIVrcm and SIVgsn/mon/mus to chimpanzees to generate SIVcpz and those of SIVcpz and SIVsmm to humans to generate HIV-1 and HIV-2, respectively. Macaque exposure to SIVsmm, SIVagm, SIVsun, and SIVlho resulted in persistent infection and induced AIDS. In the wild, SIVagm has been isolated from a yellow baboon (*Papio cynocephalus*), a chacma baboon (*P. ursinus*), and patas monkey (*Erythrocebus patas*). In captivity, in Kenya, SIVagm.ver was transmitted to a white-crowned mangabey (*Cercocebus lunulatus*). None of these recipient species have been reported to date to carry a specific SIV, which may explain the higher susceptibility to cross-species transmitted infection. It is not known if SIVagm is endemic or pathogenic in these species. SIVmnd-1 also resulted from cross-species transmission of SIVsun from sympatric *Cercopithecus lhoesti solatus*. The reasons for success of cross-species transmission infections, and the factors necessary for infection to result in pathogenicity, have not been clearly delineated.

Coreceptor Usage

Similar to HIV-1, SIVs use CD4 as the binding receptor, and chemokine co-receptors such as CCR5 and CXCR4. Most of the SIVs naturally infecting African NHPs use CCR5 as the main co-receptor. Different from HIV-1, for which a switch in viral tropism from R5 ('macrophage' tropic) to X4 ('lymphocyte' tropic) occurs with disease progression, no correlation between co-receptor usage and pathogenesis *in vivo* can be established for SIVs. SIVmnd-1, SIVagm.sab and some strains of SIVsmm use CXCR4, with no pathologic consequence. Experimental infection of sabeaus AGMs with SIVagm.sab (an X4/R5 virus) did not show a particular pattern of viral replication or disease progression. SIVrcm uses the CCR2b co-receptor for viral entry as a consequence of a 24-bp deletion in the CCR5 gene. As such, this example illustrates selected viral evolution, similar to CXCR4 infection of humans who possess the delta-32 mutation in the CCR5 gene.

Diagnosis

Antibody Detection

Serology is the gold standard for studying the prevalence of SIVs in NHPs. Commercial HIV-1/HIV-2 enzyme-linked immunosorbent assay (ELISA) and Western blot assays can be used for anti-SIV antibody screening in NHPs due to cross-reactivity with other lentiviral lineages. For a more sensitive detection of SIVs, two strategies are available: use of a highly sensitive line assay (INNO-LIA HIV, Innogenetics) as a screening test; more than 10 different new SIV types have been identified using this strategy. Alternatively, the use of SIV-specific synthetic peptides allows for increased sensitivity (Gp41/36 peptide) and specificity (V3 peptides); several SIVs have been discovered using this technique.

Propagation and Assay in Cell Culture

The efficiency of *in vitro* isolation of SIVs varies widely. The ability to replicate in human PBMC or T-cell lines has been documented for SIVcpz, SIVsm/SIVmac, SIVagm, SIVlhoest, SIVmnd-1, SIVrcm, SIVmnd-2, and SIVdrl and constitutes the major argument for the threat that these viruses may pose for humans (**Table 3**). SIVs' ability to infect human macrophages has also been reported for SIVsmm, SIVagm, and SIVmnd. SIVsun and SIVsyk cannot replicate in human peripheral blood mononuclear cells (PBMCs) or macrophages. SIVagm replication in human PBMCs is strain specific. SIVmnd-1 was reported to replicate in human PBMCs but not in macrophages. Some SIVs might require special culture conditions.

Epidemiology

Prevalence in the Wild

Due to their number, genetic diversity, and large distribution in sub-Saharan Africa, guenons (tribe Cercopithecini) are the largest reservoir species for SIV. SIV prevalence is high (50–60%) in some monkey species (AGMs, SMs, mandrills, l'Hoest and Syke's monkeys) and significantly lower (4–5%) in others (greater spotted nose monkeys, mustached monkeys, or agile mangabeys). Only two chimpanzee subspecies and one of gorilla were reported to carry SIVs at low prevalence levels. Geographical foci of SIVcpz infection were defined within the endemic area. The highest SIVcpz prevalence was observed in Cameroon (10%), in agreement with HIV-1 emergence in that area. The SIVgor strains also originated from Cameroon. No evidence of SIV infection was thus far reported for some African species, most notably baboons and some species of mangabeys.

Modes of Transmission

Epidemiologic patterns of SIV seroconversion in natural hosts showed the most efficient virus transmission during adult contact, similar to HIV-1, which is spread by sexual contact via primarily mucosal exposure. Horizontal

transmission also occurs by biting or aggressive contact for dominance. While maternal to offspring transmission has been reported, it is relatively rare compared to horizontal transmissions.

Pathogenesis and Pathology

Pathogenicity of Natural SIV Infection

For 20 years, it was believed that natural SIV infections were nonpathogenic. This was a major paradox given the context of an active viral replication and high prevalence levels. However, occasionally, natural SIV infection of mandrills, AGMs, and SMs may eventually lead to the development of immunodeficiency. Cases of progression to AIDS in African NHP hosts are rare, possibly because host↔virus adaptation has occurred, resulting in a long-term persistent infection with an incubation period that exceeds the normal life span of the naturally infected animal.

AIDS was also reported to develop in African NHPs after infection with heterologous viruses (an SIVsmm-infected black mangabey, HIV-2-infected baboons, and a subset of HIV-1-infected chimpanzees). In these cases, disease progression occurred earlier than in naturally infected African NHP hosts, and the outcome of cross-species transmitted SIV infections varied widely, with some animals clearing the cross-species transmitted SIV, others being persistently infected (albeit without disease progression) and the rest progressing to AIDS.

Cell and Tissue Tropism

Upon infection, SIVs are disseminated to tissues by the blood. The target cells are CD4+ T lymphocytes and macrophages, with lymphocytes vastly predominating in terms of infected cells. The major sites of SIV replication are the gastrointestinal tract, lymph nodes (LNs), spleen, and other lymphoid tissues. Natural hosts for SIV infection (SMs, AGMs, mandrills, and chimpanzees) express lower levels of CCR5 on CD4+ T cells in blood and mucosal tissues, compared to immunodeficiency-susceptible hosts (macaques, baboons, and humans). Moreover, chimpanzees, which are more recent hosts of SIV, show an intermediate level of CD4+ CCR5+ T cells. As CCR5 is the main co-receptor for SIVs, African species with endemic naturally occurring SIVs may be less susceptible to pathogenic disease because they have fewer receptor-expressing targets for infection, leading to an evolutionary mechanism of 'passive co-existence' between SIV replication and natural host immune system function.

Virus Replication *In Vivo*

The lack of disease in African NHPs is not associated with effective host containment of viral replication, this is in contrast to HIV/SIV pathogenic infections for which levels of plasma viral loads (VLs) are the best predictor of the disease progression. Experimental SIV infections in natural hosts (SMs, AGMs, and mandrills) showed a consistent pattern of SIV replication with a peak of viremia (10^6–10^9 copies per ml of plasma) occurring around days 9–11 post infection, followed by a sharp decline (1–2 logs) and attainment of a stable level of VL (set point), which is maintained at high levels (10^5–10^6 copies per ml of plasma) during chronic infection (**Figure 3**). Experimental data were confirmed in naturally SIV-infected African NHPs, where chronic VLs were higher than in HIV-1 chronically infected asymptomatic patients and remained relatively constant over years. Some species-specific differences in viral replication between different African NHP species can occur without significant pathogenic consequences: SIV VLs are generally lower in AGMs than in other African NHP species. SIV proviral loads in the LNs are also 100-fold lower in AGMs than in naturally infected SMs or MNDs.

Immune Response and Persistence

Acute SIV infection in the natural host induces massive mucosal CD4+ T-cell depletion, of the same magnitude as in pathogenic HIV/SIV infection. However, during chronic infection, in spite of persistent high viral replication, there is a partial immune restoration of CD4+ T-cells in natural hosts, probably as a consequence of the preservation of a mucosal immunologic barrier and normal levels of immune activation. In marked contrast to HIV infection, in which a failure of the lymphoid regenerative capacity is an important factor in the pathogenesis of the immunodeficiency, the regenerative capacity of the CD4+ T-cell compartment is fully preserved in natural hosts and may play a key role in determining the lack of disease progression. Interleukin-7 (IL-7) has a critical role in preserving T-cell regeneration and in avoiding CD4+ T-cell depletion and disease progression in natural infections.

The high level of viral replication during chronic SIV infection in natural hosts is associated with low level of immunologic pressure, T-cell activation and proliferation, and apoptosis, resulting in limited bystander pathology. Thus, natural hosts of SIV are not confronted with the massive tissue destruction observed in HIV-1/SIVmac infection. This equilibrium is probably disrupted after cross-species transmission of viruses, when virus penetrates a new ecological niche, inducing a different immune response.

In natural SIV infections, *de novo* immune responses are muted compared to pathogenic HIV/SIVmac infections that induce robust neutralizing and cellular immune responses and continuous immune escape. Therefore, it is believed that natural SIV infections are characterized by tolerance to the virus or to specific antigens or epitopes,

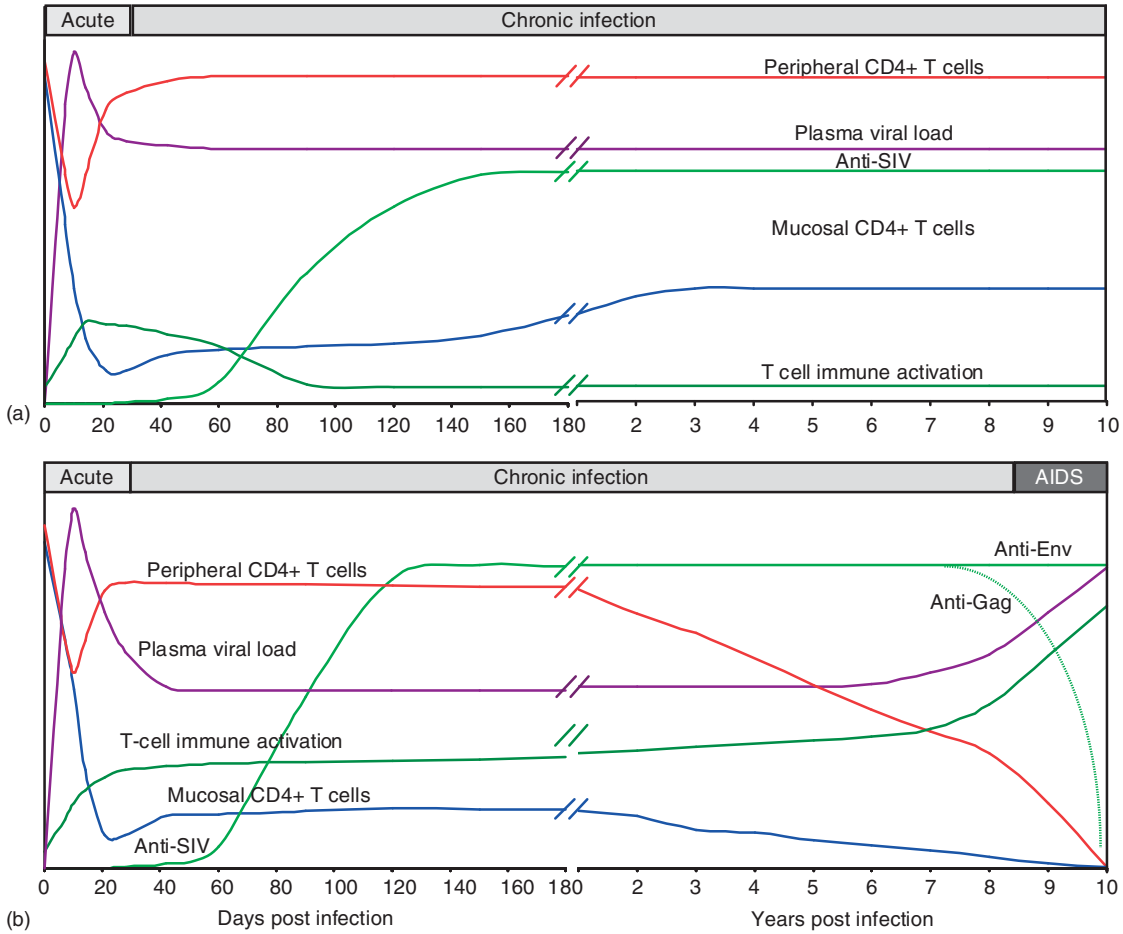

Figure 3 Pathogenesis of SIV infection in natural hosts (a) compared to the pathogenesis of HIV-1 infection (b). No significant difference can be observed between the two models during acute infection. During chronic SIV infection, natural hosts harbor higher viral loads, lower antibody titers, lower levels of T-cell immune activation. CD4+ T-cell levels are maintained at near pre-infection levels in natural hosts. Mucosal CD4+ T cells are partially restored during chronic infection, despite high levels of viral replication. Progression to AIDS is absent in most cases, being a rare outcome of SIV natural infection.

or by immune responses that differ qualitatively and quantitatively from those observed in pathogenic infections. Antibody responses are observed in natural SIV infection, but mainly directed to Env rather than Gag, as in SIVmac infection. The intensity of the antibody response is lower in natural hosts: for equivalent VL, antibody titers in SMs are about one log lower than in RMs.

Neutralizing antibodies are rarely detected in SIV-infected SMs, while SIVagm is susceptible to neutralization depending on the cell line used in the assay. In contrast to HIV-1, SIVagm infectivity is enhanced by the addition of soluble CD4 and this enhanced infectivity can be abrogated by SIVagm-specific antibodies. However, very high amounts of passively transferred specific immunoglobulins failed to prevent SIVagm infection suggesting that humoral immune response in AGMs is largely ineffective.

SIV-infected SMs and AGMs develop cytotoxic T-lymphocyte responses that are functional to some degree in controlling viral replication. Moreover, there is evidence of transient but massive expansion of CD8+ T cells in infected AGMs, SMs, and mandrills during acute infection, showing that the immune system of natural hosts is influenced by SIV infection. It is not yet clear if CD8+ T-cell expansion results from active stimulation of the specific immune response or from a nonspecific stimulation of the immune system in general.

SIV-specific T-cell responses can be detected in the majority of naturally SIV-infected NHPs. However, their magnitude is generally lower than in HIV-infected patients. In addition, no correlation was found between breadth or magnitude of SIV-specific T-cell responses and either VLs or CD4+ T-cell counts. Moreover, the magnitude of the SIV-specific cellular responses did not appear to determine the level of T-cell activation and proliferation in SMs and AGMs. Therefore, the presence of a strong and broadly reactive T-cell response to SIV antigens is not a requirement for the lack of disease progression in natural infections; conversely, the complete

suppression of SIV-specific T-cell responses (i.e., immunologic tolerance and/or ignorance) is not required for the low levels of T-cell activation that are likely instrumental in avoiding AIDS.

Both acute and chronic natural SIV infections (SMs, AGMs, and mandrills) are associated with lower levels of T-cell activation, pro-inflammatory responses, immunopathology, and bystander apoptosis than pathogenic HIV/SIV infection. In addition, natural hosts of SIV maintain T-cell regenerative capacity, with normal bone marrow morphology and function, normal levels of T-cell receptor excision circle (TREC)-expressing T cells and preserved LN architecture. This downregulation of the immune response favors preservation of CD4+ T-cell homeostasis and is completely different from pathogenic HIV/SIV infections for which chronic immune activation and proliferation drive excessive activation-induced T-cell apoptosis, and ultimately result in the collapse of the immune system and progession to AIDS. Altogether, this is consistent with the hypothesis that chronic immune activation is a major determinant of disease progression during HIV infection.

In AGMs, low immune activation levels are due to a strong anti-inflammatory response (with induction of TGF-β1 and FOXP3, and a significant increase in IL-10 expression), which occurs early in the SIVagm infection. Together with an early increase in the levels of CD4+ CD25+ T cells, this results in the rapid establishment of an anti-inflammatory environment which may prevent damages to the mucosal immunologic barrier, microbial translocation, and thus aberrant chronic T-cell hyperactivation that is correlated with progression to AIDS during HIV-1/SIVmac infection.

Virulence

Viral factors may be related to a lack of virulence in natural SIV infections. In RMs, SIVmac *nef* gene deletion mutants were reported to replicate poorly *in vivo* and to be nonpathogenic, which corroborates the description of *nef* gene mutations of HIV-1-infected long-term progressors. Nef downregulates CD4, CD28, and the class I major histocompatibility complex, resulting in virus immune evasion. Nef may also enhance the responsiveness of T cells to activation, but this effect is not uniformly observed among SIVs. All SIVs from African monkeys have open reading frames corresponding to a functional Nef, and therefore the *nef* structure cannot account entirely for differences in pathogenicity. Nef proteins from the great majority of primate lentiviruses, including HIV-2, down-modulate T-cell receptor-CD3, which subsequently blocks T-cell activation. In contrast, Nef proteins derived from HIV-1 and closely related SIVs do not induce CD3 downregulation, which may have predisposed the simian precursor of HIV-1 to greater pathogenicity in humans. However, simian counterparts of HIV-1 (SIVcpz and SIVgsn/SIVmon/SIVmus), which do not induce CD3 downregulation, do not typically induce AIDS in their natural hosts. Further, SIVmac, which induces CD3 downregulation, is even more pathogenic in RMs than HIV-1 is in humans, suggesting that this accessory gene does not solely account for virulence.

Clinical and Pathologic Features

In contrast to macaques in which SIV infection constantly leads to an AIDS-like disease characterized by opportunistic infections and cancers, SIV infection in natural hosts generally does not show any clinical or pathological abnormalities. During progression to AIDS, SIV-infected RMs initially develop lymphadenopathy with confluent follicular hyperplasia, followed by LN atrophy due to lymphoid depletion and fibrosis. In contrast, SIV-infected natural hosts display normal LN morphology without evidence of either hyperplasia or depletion. No follicular trapping or CD8+ T-cell infiltration of the germinal centers and no replacement of the normal LN architecture with connective tissue is observed in chronic SIV infection of natural hosts. Also, no thymic disinvolution, nodular lymphocytic infiltrates, or giant cell disease are seen in SIV-infected natural hosts. The few AIDS cases reported in African NHP hosts presented with the entire range of diseases and pathologic lesions of AIDS.

Host Genetic Resistance

SIV species specificity has typically been ascribed to factors such as virus–host receptor compatibility and cellular machinery needed to direct viral replication. Specific host factors also prevent SIV cross-species infections *in vitro*.

Cytidine deaminase and Vif

Vif is involved in species specificity of SIVs. Its cellular target is a member of the cytidine deaminase APOBEC family. The cellular deaminase is incorporated into the virion during the reverse transcription to direct the deamination of cytidine to uridine on the minus strand of viral DNA. Deamination results in catastrophic G-to-A mutations followed by inactivation and/or degradation of the viral genome. At least two primate APOBEC family members (APOBEC3G and APOBEC3F) play a central role in antagonizing viral replication because they are expressed in natural targets of SIVs, including lymphocytes and macrophages. Lentiviruses are able to successfully infect and replicate in host target cells containing APOBEC when host-adapted Vif interferes with this mechanism. Vif activity is species specific: human APOBEC3G is inhibited by HIV-1 Vif but not by SIVagm Vif, whereas AGM APOBEC3G is inhibited by SIVagm Vif, but not by HIV-1 Vif. This specificity relies on a single amino acid change that can alter the ability of *vif* to interfere with APOBEC activity.

TRIM5-α

The cytoplasmic body component TRIM5-α, previously referred to as REF-1 and LV-1, restricts HIV-1 infection of monkey cells. TRIM5-α interferes with the viral uncoating step that is required to liberate viral nucleic acids into the cytoplasm upon viral binding and fusion with the target cell. Sensitivity to TRIM5-α restriction is dictated by a small region in the viral capsid gene, previously shown to be involved in cyclophilin A binding. Subtle amino acid differences in this region influence the strength of binding to TRIM5-α and, hence, relative sensitivity to its restriction. HIV-2, but not closely related SIVmac, is highly susceptible to RM TRIM5-α. Furthermore, HIV-2 is weakly restricted by human TRIM5-α, which may contribute to the lower pathogenic potential of the HIV-2 vs. HIV-1 in humans. Strategies to exploit TRIM5-α restriction for intervention of HIV-1 replication are under development.

Glossary

Codon The basic unit of the genetic code consisting of three consecutive nucleotides in DNA that specify the order of amino acids in a protein.

Monocistronic mRNA Messenger RNA that codes for a single protein.

Monoclonal antibody Antibody made *in vitro* that reacts with a single protein.

Pneumocystis carinii A fungus that causes pneumonia, especially in persons or animals with suppressed immune systems.

Polyprotein A precursor protein that is cut after its synthesis into smaller functional proteins.

Ribosomal frameshifting A change in the translational reading frame that allows the synthesis of different proteins from a single region of overlapping genes. For example, if the genetic code begins on the first of the three nucleotides of a codon, the out-of-frame code would begin on the second nucleotide. A second frameshift beginning on the third nucleotide is also possible. Frameshifting is an economical way to code for proteins.

Syncytium Cell-derived structure in culture or *in vivo* giant cell consisting of fused cells having more than one nucleus.

Virion Infectious viral particle containing the genome of the virus and a full complement of viral proteins required for growth and replication.

Western blot Nitrocellulose blotting paper containing viral polypeptides sorted by molecular size. The blot is soaked in diluted serum suspected of containing antibodies. A positive test requires binding to polypeptides from at least two different viral genes. More weight is often given to env polypeptide reactions. False results against a single *gag* coded protein commonly occur and are reported as indeterminant.

Zoonosis Microbial infection (virus, bacteria, or parasite) acquired directly through animal contact that progresses to a clinical disease.
Zoonotic infection Microbial infection (virus, bacteria, or parasite) acquired directly through animal contact that may or may not progress to disease.

Introduction

Simian type D retroviruses (SRVs) and Mason–Pfizer monkey viruses (MPMVs) are members of the family *Retroviridae* and comprise one species belonging to the genus *Betaretrovirus*. These viruses naturally infect members of the nonhuman primate genus *Macaca*, commonly known as macaque monkeys. SRV appears to be highly species specific, although the virus will replicate in the cells of other primate species, including tissue culture cells of human origin. Betaretroviruses are characterized by their simple genomic structure consisting of 4 genes, *gag*, *pro*, *pol*, and *env* (**Figure 1**).

MPMVs and SRVs are exogenous retroviruses, meaning that the virus is acquired from another infected macaque monkey. This transmission mechanism distinguishes SRVs from endogenous D retroviruses that are inherited and are a part of the genome of the host species. Endogenous D retroviruses occur in both New and Old World monkeys, including African baboons as well as Asian langur and South American squirrel monkeys.

Seven distinct isolates are known and each can be distinguished by serum neutralization tests or competitive binding tests between homologous p27 *gag* proteins. They are named SRV serotypes 1–7. Serotype 3 is also known as MPMV. A nomenclature has been devised that is similar to that used for influenza viruses and is an aid for tracking isolates and their origins. For example, D1/rhe/CA/84 represented the D retrovirus that was isolated at the California Primate Center Davis, CA from a rhesus macaque with an acquired immune deficiency syndrome (AIDS)-like disease and was reported in 1984. D2/Cel/OR/85 was a 1985 SRV-2 isolate from a Celebes black macaque with retroperitoneal fibromatosis (RF) at the Oregon Primate Center. MPMV is the prototype of this viral species and retains its original name for historical reasons.

History

In 1971, the first D retrovirus isolate was reported. The virus was recovered from a rhesus monkey with a

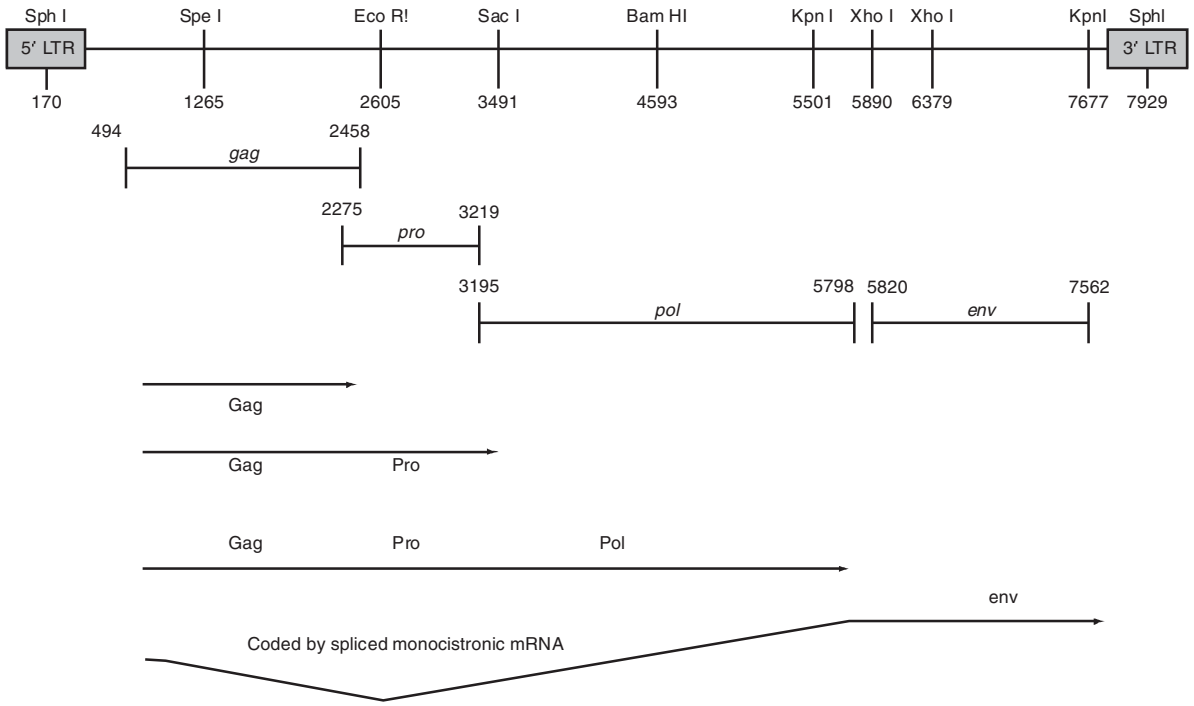

Figure 1 Map of the genome of primate D retroviruses. Top is the provirus that is 8105 nt and codes for four genes in three separate reading frames, *gag*, *pro*, *pol*, and *env*. The messenger RNAs consist of two forms, a genomic-length mRNA that is translated into the polyprotein Gag. After frameshifting(s), Gag-Pro and Gag-Pro-Pol precursors are made. Polyproteins are cleaved into smaller functional virion proteins. The second mRNA form is a spliced mRNA that encodes the Env proteins, SU (also named gp70) and TM (also named gp20). Reprinted from Marracci GH, Avery NA, Shiigi SM, *et al*. (1999) Molecular cloning and cell-specific growth characterization of polymorphic variants of type D serogroup 2 simian retroviruses. *Virology* 261: 43–58, with permission from Elsevier.

mammary carcinoma. The virus was named after the Mason Institute in Worcester, Massachusetts, where the macaque had been housed. The Pfizer Pharmaceutical Company had supported research using this female monkey, hence the name Mason–Pfizer monkey virus (MPMV). The impact of MPMV was greatly enhanced because the virus was isolated directly from cancerous breast tissue. Because of this association with neoplasia, MPMV was classified as an oncornavirus (Onco RNA for cancer-causing RNA virus). This classification persisted for many years.

The finding of MPMV in monkey breast cancer tissue prompted numerous reports in the 1970s of D retroviruses in association with human breast cancer. With the development of sensitive detection techniques along with complete sequencing of the MPMV and SRV genomes, it became apparent that nonhuman primate D retroviral sequences were not causally associated with human tumors. A 1975 report on immune impairment in neonatal monkeys infected with MPMV marked the beginning of our understanding of primate D retroviruses as a causative agent of simian AIDS. The modern era of type D retrovirus research deals with its immunosuppressive properties.

AIDS, the disease, was discovered in 1981 in persons displaying symptoms of a severe and fatal immunodeficiency. The first detailed report consisted of four men with *Pneumocystis carinii* pneumonia, evidence of cytomegalovirus infection (CMV), and Kaposi sarcoma, a skin cancer not commonly seen in young men. Early theories on the cause of AIDS implicated drug-induced impairment of the immune system. Drugs were known to suppress the immune system, but the idea that severe and fatal immune deficiency could be caused by a virus was not yet appreciated. A breeding group of rhesus monkeys that was housed outdoors at the California National Primate Research Center in Davis, CA, played a significant role in changing that perception. This breeding group had a higher mortality rate than monkeys in other outdoor groups only a short distance away. The affected animals had diarrhea, cytomegalovirus infections, and fibrosarcoma, a tumor that resembled Kaposi sarcoma upon microscopic inspection. A link was made between AIDS in monkeys and AIDS in humans. The study of this group of monkeys resulted in the isolation and characterization of a virus related to MPMV. This distinct D retrovirus was named simian retrovirus (SRV) and was used to prove the retroviral etiology of this fatal immune deficiency disease in monkeys. A similar virus was isolated from rhesus macaques at the New England Primate Research Center.

Replication

The synthesis of new progeny virus begins with the DNA provirus that is integrated into a host DNA chromosome (**Figure 1**). The provirus is a double-stranded (ds) DNA copy of the virus genome. The provirus is flanked by two repeated sequences called the long terminal repeat (LTR). The order of the coding and noncoding regions are the LTR, *gag* (for group antigen), *pol* (polymerase), *env* (envelope), and a second copy of the LTR. The viral genome is synthesized from the minus DNA strand of the provirus by host cell enzymes. The newly made viral genome is the same sense as messenger RNA (+-stranded) and is exported from the nucleus without being spliced. The cellular requirement for splicing is bypassed by the interaction of the constitutive transport element (CTE) with cellular proteins. This genomic RNA is translated in the cytoplasm into Gag and Pol viral proteins in a process that involves several steps.

The *gag* gene codes for 654 amino acids that are synthesized as a 78 kDa polyprotein precursor of smaller functional virion proteins. The *gag*-encoded polyprotein is cleaved by a protease enzyme, which in turn is coded by the *pro* gene. This Gag precursor is cleaved into six mature virion proteins, the p10 matrix protein (polypeptide 10 000 Da molecular weight (MW)), pp24 (phosphoprotein), p12 (assembly scaffold domain), p24 major capsid protein, p14 nucleocapsid protein, and p4 (chaperonin binding domain). The major capsid protein, p24 (in M-PMV, p27), is the most abundant protein in the mature virion (**Figures 2(b)** and **3**). The p10 protein is the matrix protein and resides just under the external envelope of the virion (**Figure 3**). The nucleocapsid protein p14 forms a tightly associated complex with the RNA genome. Unlike most other retroviruses, D-type retroviruses form immature capsids that are preassembled in the cytoplasm (**Figure 2** – see arrows). This is facilitated by a cytoplasmic targeting and retention signal in the matrix domain of Gag, which binds to the microtubule motor dynein and targets translating polysomes to the pericentriolar region of the cell where assembly occurs. The p12 region of Gag acts to facilitate this intracytoplasmic assembly process.

The protease (*pro*) gene overlaps the *gag* region by 61 codons (183 nt). The protease is an enzyme that cleaves protein and is highly conserved across the genus with 82.8% and 83.8% identity between SRV-1 and MPMV, respectively. The protease itself is translated from the genome-length mRNA (**Figure 1**) as two polyproteins (Gag-Pro) and Gag-Pro-Pol. Because the *pro* gene is out of frame with respect to *gag*, the polyprotein that contains the protease results from a ribosomal frameshifting mechanism during translation of genome-length mRNA. The final protease protein is produced by two autocatalytic cuts, one at the N-terminus producing a 17 kDa product and a second cut producing the final 13 kDa protease enzyme. The protease is incorporated into the immature capsids in the cytoplasm (**Figure 2** – see arrows). It functions to cleave the *gag*-coded polyprotein into smaller proteins that make up the internal capsid structure of

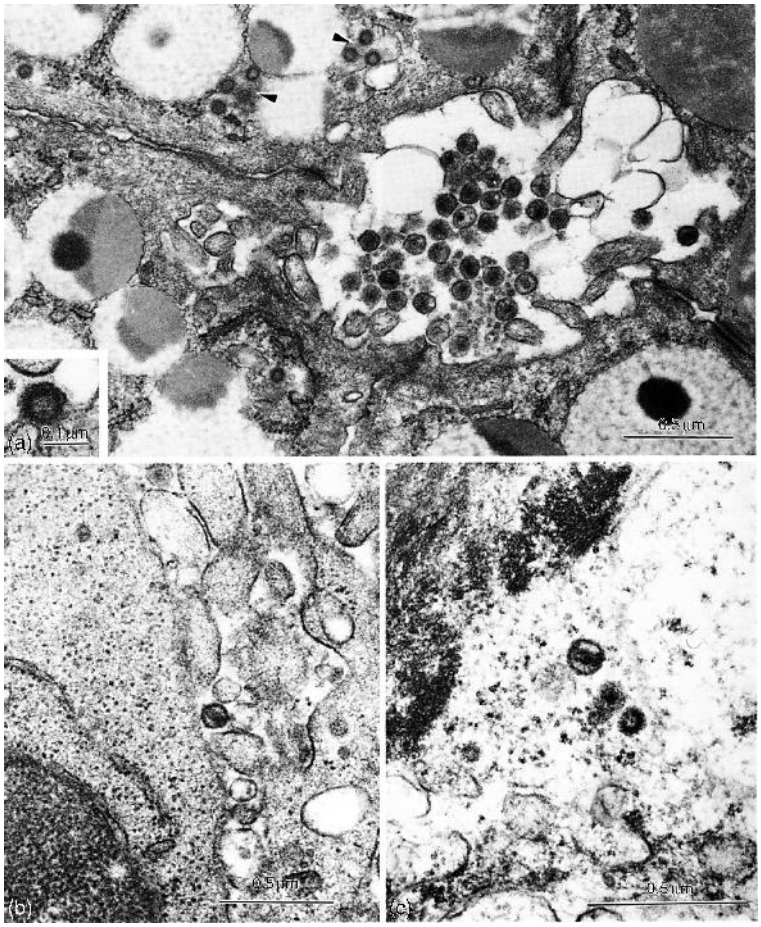

Figure 2 Electron microscopic demonstration of type D retroviral particles in (a) salivary gland, (b) germinal center of a lymph node, and (c) spleen of rhesus monkeys with AIDS. In the salivary gland (a), numerous mature extracellular particles in a small acinar lumen, as well as immature intracytoplasmic A particles (arrows) and a budding particle (inset) are seen. In the germinal center (b), a single mature virion particle adjacent to a lymphoid cell and numerous cellular processes possibly belonging to follicular dendritic cells are seen. (c) In the spleen, a single mature particle is seen in the extracellular space. Modified from Lackner AA, Rodriguez MH, Bush CE, *et al.* (1988) Distribution of a macaque immunosuppressive type D retrovirus in neural, lymphoid, and salivary tissues. *Journal of Virology* 62: 2134–2142, with permission from American Society for Microbiology.

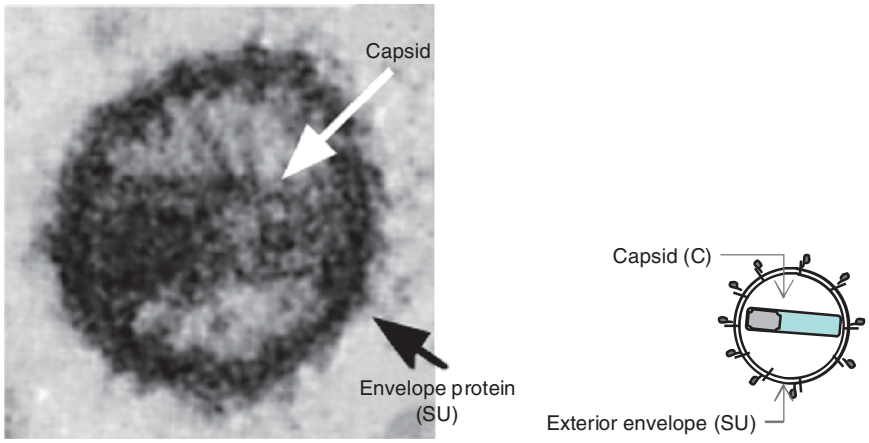

Figure 3 Mature D retrovirus virion showing the external envelope and the major capsid core. Modified from Marx PA, Maul DH, Osborn KG, *et al.* (1984) Simian AIDS: Isolation of a type D retrovirus and transmission of the disease. *Science* 223: 1083–1086, with permission from AAAS.

the virion. The three-dimensional (3-D) structure of the protease has been resolved and this 3-D structure is well conserved across the retrovirus family.

A second ribosomal frameshift within the *pro-pol* overlap region generates a larger polyprotein precursor containing the pol proteins (**Figure 1**). The *pol* gene encodes the reverse transcriptase (RT)-endonuclease and integrase proteins. The gene encoding the integrase of MPMV is located at the 3′ end of the *pol* open reading frame and the RT is encoded by the 5′ end of the gene. The RT, integrase, and endonuclease enzymes function after the progeny virus infects a new cell, and are incorporated into the immature capsids as Gag-Pro and Gag-Pro-Pol precursors. These polyproteins undergo post-translational cleavage during virion maturation to produce separate RT and endonuclease/integrase proteins. They are required to initiate the early steps of replication after the virus enters a host cell to begin a new cycle of replication.

The *env* gene is expressed from the 3′ end of the genome (**Figure 1**). *env* encodes two proteins, the external envelope spike protein (SU for surface) and the transmembrane protein (TM). The mRNA coding of the Env proteins is spliced in the nucleus to remove *gag* and *pol* coding regions. The mRNA is exported to the cytoplasm and is handled like a monocistronic mRNA. The *env* gene product is cleaved into the SU or gp70 (glycoprotein 70 000 Da) (**Figure 1**) and the TM (or gp20). Both the SU gp70 and TM gp20 proteins have sugar molecules bound to some of the amino acids that make up these two proteins. The SU glycoprotein can potentially contain 22 sugar residues. The TM is a membrane-spanning protein that anchors the complex in the virion membrane. An immunosuppressive motif is present within the TM protein and this protein motif may play a role in immune suppression. A monoclonal antibody is available against the TM-gp20 and this antibody is useful for diagnostic testing. The external glycoprotein is the least conserved among the macaque D retroviruses and is reflected in different serotypes. Neutralizing antibodies are defined by binding to the external glycoprotein. Therefore the major biological differences between SRV-1, SRV-2, MPMV, SRV-4, and SRV-5 are in fact differences in the amino acid sequence of Env.

Immature capsids (see arrows in **Figure 2**) are transported to the plasma membrane where they bud through the membrane (**Figure 2** inset) and acquire the Env proteins. The morphology of the completed D-type virion consists of an envelope and a cylindrical or rod-shaped core (**Figure 3**; a virion grown in tissue culture (**Figure 2**), and virions in the extracellular tissue space of an infected rhesus monkey).

The extracellular infectious virion initiates a new round of replication by attaching itself to a susceptible cell via a specific receptor on the surface membrane of the host cell. The receptor molecule for SRV and MPMV is an amino acid transport protein (ATBo) that is present in human tissues and cell lines, including white blood cells.

After entry in the cell, the RT synthesizes a minus DNA strand from the +-sense incoming SRV RNA genome. The RT next catalyzes the synthesis of a complementary plus sense DNA strand, making a dsDNA copy of the D retrovirus RNA genome that contains two LTRs. The LTRs flank the viral genes and, through their interaction with the viral integrase, ensure that the genome will integrate in the correct orientation for expression of the viral genes. Usually DNA codes for RNA, but the RT reverses the process by making DNA from an RNA template, hence its name reverse transcriptase. The integrase then enzymatically integrates the linear dsDNA copy of the original RNA genome into host cell DNA. This dsDNA copy of the virus genome is called a provirus. With transcription of the provirus to form full-length genomic mRNA and spliced env mRNA, the replication cycle is completed and begins a new round.

Natural Hosts

The natural host of SRV and MPMV is the Asian monkey genus *Macaca* or macaques. The known hosts are primarily common laboratory monkeys, such as the rhesus monkey (*M. mulatta*) of northern India, southern China, and geographical areas in between. SRV infection of rhesus macaques in China has been reported. Other macaque species housed at Primate Research Centers are also commonly infected. They include the cynomolgus macaque (*M. fascicularis*), also known as the long-tailed macaque and crab-eating macaque of Southeast (SE) Asia; *M. nemistrina*, the pig-tailed macaque of SE Asia; *M. nigra*, the Sulawesi or Celebes black macaque; and the bonnet macaque, *M. radiata*, of southern India. Feral cynomolgus macaques are infected, showing a natural Asian origin of this virus. Type D retroviruses are a significant problem for laboratory research, since infected animals may develop an AIDS-like disease. The most common SRV isolate in primate centers is SRV-2, followed by SRV-1, SRV-5, and MPMV. SRV-4 is only known from a single outbreak in cynomolgus macaques at a public health laboratory in Berkeley, California.

Transmission

SRV is present in blood, urine, saliva, lymphoid, and nonlymphoid tissues of infected macaques (**Figure 2**). With the possible exception of brain tissue, infectious SRV is found throughout the body. Inoculation of any of these fluids or tissues to rhesus monkeys will transmit the

infection and disease. Although infection is easily transmitted under laboratory conditions, a classic experiment on SRV infections transmitted in outdoor enclosures strongly pointed to natural transmission by bite from infected saliva. In these experiments at the California Primate Center, it was first shown that uninfected monkeys must be in physical contact with infected monkeys for transmission to occur. The need for this contact was proven by keeping uninfected monkeys in the same enclosure with infected monkeys, but separated by two fences creating a 10-foot barrier. The barrier prevented contact between infected and uninfected groups, but allowed birds, rodents, and insects to move freely between the enclosures as well as allowing rainwater to wash back and forth. The result was that only monkeys in physical contact with infected monkeys became SRV infected even after 5 years of testing.

SRV transmission to healthy monkeys was linked to healthy carriers, in particular to female healthy carriers that occupied socially dominant roles in the enclosure. Healthy carriers were infected for as long as 10 years without developing the AIDS-like disease that is characteristic of SRV infections. Repeated testing of the saliva of healthy carriers showed >1 million infectious units of SRV per ml of saliva, hence the likely link between saliva and transmission. Healthy carriers were a major problem for laboratory colonies because they could spread the SRV immune deficiency and themselves remain undetected, compromising the usefulness of these research colonies. The problem is now largely controlled by screening for SRV infection by antibody enzyme-linked immunosorbent assay (ELISA) and polymerase chain reaction (PCR) testing. Infected animals are removed from contact with the rest of the laboratory colony. This test and removal program is a highly successful approach to developing specific pathogen-free colonies for research.

Broad *In Vitro* and *In Vivo* Cell Tropism

SRV has a broad cellular tropism and infects lymphoid, monocytes, and epithelial cells *in vitro*. SRV readily infects human T-cell lines, HuT-78, CEM-SS, MT-4, and SubT-1. The human B Raji cell line is also infected and SRV induces syncytia formation in this cell line. Adherent mononuclear cells from rhesus macaques were also infected *in vitro*. Peripheral blood mononuclear cells collected from infected animals and separated into CD4+ and CD8+ T-lymphocytes were also infected.

In vivo studies carried out on SRV-1-infected rhesus macaques showed infection of epithelial and lymphoid cells in the gut and elsewhere (**Figure 2**). The oral cavity and salivary glands have also been examined. Mucosal epithelia cells were heavily infected as early as 1 month post inoculation. Rarely, Langerhans cells were also shown to be infected using immunohistochemical techniques. Southern blot analyses showed salivary glands and lymphoid tissue to be more heavily infected than brain tissue. The infection of epithelia cells *in vivo* is striking in its widespread nature.

Pathogenesis

The pathogenesis of SRV, MPMV, and SRV-2 is well described. Inoculation of any of these three grown in rhesus monkey tissue culture will induce an AIDS-like disease in most of the infected macaques. Pathogenesis studies are best carried out using virus grown in cells of the original host. Cultivation of the virus in human cells, especially Raji B cells, may attenuate the virus. The clinical course for SRV-1 is typically one-third developing disease in less than 6 months, one-third developing disease in 6 months to 2 years, and a third recover but remain antibody positive for SRV. Recovered animals may develop AIDS after a long clinically latent normal period. The disease is very similar to AIDS in human beings and includes opportunistic infections such as generalized cytomegalovirus disease and its associated pneumonia, wasting, chronic diarrhea unresponsive to therapy, and severe anemia. Infecting with a molecular clone, ruling out adventitious agents, proved the pathogenesis of SRV-1.

The disease induced by SRV is AIDS, but SRV should not be confused with simian immunodeficiency virus (SIV), a lentivirus related to human immunodeficiency virus 2 (HIV-2) that also causes AIDS in rhesus macaques. Macaques are not the natural hosts of SIV, since SIV naturally occurs in only sub-Saharan African cercopithecine monkeys and apes. The species naturally infected with SRV are all Asian macaque species. These two infections can be easily distinguished by specific Western blot. AIDS caused by SRV and SIV are both severe immunodeficiency syndromes, but differ in that SIV-induced AIDS is frequently associated with pneumocystis pneumonia, atypical tuberculosis, and B-cell lymphomas. In contrast, Kaposi sarcoma-like neoplasias are seen exclusively in type D SRV-induced AIDS.

Simian RF

A tumor that occurs in the space behind the abdominal cavity (retroperitoneum) is associated with SRV-2 infections and the retroperitoneal fibromatosis herpesvirus (RFHV). RFHV is the macaque homolog of the human rhadinovirus that is associated with the Kaposi's sarcoma herpesvirus (KSHV). This monkey tumor is therefore an excellent model for Kaposi's sarcoma, one of the tumors that commonly occur in AIDS patients. DNA sequence data identified KSHV related herpes viruses in the RF

tissue of pig-tailed and rhesus macaques. The basic fibroblast growth factor was found to be associated with RF tissues in SRV-2-infected macaques. The fibrosarcoma associated with SRV-1-induced AIDS is also a Kaposi-like tumor.

Vaccines

Two types of vaccines have been successfully tested in the SRV AIDS model. The first used a killed-virus formulation. The virus was inactivated with formalin and injected intramuscularly to induce antibody. The SRV challenge virus used to test the efficacy of the vaccine was prepared in isogenic rhesus monkey kidney cells, therefore ruling out induction of anticellular antibody as a protective mechanism. Protection was associated with neutralizing antibody. This was the first vaccine shown to be effective against a primate retrovirus. The second vaccine used a recombinant vaccinia virus vector. The vaccinia virus vector expressed the envelope proteins (gp70 and gp20) of SRV-1 and MPMV. Upon challenge with live SRV-1 by the intravenous route, both MPMV- and SRV-1-immunized animals were protected. The vaccine therefore conferred cross-protection for SRV types 1 and MPMV, demonstrating *in vivo* their close relationship. The neutralizing antibody did not cross-react with the more distant SRV-2.

Human Infections with SRV and Related Viruses

D-type retroviruses easily infect tissue culture cells derived from humans. Consequentially, several research groups have reported contamination of tissue cell lines. Therefore, there is a strong risk of contaminating cell cultures with this virus in the laboratories. Evidence for human infection that is based only on isolation of a D-type retrovirus from cultured human cells must be viewed with caution.

Human infections with SRV or MPMV have been reported in widely different diseases such as cancer and schizophrenia. Evidence of D-type virus has been reported in children with Burkett's lymphoma and in adult humans with breast cancer. However, direct evidence of SRV as an etiologic agent of human disease is thus far lacking.

An MPMV serological survey of European and African blood donors in Guinea-Bissau revealed 1 of 61 to be weakly positive for the MPMV p27 Gag polypeptide using Western blots. Squirrel monkey retrovirus-specific Western blots also revealed a few additional positive samples. Reaction in a blood donor consisting of only a single polypeptide is usually reported as an indeterminant result and is a false positive reaction. Nevertheless, D virus is widespread in nature and sequences related to the SRVs are found in the genomes of several primate species. Therefore, exposure to the virus is clearly possible. Nevertheless, extensive studies on over 1000 persons with various diseases have failed to find evidence of SRV infections in humans. Diseases tested included lymphoproliferative disease patients, HIV-1 infected persons, persons with unexplained low CD4 lymphocyte counts, blood donors, and intravenous drug users from the USA and Thailand. Serum samples were screened for antibodies against SRV by an ELISA, and reactive samples were re-tested by Western blot. None of the samples were seropositive.

The most convincing evidence for nonpathogenic SRV infections in humans comes from a serosurvey of workers occupationally exposed to macaque D-type retroviruses at primate centers in the USA. Occupational exposure could come from an accidental bite from infected monkeys during routine care such as cage cleaning or accidental exposure by a contaminated needle stick. Two of 231 persons tested were strongly positive by Western blot. Each person displayed antibody to more than one gene of SRV (**Figure 4**). Lanes 1 and 2 showing a reactive band at the 70, 31, 24, and 20 Da markers indicated reaction with the *pol*, *env*, and *gag* gene products. One individual had neutralizing antibody to SRV-2, providing convincing evidence of an

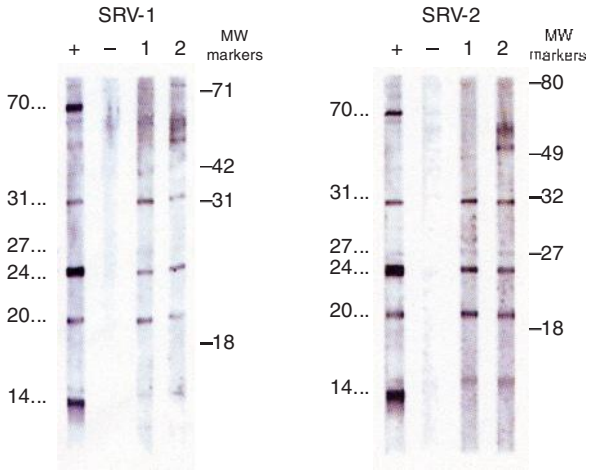

Figure 4 WB reactivity against SRV-1 and SRV-2 on initial screening in sera from two persons occupationally exposed to nonhuman primates. Lanes: (+)-lane is known SRV-positive serum from a rhesus monkey; (–)-lane is SRV-negative serum from a known negative rhesus monkey; lane 1, subject 1, lane 2, subject 2. MW, molecular weight (weights are in thousands of daltons). gp70 is the surface spike of SRV. active SRV infection in the past. The most important tests to document active infections were negative. Repeated attempts to amplify the genomic DNA specific for SRV from specimens, as well as attempts to recover infectious virus, were not successful.

These findings are nevertheless important for understanding zoonotic infections and the related but more dangerous outcome of zoonosis. Zoonotic infections are fairly common under the right exposure conditions, but a zoonosis is a rare outcome. Even though SRV may infect human blood cells *in vivo* and grow temporary in the new host, the immune system of the non-natural human host is capable of eliminating the zoonotic infection. The past infection will be evident from trace amounts of specific antibody that was induced during the transient infection. Infection of humans with simian D and other simian retroviruses is well documented, but evidence of zoonosis has not been found.

Simian Virus 40

A L McNees and J S Butel, Baylor College of Medicine, Houston, TX, USA

History

Simian virus 40 (SV40) was discovered in 1960 as a contaminant of poliovaccines. Hundreds of millions of people worldwide were inadvertently exposed to infectious SV40 in the late 1950s and early 1960s when they were administered contaminated virus vaccines prepared in rhesus macaque kidney cells. SV40 had unknowingly contaminated batches of both the inactivated and live attenuated forms of the poliovaccine and preparations of some other viral vaccines. Although primary cultures of monkey cells were known to be commonly contaminated with indigenous viruses and safety testing was carried out, SV40 had escaped detection in part because it failed to induce cytopathic effects in rhesus cells. However, when it was inoculated into African green monkey kidney cells, a prominent cytoplasmic vacuolization developed. Originally christened as 'vacuolating virus', the name was later changed to SV40 to conform to a numerical system of designating simian virus isolates.

Concern about the vaccine contaminations heightened considerably when it was found in 1962 that SV40 was tumorigenic in newborn hamsters and could transform many types of cells in culture. Subsequently, manufacturers

treated poliovirus vaccine seed stocks to remove infectious SV40, and screening methods were implemented to increase detection of infectious SV40 in vaccine lots.

Because of the potential risk to public health posed by the previous distribution of contaminated poliovaccines, SV40 became the focus of intensive investigation. For scientists, SV40 has turned out to be an invaluable tool for dissecting molecular details of eukaryotic cell processes. Numerous techniques now commonly used in molecular biology were pioneered in the SV40 system. It continues to serve as a model for basic studies of viral carcinogenesis.

Taxonomy and Classification

Viral species *Simian virus 40* is classified in the genus *Polyomavirus* in the family *Polyomaviridae* (**Table 1**). It was previously classified as a member of the *Papovaviridae* family. The International Committee on Taxonomy of Viruses has designated SV40 as the type species of the 13 members of the family *Polyomaviridae*, which includes murine polyomavirus, human polyomaviruses BK virus (BKV) and JC virus (JCV), as well as isolates from hamsters, rabbits, cattle, birds, and baboons. The human and animal polyomaviruses are antigenically distinct, and in most cases there is only one recognized serotype for each virus.

Properties of the Virion

SV40 particles are small and spherical, with a diameter of approximately 45 nm. Infectious virions have a sedimentation coefficient of 240S in sucrose and band at a density of 1.34 g ml ^{1} in CsCl; empty capsids have a density of 1.29 g ml^{-1}. The molecular mass of the SV40 virion has been estimated at 270 kDa. The DNA content is 12.5% (w/w). The major capsid protein (VP1) accounts for 75% of the total virion protein. VP2 and VP3 are minor capsid proteins. Cellular histones (H2A, H2B, H3, H4) are used to condense the viral DNA for packaging and are present in the core of the particle. There is no lipid envelope. SV40 does not agglutinate erythrocytes.

Table 1 Properties of SV40

Classification	Family *Polyomaviridae*
Strain variation	Genetically stable; one serotype, multiple strains
Virion	Icosahedral, 45 nm in diameter, no envelope
Genome	Circular covalently closed dsDNA, 5200 bp
Proteins	Three structural proteins, VP1, VP2, VP3; cellular histones condense DNA in virion; nonstructural replication protein, T-antigen, is potent oncoprotein
Replication	In certain primate kidney cells; nucleus; stimulates cell DNA synthesis; long growth cycle
Natural host	Asian macaques, especially the rhesus monkey
Diseases	Asymptomatic persistent infections in natural hosts; tumors in experimentally infected rodents; associated with human tumors and with kidney disease
Historical note	Contaminant in early poliovaccines administered to millions of people

SV40 particles exhibit icosahedral symmetry. The virion is composed of 72 pentameric capsomeres composed of the VP1 protein arranged on a $T = 7$d icosahedral surface lattice. This structure (hexavalent capsomeres having pentameric substructure) demands nonequivalent contacts between pentamers. This seems to be accomplished by the C-termini of the VP1 polypeptides, which extend as arms from one pentamer and fit into binding sites on adjacent pentamers, providing the necessary flexibility to build a capsid. The N-terminal arm of VP1 is completely internal in the virus particle. Minor capsid proteins VP2 and VP3 are predominantly internal as well and do not contribute to the basic structure of the virus outer shell.

The virus particles are very resistant to heat inactivation but are relatively labile when heated in the presence of divalent cations. Whereas SV40 is stable at 50 °C for hours, incubation in the presence of 1 M $MgCl_2$ at 50 °C for 1 h will effectively inactivate the virus if it is monodispersed. At a higher temperature (60 °C), ~99% of infectious virus is inactivated within 30 min in the absence of divalent cations. Purified virions can be disrupted by strong alkaline conditions (pH 10.5), by lower pH (9.2) plus a reducing agent, or by detergent treatment. Virus particles are resistant to acid treatment (pH 3.0). Intact virus particles are not affected by nucleases, but in the presence of a reducing agent nuclease can enter the virion and cleave the viral DNA. SV40 is efficiently inactivated by UV light irradiation, following single-hit kinetics.

Properties of the Viral Genome

The SV40 genome is a circular, covalently closed, double-stranded (ds) DNA molecule of about 5 kbp (**Figure 1**). The native DNA assumes a superhelical configuration (form I) that sediments at 21S in a neutral sucrose gradient. A single-stranded (ss) nick generates relaxed circular dsDNA molecules (form II) that sediment at 16S, whereas a ds break produces linear dsDNA (form III, 14S). Alkaline denaturation of form I DNA produces dense cyclic coils that sediment at 53S. Form II DNA is converted to ss circular (18S) and ss linear (16S) molecules by denaturation. The supercoiled (form I) molecules can be separated from relaxed circular and linear forms by centrifugation of a DNA preparation in CsCl gradients with ethidium bromide. The form I molecules will band in a lower

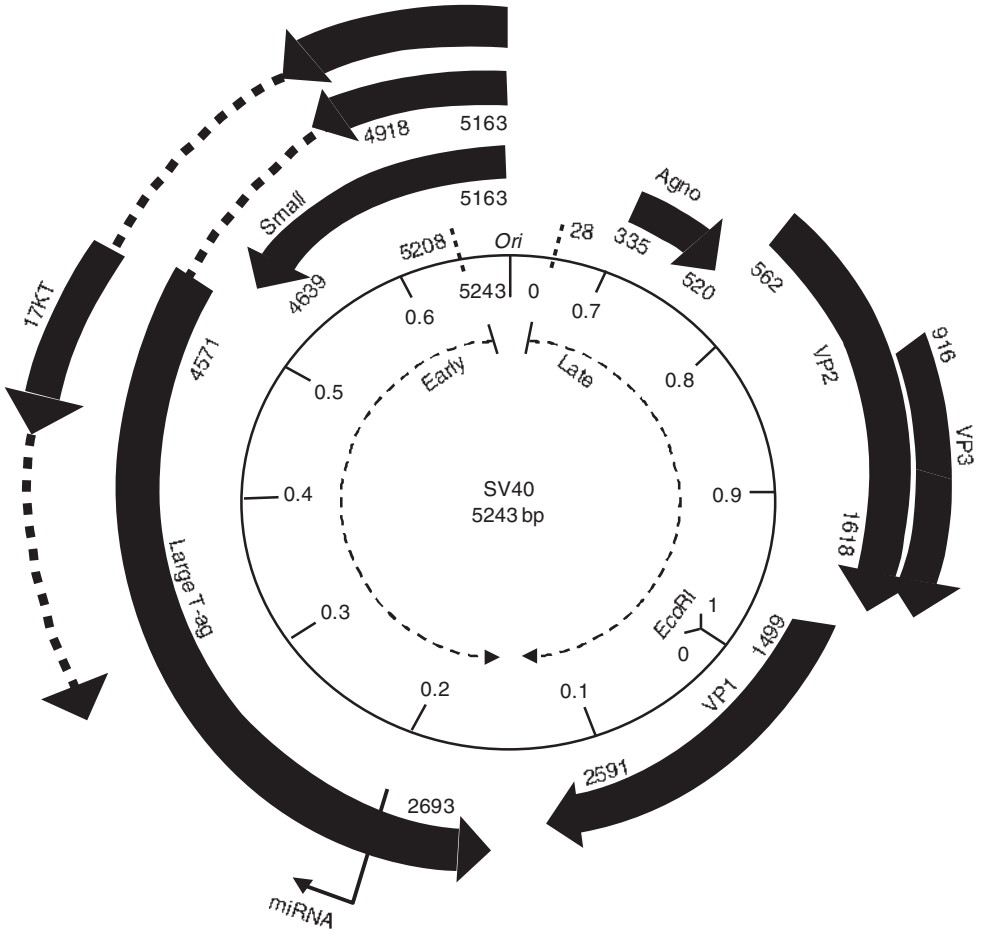

Figure 1 Genetic map of SV40. The circle represents the circular SV40 DNA genome. The unique *Eco*RI site is shown at map unit 0/1. Nucleotide numbers begin and end at the origin (*Ori*) of viral DNA replication (0/5243). Boxed arrows indicate the open reading frames that encode the viral proteins. Arrowheads point in the direction of transcription; the beginning and end of each open reading frame is indicated by nucleotide numbers. Note that T-ag is coded by two noncontiguous segments on the genome. The genome is divided into 'early' and 'late' regions that are expressed before and after the onset of viral DNA replication, respectively. Only the early region is expressed in transformed cells.

position in the gradient. The DNA forms also separate during electrophoresis in a neutral agarose gel; the supercoiled molecules migrate the fastest, the linear forms move at an intermediate speed, and the relaxed circles migrate the slowest.

The viral DNA both in virions and infected cells is associated with cellular histones H2A, H2B, H3, and H4. The histones are assembled in 24–26 nucleosomes on the viral DNA. The nucleosome structure and histone composition of the viral minichromosome mimic the chromatin structure of cellular DNA.

SV40 DNA was the first eukaryotic viral genome to be physically mapped by restriction endonuclease analysis (1971) and to be completely sequenced (1978). The DNA of reference strain 776 with a duplicated enhancer region contains 5243 bp for a calculated molecular weight of 3.5×10^6 Da. The genome is numbered in a clockwise direction from 1 to 5243, the central nucleotide of the unique *Bgl*I recognition site being assigned as 0/5243. Numbering continues through the late region in the 'sense orientation' and the early region in the 'antisense orientation'. The numbering system begins and ends (0/5243) in the middle of the functional origin of DNA replication. The unique *Eco*RI site at nucleotide 1782 was arbitrarily chosen as a point of reference and assigned a value of 0/1.0 on the circular map. Laboratory-adapted strains of SV40 contain a duplication or rearrangements of the 72 bp element in the enhancer region, whereas most natural isolates do not.

The SV40 genome has compact regulatory sequences and overlapping genes. The single origin of replication (core *Ori* = 64 bp in size) is embedded within a nontranslated regulatory region. These elements control transcription and replication and span about 400 bp. The coding regions are expressed early or late in infection, and represent the 'early' nonstructural genes and the 'late'

structural genes, respectively, and are transcribed off opposite strands of the viral DNA.

There is a variable domain at the 3′ end of the T-ag gene, encompassing about 270 bp. Nucleotide changes within this region can be used to distinguish strains of SV40. Although genetic variation among SV40 strains is minimal, three different genogroups have been distinguished. Sequence variations in this region are detected in human-tumor-associated SV40 sequences. Possible *in vivo* biological differences among SV40 strains are unknown but variations in oncogenic potential in rodent models have been observed.

Properties of Viral Proteins

SV40 encodes seven gene products: three 'early' nonstructural proteins (large T-antigen (T-ag), small t-antigen (t-ag), 17K T-ag (17KT)), three 'late' structural proteins (VP1, VP2, VP3), and a maturation protein (LP1 or agnoprotein).

The nonstructural proteins are expressed early in infection, before the onset of viral DNA synthesis. The coding regions of the two T-ags and 17KT overlap; alternative splicing of viral transcripts determines each protein sequence. Large T-ag of strain 776 (**Table 2**) contains 708 amino acids (~90 kDa), and small t-ag contains 174 residues (~20 kDa). The large and small T-ags share 82 N-terminal amino acids, whereas the remainder of each protein is unique. The T-ag/t-ag common exon contains a 'J-domain', believed to modulate hsc70 activity in the assembly and disassembly of multiprotein complexes.

Large T-ag is an essential replication protein required for initiation of viral DNA synthesis. It stimulates host cells to enter S-phase and undergo DNA synthesis and is the SV40 transforming protein. Large T-ag contains a nuclear transport signal (126-Pro-Lys-Lys-Lys-Arg-Lys-Val-132) that targets the protein into the nucleus. However, about 10% of the T-ag in the cell is found in the cytoplasm and the plasma membrane. The biology of small t-ag is enigmatic. It is a cytoplasmic protein that is not essential for viral replication in cultured cells. It associates with the regulatory and catalytic subunits (36 and 63 kDa) of protein phosphatase 2A and is believed to cause cellular growth stimulation. It is required for transformation of some human cells by SV40. Its role during natural infections by SV40 remains to be elucidated. The function of 17KT is unknown.

The functions of large T-ag in SV40 DNA replication are regulated by phosphorylation (**Figure 2**). The sites of phosphorylation are clustered near the ends of the molecule, one region lying between residues 106 and 124 and the other between residues 639 and 701. The majority of the phosphorylated residues are serines, although two threonine residues also become phosphorylated. Unlike many oncoproteins, T-ag is not phosphorylated at tyrosine residues.

T-ag is a DNA-binding protein that recognizes multiple copies of the sequence GAGGC in three T-ag-binding sites in the viral *Ori*. The minimal origin-specific DNA-binding domain of T-ag lies between residues 131 and 259. T-ag is predicted to have a zinc finger motif, typical of DNA-binding proteins, between amino acids 302 and 320. T-ag-specific ATPase and helicase activities are required in addition to DNA-binding activity in order for T-ag to function in initiation of DNA replication. The ATP-binding domain of T-ag is similar in structure to other ATP-binding proteins and is located between residues 418 and 627.

Large T-ag forms complexes with several cellular proteins. Such interactions are involved in T-ag functions in viral DNA replication, induction of cellular DNA synthesis, and cell-cycle progression. Target cellular proteins found in heterooligomeric structures with T-ag include transcriptional coactivators (CBP, p300, p400), tumor suppressor proteins (p53, pRb, p107, p130), DNA polymerase α, the molecular chaperone heat-shock protein hsc70, cell-cycle regulatory proteins cdc-2 and cyclin, and tubulin. The

Table 2 Properties and functions of SV40 T-ag

Structural properties	
Size[a]	708 amino acid residues, 82 N-terminal residues shared with t-ag, 81 632 Da, M_r 90 000–100 000 Da
Modifications	Phosphorylation, N-terminal acetylation, *O*-glycosylation, poly-ADP-ribosylation, palmitylation, adenylation
Supramolecular structure	Zinc finger, nuclear localization signal, J domain, monomers, dimers, higher homooligomers; heterooligomers with transcriptional coactivators (CBP, p300, p400); heterooligomers with DNA polymerase α; hsc70; cdc-2, cyclin, tubulin, Bub1, TEF-1, Cul7, Nbs1, Fbw7; tumor suppressor proteins (p53, pRb, p107, p130)
Subcellular distribution	Predominantly nuclear
Functions	
Replication and transactivation	Specific DNA binding (viral origin of replication), initiation of viral DNA replication; ATPase activity, helicase activity; autoregulation of viral early transcription, induction of viral late transcription
Host cell effects and transformation	Entry of cells into S phase and initiation of cellular DNA replication, complex formation with cellular proteins p53, pRb, p107, p130; adenovirus helper function; effect on host range, initiation and maintenance of cellular transformation, induction of immunity to SV40 tumor cells, target for cytotoxic T cells

[a]SV40 strain 776.

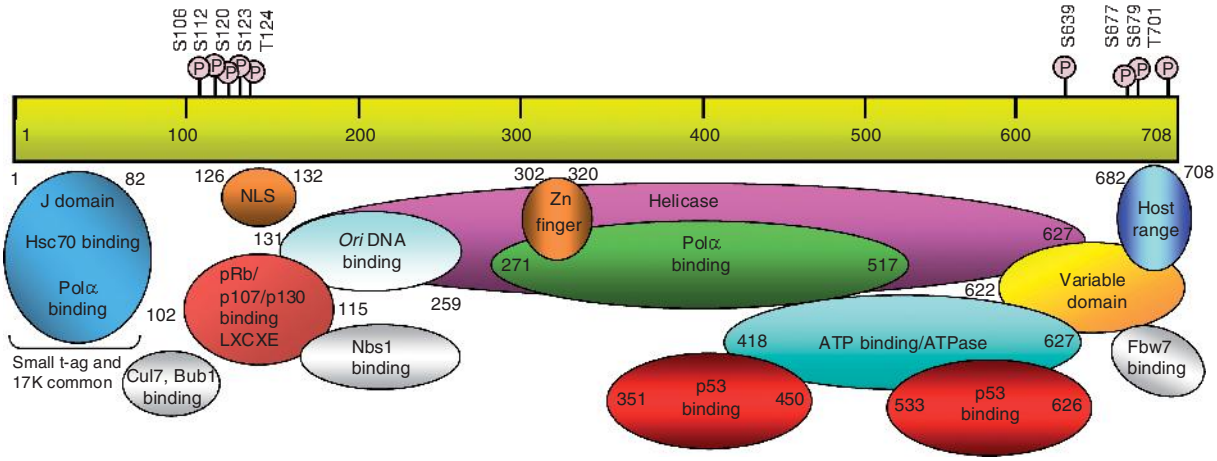

Figure 2 Functional domains of SV40 large T-ag. The numbers given are the amino acid residues using the numbering system for SV40-776. Regions are indicated as follows. Small t-ag common: region of large T-ag encoded in the first exon. The amino acid sequence in this region is common to both large T-ag and small t-ag. Polα binding: regions required for binding to polymerase α-primase. Hsc70 binding: region required for binding the heat shock protein hsc70. Cul7 binding: region required for binding of Cul7. pRb/p107/p130 binding: region required for binding of the Rb tumor suppressor protein, and the Rb-related proteins p107 and p130. NLS: contains the nuclear localization signal. *Ori* DNA binding: minimal region required for binding to SV40 *Ori* DNA. Nbs1 binding: region required for binding of Nbs1. Helicase: region required for full helicase activity. Zn finger: region which binds zinc ions. p53 binding: regions required for binding the p53 tumor suppressor protein. ATP binding/ATPase: region containing the ATP binding site and ATPase catalytic activity. Host range: region defined as containing the host range and Ad helper functions. Variable domain: region containing amino acid differences among viral strains. Fbw7 binding: region required for Fbw7 binding. The circles containing a P indicate sites of phosphorylation found on large T-ag expressed in mammalian cells. S indicates a serine and T indicates a threonine residue.

indicated cellular proteins are not all found in the same T-ag-associated complex; many subpopulations of T-ag exist in a cell.

The variable domain at the C-terminus of T-ag encompasses the host range–adenovirus helper function exhibited by SV40 (and mapped to T-ag) in some monkey kidney cell lines. The significance of the variable domain to natural infections by the virus is unknown.

The structural (capsid) proteins are expressed late in infection, after the onset of DNA replication. They are synthesized in much greater abundance than the early proteins. The major capsid protein, VP1, contains 362 amino acids (~45 kDa). The minor structural proteins are VP2 (352 residues, ~38 kDa) and VP3 (234 residues, ~27 kDa). The coding regions for VP2 and VP3 overlap, and they are translated in the same reading frame, so the sequence of VP3 is identical to the C-terminal two-thirds of VP2. VP3 is synthesized by independent initiation of translation via a leaky scanning mechanism, not proteolytic cleavage of VP2. The N-terminal portion of VP1 is derived from sequences that encode the C-termini of VP2 and VP3. However, VP1 is translated in a different reading frame from a different spliced transcript, so it shares no sequences with VP2 and VP3. VP1 is modified by phosphorylation and acetylation.

The late proteins are required only for the assembly of progeny virions during lytic infection. They are not involved in the early phases of viral replication. They are synthesized in the cytoplasm and move into the nucleus where particle morphogenesis occurs. The minor capsid proteins contain nuclear transport signals. The VP2/3 signal is Gly-Pro-Asn-Lys-Lys-Lys-Arg-Lys-Leu (VP2, residues 316–324; VP3, residues 198–206). For VP1, two clusters of basic residues within the N-terminal 19 residues are independently important for nuclear targeting. Mutations in VP1 affect capsid assembly and/or virion stability. Mutations in VP2 and VP3 affect the uncoating process when virions penetrate new host cells.

The agnoprotein LP1 is synthesized late in infection but is not found in virus particles. It is a small (62 residue, ~8 kDa) basic protein involved in particle assembly. It is believed that LP1 interacts with VP1 molecules to inhibit self-polymerization until they interact with viral minichromosomes in the nucleus to form virions.

Replication

Overview of SV40 Replication Cycle

The SV40 replication cycle is cleanly divided into early and late events, with the onset of viral DNA replication being the dividing landmark. SV40 virions attach to receptors on the cell surface, become internalized, and are transported to the cell nucleus where the viral DNA is uncoated. After uncoating, the half of the genome that contains the early region is transcribed ('early' mRNAs).

Viral early proteins (T-ags) are synthesized, cellular genes are expressed, and the cells enter S-phase. Viral DNA replication then begins. 'Late' mRNAs are transcribed from the other half of the viral genome (the opposite strand), and viral structural proteins are synthesized. Virus particles are assembled and SV40 is released from the cell surface in a manner dependent on intracellular vesicular transport. The SV40 multiplication cycle can take 24–72 h to complete. New particles are detected by 24 h. The time course of the virus growth cycle is dependent upon the virus strain and host tissue, the viral multiplicity of infection, and the growth state of the host cell at the time of infection.

Strategy of Replication of Nucleic Acid

SV40 DNA is replicated in the cell nucleus as a free unintegrated minichromosome. The only viral components required are the viral origin of replication on the DNA and the T-ag protein; all other factors are provided by the host cell replication machinery. T-ag is required for the initiation of DNA replication. The specific T-ag functions required are its DNA-binding ability and its ATPase/helicase activities. The relative simplicity of the SV40 system has allowed the development of cell-free replication systems and the identification of factors involved in mammalian DNA replication.

T-ag binds to the viral *Ori*, a 64 bp segment that contains binding site II for T-ag. In an ATP-dependent process, T-ag causes localized unwinding of the *Ori* region; cellular ss binding protein is required to stabilize the unwound single strands. The cellular DNA polymerase α-primase complex initiates DNA replication, and replication proceeds bidirectionally, with the two forks advancing at equal rates. Elongation involves DNA polymerase α, DNA polymerase δ, and proliferating cell nuclear antigen. Termination occurs 180° away from the viral *Ori*; topoisomerase II segregates the newly synthesized daughter molecules. Cellular histones are added to the new strands during the process of DNA replication.

Replication of SV40 DNA occurs in certain cell types of humans, monkeys, and possibly hamsters, and this permissiveness seems to depend in part on the nature of the DNA polymerase α-primase complex.

Characterization of Transcription

Transcription of the viral DNA is carried out by the cellular RNA polymerase II. In the noncoding region of SV40 DNA near the origin of replication are early and late promoter structures and enhancer elements. Early transcription begins at about nucleotide 5237, proceeds in the counterclockwise direction, and ends at the polyadenylation site at nucleotide 2694. The early promoter contains a TATA box about 30 bp upstream of the early RNA initiation site. (This start site is about 70 nucleotides upstream of the initiation codon shared by the early proteins.) There are three G + C-rich regions, the '21 bp repeats', located 40–103 nucleotides upstream, which are binding sites for the Sp1 cellular factor. Even farther upstream are the SV40 enhancer elements, the 72 bp elements, which contain binding sites for other cellular factors that regulate transcription. The primary early transcripts are differentially spliced to generate the mRNAs that code for the three T-ags.

There is no requirement for virus-encoded proteins, but early transcription is regulated by T-ag. T-ag regulates its own synthesis as it first binds to site I and then to sites II and III on the viral DNA. The presence of T-ag at site II blocks the binding of RNA polymerase.

Late transcription begins after viral DNA synthesis is underway. The abundance of late transcripts is much greater than the early transcripts because progeny DNA molecules are utilized as templates. A heterogeneous collection of late mRNAs is made, with late transcription beginning at multiple sites between nucleotides 120 and 482 and proceeding in the clockwise direction, ending at a polyadenylation site at nucleotide 2674. Both the 21 bp repeats and the 72 bp elements have positive effects on late transcription. The late transcripts are alternatively spliced into two size classes (19S, 16S). VP1 is synthesized from 16S RNA, and both VP2 and VP3 are translated from the 19S species. The agnoprotein is synthesized predominantly from the most abundant species of 16S RNA.

SV40 microRNAs (miRNAs) have been described that accumulate during the late phase of the infection cycle and are complimentary to early viral mRNAs. The SV40 miRNAs function to target the early mRNAs for cleavage, which effectively reduces the expression of T-ag.

Post-Translational Processing

No post-translational cleavages are involved in the production of SV40 proteins. As noted above, T-ag and VP1 are modified in various ways, including phosphorylation.

Uptake and Release of Virions

The attachment of SV40 particles to the cell surface is mediated by VP1. The major histocompatibility class I molecules and the ganglioside GM1 molecules function as receptors. Attached particles are internalized by caveolae-mediated endocytosis into vesicles that contain caveolin-1. These vesicles fuse with caveosomes and the virus particles are transferred to the endoplasmic reticulum, from which they exit and then enter the nucleus. Conformational changes are thought to occur that expose the nuclear localization signals on capsid proteins and allow the virions to squeeze through the nuclear pore

complex. The capsid disassembles in the nucleus, releasing the viral DNA.

Maturation of progeny virions occurs in the nucleus, where the viral nucleic acid is replicated. Viral proteins are synthesized in the cytoplasm off viral transcripts exported from the nucleus, and the proteins are then transported back into the nucleus. The structural proteins condense around the viral minichromosomes. There is a packaging signal on SV40 DNA that includes the *Ori* and part of the enhancer element. During the maturation process, the agnoprotein is released and is not retained as a component of mature virions. There are size constraints for packaging DNA – molecules ranging from 3.5 to 5.7 kbp can be encapsidated into SV40 particles.

Some progeny virions are released from the surface of infected cells via a mechanism dependent on intracellular vesicular transport, but the majority stay associated with the cell until cell death. The release of virus from ruptured and fragmenting cells may also be a mechanism of virus exit from infected cells. SV40 infections are not lytic and host cells are killed as the result of a variety of effects, including the release of lysosomal enzymes into the cytoplasm and damage to the cell mitochondria. Late in infection, monkey kidney cells develop a characteristic cytopathic effect, cytoplasmic vacuolization. As many as 10^4 virus particles can be produced by an infected cell, although some cells produce fewer particles.

Geographic and Seasonal Distribution

The geographic distribution of SV40 can only be inferred, as no comprehensive surveys have been conducted. SV40 is found naturally in wild populations of certain Asian macaque species, and its geographic distribution in the wild presumably reflects its narrow host range. Infections in humans are more widespread geographically, possibly because contaminated poliovaccines were broadly distributed. Nothing is known about seasonal effects on natural infections by SV40.

Host Range and Virus Propagation

Polyomaviruses, in general, have a narrow host range, with each virus infecting only one or a few closely related species. Based on antibody surveys of wild populations of primates, the natural hosts for SV40 appear to be a few species of Asian macaque monkeys, especially the rhesus (*Macacca mulatta*). In captivity, several related species are easily infected, including the cynomolgus macaque (*M. fascicularis*) and the African green monkey, which belongs to the same family as macaques (Cercopithecidae). The virus grows poorly in more distantly related primates. SV40 can infect humans.

SV40 is propagated in tissue culture in established cell lines derived from kidneys of African green monkeys. Characteristic vacuolated cells appear in response to viral replication. The virus grows in rhesus kidney cell lines in which it establishes a persistent infection but produces no cytopathic effects.

SV40 typically does not cause tumors in its natural hosts. To demonstrate its tumorigenic potential, the virus must be inoculated into experimental animals (newborn hamsters are most susceptible). Many types of cells can be transformed in culture, including those of rodent, monkey, and human origin.

Genetics

SV40 is genetically stable, although rearrangements in the regulatory region can occur *in vivo*. Sequence variations exist at the 3′ end of the T-ag gene among different isolates, which are stable on passage *in vivo* and *in vitro*. Adaptation of natural isolates to tissue culture often involves the selection of viruses with duplications or rearrangements in the viral regulatory region. The origins of several SV40 strains are listed in **Table 3**.

Serologic Relationships and Variability

Only one serotype of SV40 is known. The virus does not undergo noticeable antigenic variation. Perhaps restrictions imposed by the symmetry of the capsid permit only minimal deviation in amino acid sequence of the structural proteins, making most changes lethal for the virus.

There is a genus-specific antigenic determinant on the major capsid protein, VP1, that is shared by all animal and human polyomaviruses. It is expressed in infected cells and is internal in the virion. Antibodies are elicited against it by immunization with disrupted capsids or with purified VP1 protein. Antibodies against the shared determinant are not neutralizing, as the site is not exposed on the surface of virus particles. The structural proteins of SV40 and the two human polyomaviruses (BKV and JCV) are antigenically distinct, but display some cross-reactive determinants in enzyme-linked immunosorbent assay (ELISA) tests. The T-ags of SV40, BKV and JCV show antigenic cross-reactivity.

Epidemiology

Most adults of the Asian macaque species believed to be natural hosts for SV40 have neutralizing antibodies to the virus. Few of the juvenile animals of those species, in the wild, have antibodies. However, in captivity the young

animals are readily infected if they have contact with a virus-positive animal.

Serologic surveys have detected SV40 neutralizing antibodies in humans with prevalences ranging from 2% to 10%. However, whether SV40 infection typically induces a detectable and sustained humoral or cellular immune response in humans has not been determined. SV40 DNA has been detected in human tumors, but epidemiological studies based on SV40-reactive serum antibodies in ELISA tests do not support an association of SV40 exposure with human cancers. The results of such epidemiological studies should be interpreted with caution, however, due to an inability to differentiate with certainty those who were exposed to an SV40-contaminated vaccine and those who were not. The working stocks in use between 1961 and 1978 by a major eastern European manufacturer of poliovirus vaccines have been shown to contain infectious SV40. This finding raises questions as to whether all poliovirus vaccines used worldwide after 1963 were free from SV40 contamination.

Transmission and Tissue Tropism

SV40 establishes persistent infections in the kidneys, and possibly lymphocytes, of susceptible hosts. The level of persistent virus present may be very low. Modes of transmission are not known, but transmission probably occurs due to virus shed in the urine or stool. Experiments have established that susceptible animals can be infected by the oral, respiratory, or subcutaneous routes. Both viremia and viruria occur in infected animals. SV40 may cause neurologic disease in immunocompromised hosts.

The major known source of human exposure to SV40 was via the administration of contaminated viral vaccines before SV40 was recognized. Human exposure could also occur by contact with infected monkeys, a situation limited to small numbers of animal handlers. Transmission between human hosts is hypothesized to occur but has not been documented. It is presumed that patterns of tissue tropism and transmission similar to those described in monkeys would be observed in humans infected by SV40.

Pathogenicity and Pathology

SV40 infections in normal monkeys appear to be asymptomatic and harmless. However, SV40 has been associated with a fatal case of pulmonary and renal disease, as well as with cases of progressive multifocal leukoencephalopathy, in unhealthy rhesus monkeys. SV40 can cause widespread infections in monkeys suffering from simian acquired immune deficiency syndrome and has been found in a brain tumor; no tumors have been found in immunocompetent, natural hosts. Transgenic mice carrying wild-type SV40 DNA develop choroid plexus papillomas and die rapidly because of the physiological importance of the tumor site. When foreign tissue-specific regulatory sequences are substituted for the native promoter-enhancer of the virus, SV40 expression can be directed to other tissues in transgenic animals and lethal tumors usually appear. Intraperitoneal inoculation of SV40 into weanling hamsters produces mainly mesotheliomas, intravenous inoculation of SV40 leads to leukemia, reticulum cell sarcoma, and osteogenic sarcoma, and subcutaneous inoculation induces undifferentiated carcinomas or sarcomas. SV40 DNA has been detected in several types of human cancers, including brain tumors (especially those from children in the first decade of life), mesotheliomas,

osteosarcomas, and non-Hodgkin's lymphomas. SV40 DNA is sometimes found in tumors arising in persons too young to have been exposed to the contaminated vaccines in use between 1955 and 1963. The role SV40 may have played in the induction of those tumors is under investigation.

Immune Response

SV40, like other members of the genus *Polyomavirus*, induces an asymptomatic, persistent infection in natural hosts. An antibody response to capsid antigen is elicited that can be detected in neutralization assays. It is well documented with the human viruses BKV and JCV that impaired cell-mediated immunity is associated with virus re-activation, showing that viral replication is under the influence of the immune system of the host; the same presumably applies to SV40.

Little is known about the immune response of humans to infection by SV40. Small numbers of individuals exposed to contaminated vaccines were analyzed for neutralizing antibody responses to SV40. Humoral responses were detected in some vaccinees and were variable and dependent on the size of inoculum and route of inoculation. Recent serological surveys have detected SV40 neutralizing antibody in 2–10% of persons not exposed to SV40-contaminated viral vaccines. Antibodies to SV40 were most often detected in people with some type of immune suppression. ELISA-based assays detected some cross-reactive antibodies against SV40, BKV, and JCV. SV40 T-ag specific cellular immune response has been detected in some patients with SV40 DNA-positive tumors.

Experimental studies have shown that animals with active infections by SV40 may produce humoral antibodies against the replication oncoprotein, T-ag. It should be noted that a T-ag antibody response could not be used to monitor SV40 infections in humans because of the cross-reactivity among the T-ags of SV40, BKV, and JCV.

In vitro and *in vivo* studies demonstrate that SV40 tumor-bearing rodent animals develop a strong immune response to T-ag. Both humoral and cell-mediated responses occur and are sufficient to prevent tumor growth in some cases. In studies using the Syrian golden hamster model, inoculated animals frequently produced virus-neutralizing antibody and T-ag antibody responses, and the titers of both tended to be higher in tumor-bearing animals. In murine models, cytotoxic T cells directed against T-ag determinants at the cell membrane limit tumor progression.

Interferon is induced only weakly by the polyomaviruses and is not thought to be an important component of the host response to SV40.

Prevention and Control

No control measures are available to prevent SV40 infection.

Future Perspectives

The reports of antibodies to SV40 in humans and the infrequent association of SV40 markers with human tumors suggest that SV40 may be present in the human population. It is important to determine the natural history of SV40 in humans, including modes of transmission and factors affecting susceptibility to infection. Because of its small genetic content and dependence on host cell functions, SV40 will continue to be a useful model system for discerning mechanisms of cellular processes, such as mammalian cell DNA replication, cell cycle progression, and growth control processes altered in neoplasia.

Glossary

Enanthem Eruptive lesion of mucous membranes.
Exanthem Eruptive lesion of skin.
Papule A small, solid, elevated lesion of the skin that is often inflammatory.
Pock A pustule on the body caused by an eruptive disease.
Pustule A small elevated pus-containing lesion of skin.
Vesicle A small cavity within the epidermis containing serous fluid.

Variola Virus

Smallpox is caused by variola major virus (VARV), which is a member of family *Poxviridae*, subfamily *Chordopoxviriniae*, genus *Orthopoxvirus*. VARV is a 200–250 nm brick-shaped enveloped virus with a double-stranded DNA genome of approximately 186 kbp. Compared with other orthopoxviruses, VARV exhibits gene conservation toward the center of the genome, with genetic variation increasing toward the termini. The genes in the terminal regions appear to encode virulence factors that differ among orthopoxviruses. Virus replication occurs in the cytoplasm of the host cell where intracellular mature virions (IMVs) and extracellular enveloped virions (EEVs) are produced. Humans are the only natural host of VARV, although monkeys can be infected when exposed to artificially high doses and baby mice and rabbits can briefly propagate the virus. For additional information regarding the replication and architecture of VARV, the reader is refered to the article on vaccinia virus in this encyclopedia. Vaccinia virus is an extensively studied orthopoxvirus that has many biological similarities to VARV.

History

Smallpox, so named to differentiate it from great-pox (*syphilis*), was described by Edward Jenner as "the most dreadful scourge of the human species." Although the exact number of deaths during Jenner's time is unknown, it is estimated to have been approximately 400 million in the twentieth century alone. Historically, smallpox has had a close association with humans. The origin of VARV remains unknown, but the dubious accolade probably goes to Egypt or India. Unmistakable descriptions of smallpox were documented in fourth-century China, seventh-century India, and tenth-century Mediterranean and southwestern Asia. Moreover, Egyptian mummies buried over 3000 years ago have skin lesions that are consistent with smallpox. Before the fifteenth century, smallpox was generally confined to the Eurasian landmass. However, European colonists introduced smallpox to the Americas, central and southern Africa, and Australia between the fifteenth and eighteenth centuries with devastating consequences, as indigenous populations were decimated with case–fatality rates approaching 90%. Smallpox enabled a handful of conquistadors such as Cortez and Pizarro to subjugate large parts of central and South America to Spanish rule, thereby permanently altering the future of these regions. This was not an isolated pattern.

By the end of the nineteenth century a milder and less lethal form of smallpox, named variola minor, became apparent. This virus was first documented in South Africa during 1904, but had been clinically apparent in the USA since 1896. Originally described as Amass (alastrim in South America), this virus eventually became recognized in Brazil during the 1960s and in Botswana, Ethiopia, and Somalia during the 1970s. The variola minor derivatives of variola major (classical smallpox) are believed to have originated in several places throughout the globe as the virus adapted to humans. The case–fatality rates for variola major were 16–30% and 1% for variola minor.

Clinical Features

Clinically, smallpox in an unvaccinated person has a 7–19 day incubation period from the time infection is established within the respiratory tract until the first symptoms of fever, malaise, headache, and backache occur, culminating in the start of the characteristic rash. The rash starts with papules, which sequentially transform into vesicles and then pustules; a majority of these lesions are located on the head and limbs (often confluent) compared to the trunk. The rash is typically centrifugal (head and limbs),

but centripetal (trunk) rashes have been reported. Lesions are 0.5–1 cm in diameter and can spread over the entire body. Once pustules have dried, scabs will form which eventually desquamate during the following 2–3 week period. The resultant feature of these cutaneous lesions is the formation of the classic pock scar that is apparent on the skin of surviving patients.

Two clinical variations of smallpox have been identified. Flat-type smallpox is a rare form of the disease (about 6% in unvaccinated people), and is characterized by lesions that remain level with the skin. It was more frequently observed in children and usually resulted in death. Another variation of the disease is hemorrhagic smallpox (<2% in unvaccinated people), which occurred mainly in adults. Although this was a rare form of the disease, it also had a high mortality rate and is characterized by hemorrhages into the skin and/or mucous membranes early in the course of illness. Subconjuctival hemorrhages were most common as well as bleeding from the gums and other parts of the body.

Although smallpox is typically spread by respiratory droplets over a short distance, some examples of long-distance transmission are evident. One such case occurred in 1978 at the University of Birmingham, UK, where a woman who was vaccinated 12 years earlier died of smallpox. She is identified as the last human fatality of the disease. It is widely believed that VARV traveled up through an air duct that connected a smallpox virology laboratory to her work station. Other theories suggest that this woman was exposed by using the laboratory telephone or simply from laboratory personnel. Another case occurred in a hospital at Meschede, Germany in 1970. In this case, a recent returnee from Pakistan is believed to have initiated 19 other cases of smallpox on all levels of a large general hospital, despite being isolated for the 5 days of his stay. Factors that enabled VARV to travel long distances in the hospital were likely: a building design that facilitated strong rising air currents when it was heated, the patient's severe cough, and the humidity level in the hospital.

Variolation and Vaccination

Historically, it was understood that humans who survived an initial smallpox infection never developed the disease again. Furthermore, persons infected with VARV by cutaneous scratches suffered a less severe form of the disease. For these reasons, the practice of inoculating naive persons with pustular fluid collected from smallpox victims became a common practice; this type of inoculation was called variolation. Variolation usually induced a milder form of the disease, which was typified by a severe, local, cutaneous lesion at the site of variolation with smaller satellite cutaneous lesions; however, variolation sometimes led to generalized rashes with associated deaths. Variolation was likely developed in both India and China and was subsequently introduced to Egypt and the rest of Africa in the seventeenth century and Europe and its colonies in the eighteenth century.

By the end of the eighteenth century, variolation had been widely accepted throughout the world as a means to prevent smallpox. The widespread use of variolation in Great Britain and her North American colonies widely reduced the impact of the virus in the upper classes but not in the general population as a whole. Despite its successes, the mortality rate and the frequent development of classical smallpox in many patients, with associated disease transmission, meant that variolation was less than ideal. Fortunately, a solution emerged from the common observation that milkmaids were rarely susceptible to smallpox. This lack of susceptibility was widely attributed to a zoonotic disease, cowpox. Based on these observations, Edward Jenner inoculated a boy with cowpox virus and observed the child's resistance to smallpox. Over time, more children were inoculated, exposed, and subsequently resisted smallpox. By the beginning of the nineteenth century this method of vaccination (*vacca,* Latin for cow) had become accepted, as it afforded the same level of protection as variolation without the associated risks of mortality and transmissibility. In some countries (France in particular), vaccination was substituted with orthopoxviruses causing horsepox (a method called equination). Moreover, in a recent study it was found that the causative agent of horsepox is closely related to the vaccinia virus strains derived from the historic smallpox vaccine, supporting the hypothesis that horsepox, or close relatives, replaced cowpox virus as the preferred virus used for worldwide vaccination at some point in the mid-nineteenth century. By the 1950s, endemic smallpox had been eliminated from most industrial nations.

All smallpox vaccines used during the eradication campaign were prepared from vaccinia virus; however, this vaccine was not without complications. In some cases, atypically severe lesions developed, coupled with severe symptoms and occasionally death. The most common complications of vaccination were noted in persons with eczema, where the eczematous region became rapidly inflamed and necrotic with frequent spread of the virus to healthy tissue. Immunocompromised individuals also presented with complications because the vaccination site failed to heal and secondary lesions appeared and spread; this complication was typically fatal.

Smallpox Eradication

In May 1959 the World Health Assembly tasked the World Health Organization (WHO) with the goal of eradicating smallpox globally. Although this was not the first eradication program, it was the only successful one.

Approximately 20 years later, in 1980, the WHO declared that smallpox had been eradicated from the world. Despite plans to destroy all stocks of the virus by the end of the twentieth century, none have been realized. Their preservation is due to the stated need (among others) to develop and evaluate antiviral agents, as VARV is a potential bioweapon. The virus which once dominated the health of mankind is categorized as a bio-safety level (BSL)-4 agent, and virus collections are still kept officially in two BSL-4 WHO reference laboratories in the USA and Russia (as of 2007). Any work with live VARV has to be approved by a WHO advisory committee. The genome sequences of 45 VARV strains are freely available online (see the 'Relevant website' section).

Monkeypox Virus

Monkeypox virus (MPXV) is also a member of the genus *Orthopoxvirus*. The MPXV virion is consistent in structure with other orthopoxviruses, that is, a 200–250 nm brick-shaped, enveloped virus with characteristic surface tubules and a dumbbell-shaped core (**Figure 1(b)**). Its genome is approximately 199 kbp of double-stranded DNA. Orthopoxviruses have host specificities ranging from narrow (e.g., VARV and ectromelia virus) to broad (e.g., cowpox and vaccinia viruses), and the capability of MPXV to infect rodents, nonhuman primates, and humans places it in the latter group. MPXV and VARV cause similar diseases in humans, although they are distinct viruses.

History

MPXV was first isolated in 1958 from the vesiculo-pustular lesions found on infected cynomolgus macaques imported to the State Serum Institute of Copenhagen, Denmark. During the next few years, similar outbreaks were reported in monkey colonies in the USA and in a zoo in Rotterdam, The Netherlands. In the latter case, the first animals affected were giant anteaters from South America, but the disease spread to various species of apes and monkeys. The viruses isolated from these animals were found to be similar to each other and to represent a species of orthopoxvirus that had not been described previously. Currently, MPXV is classified as a BSL-3 agent for animal studies.

Human Monkeypox

MPXV remained primarily of academic interest throughout most of the 1960s. Attitudes changed radically when it was realized that MPXV could infect humans in known smallpox-free locales. This gave rise to concerns that MPXV could fill the niche vacated by VARV. However, a WHO-driven campaign suggested that this was unlikely. It was generally assumed that MPXV infections in humans had been occurring before VARV was expunged, but that they were masked under the guise of smallpox.

The most severe human MPXV infections have been reported in the Congo Basin area of Africa, whereas attenuated human infections have generally occurred in West African countries. Human infections usually result from handling MPXV-infected animals (bush-meat); however, cases of human-to-human transmission have been reported. In 2003, an MPXV outbreak occurred when MPXV-infected West African rodents were imported into the USA and thereafter infected native prairie dogs destined for sale in the pet industry. Human infections were initiated by several routes, which appeared to affect the clinical manifestations of the disease. No fatalities occurred, but the virus was of the less aggressive West African type (see below). Nevertheless, this incident demonstrated the ease with which MPXV can penetrate the interspecies barrier.

Clinical Features

MPXV-infected humans develop a skin rash and follow a disease course similar to that observed in smallpox victims (see above). However, some differences exist between smallpox and human monkeypox. First, humans infected with MPXV frequently present with severely swollen lymph nodes (lymphadenopathy of the neck, inguinal and axillary regions), which is not clinically apparent with smallpox victims. Second, a hemorrhagic form of monkeypox has not been reported (however, it has been reported in some laboratory-housed African dormice infected with MPXV). Interestingly, humans infected with MPXV typically present with a rash similar to that observed in less severe cases of smallpox; to quantify this somewhat, approximately 58% of smallpox patients and 11% of human monkeypox (Congo Basin strain) cases had >100 pocks, respectively.

Epidemiology of Human Monkeypox

In humans, MPXV is a zoonotic infection that has limited capacity to transmit within the population. Between 1970 and 1979, only 47 cases of human monkeypox were reported in five African countries. Most (81%) of the cases were in the Democratic Republic of the Congo (DRC), and mathematical modeling experiments concluded that MPXV could not sustain itself in the unvaccinated human population without zoonotic amplification. Conversely, between 1970 and 2005, 2131 cases were reported in 12 countries. Most (94%) of the cases were in the DRC, and many were not confirmed in the laboratory. The majority of cases were reported in villages within, or close to, the tropical rainforest. African children were the most affected, with a 10% case–fatality rate. The reason for the upsurge, particularly in Africa, is unknown, but it has been suggested that a number of reported cases were

(5) Primary viremia and infection of internal organs and lymphatic system (white arrows). (6) Secondary viremia and development of exanthem and enanthem (red arrows). (b) A transmission electron micrograph (approximately ×10 000) of a BSC-1 cell infected with MPXV (red arrows). Virus replication occurs in the cytoplasm (not the nucleus, N). The inset image is an MPXV EEV particle (approximately ×165 000). Note the biconcave core and loose-fitting outer membrane. Adapted from Parker S, Nuara A, Buller RML, and Schultz DA (2007) Human monkeypox: An emerging zoonotic disease. *Future Microbiology* 2: 17–34, with permission from Future Medicine Ltd.

actually cases of chickenpox, caused by varicella-zoster virus (a herpesvirus). A likely contributing factor is the cessation of smallpox vaccination by the WHO *c.* 1980, because recent vaccination with vaccinia virus is 85% effective at protecting against severe MPXV-induced disease. The broad host range of MPXV is also likely to permit additional species to become reservoirs or incidental hosts, thus increasing the exposure risk for humans.

Studies between 1981 and 1986 revealed that most human monkeypox cases occurred as single sporadic infections after contact with animals. The first-generation secondary attack rate in nonvaccinated household contacts was approximately 9% (compared to 58% with smallpox). The attack rate decreased over the second and third generations, and fourth generation attacks were very rare. That said, it has recently been reported that the transmissibility of MPXV is increasing in human hosts. Genetic changes that improve transmissibility to similar levels as those seen in VARV would be required for MPXV to infect humans in an endemic fashion.

Genetics

Although MPXV and VARV present similar disease profiles in humans, neither of the viruses is believed to have given rise to the other. Rather, both are considered to have arisen from a progenitor virus(es) similar to the cowpox virus lineage. MPXV isolates from West Africa are less virulent and less transmissible in human populations than isolates from the Congo Basin. Consistent with other orthopoxviruses, MPXV strains exhibit gene conservation toward the center of the genome, with variation increasing in frequency toward the termini, which encode for specific virulence genes. Genomic differences between strains have been mapped with restriction fragment length polymorphism studies and DNA sequencing techniques. Sequence analyses of strains from West Africa and the Congo Basin have revealed that isolates are approximately 95% identical to each other and approximately 96% identical to VARV. This value increases to 99% when comparing isolates from only West African or only the Congo Basin regions, allowing a separation into two groups or clades. The genomic sequences of eight MPXV strains are available online (see the 'Relevant website' section).

Ecology

The broad host range of MPXV and seroprevalence studies suggest that several animal species, rather than a single species, may act as reservoirs for MPXV in nature. In the latter part of the twentieth century, several field studies were conducted in the lowland tropical forests of the Congo Basin and West Africa; these studies revealed that MPXV can infect many animal species, including squirrels (*Funisciurius* spp. and *Heliosciurus* spp.) and nonhuman primates (such as *Cercopithecus* spp.). Species that are seropositive for MPXV antibodies have some similar and some dissimilar traits in relation to diet and habitat preference; approximately 40% are arboreal, 40% are semiterrestrial, and 20% are terrestrial. Therefore, MPXV infects species that inhabit all levels of the lowland tropical rainforest in the Congo Basin and West Africa. For a thorough discussion of this topic, the reader is directed to the article by Parker *et al.* listed in the 'Further reading' section.

New Hosts and Geographic Expansion

The interaction of MPXV with reservoir and incidental hosts is still poorly understood, as is the potential for virus transmission to humans within and outside its geographical range. Until the outbreak in the USA in 2003, MPXV had remained fairly localized to a handful of countries in central and West Africa, with the majority of cases detected in the DRC. The USA outbreak added to the breadth of host species capable of supporting MPXV replication, and demonstrated the potential of the virus to expand its geographical range. No human infections were attributed to the shipment of animals that entered the USA from Africa; rather, most patients had direct contact with infected native prairie dogs that had been housed with the imported African rodents. Subsequent to the USA outbreak, prairie dogs that were experimentally infected with MPXV were found to have ulcerative lesions on their lips, tongues, and buccal mucosa. High titer MPXV could be cultured from the nasal discharge and oropharynx of these animals for up to 22 days post infection, indicating that transmission from prairie dogs was likely via the respiratory and mucocutaneous routes. The USA outbreak was caused by the less virulent West African strain, which probably made it easier to bring under control.

A more recent example (2005) of MPXV expanding its environs is found in 19 human monkeypox infections discovered in the previously MPXV-free country of Sudan. This outbreak occurred some 300 miles northeast of the edge of the tropical rainforest – the traditional home of the Congo Basin strain of MPXV. From experience with vaccinia virus, it would not be surprising if MPXV continues to adapt to new species. Such adaptation has already occurred with prairie dogs in the USA and is possibly the reason for the outbreak in Sudan.

Person-to-Person Transmission

MPXV and VARV transmission are likely similar. Human-to-human transmission can be separated into six steps, as demonstrated in **Figure 1**. Step 1: release of virions from lesions in the oropharyngeal mucosa and their aerosolization into the new host's breathing space. Step 2: virus particles, most likely in the EEV form, are transmitted by aerosols. Step 3: seeding of the new host's respiratory mucosa is initiated. Step 4: MPXV replication creates foci of infection and production of specific proteins to neutralize the immune response. Step 5: the primary viremia denotes successful virus replication and spread from the initial site(s) of infection to lymphoid tissues and internal organs. Step 6: the secondary viremia occurs when the virus moves from the infected lymphoid tissues and internal organs to the cornified and mucosal epithelium to cause the exanthem and enanthem, respectively. Transmissibility is dependent on the number of lesions in the host oropharyngeal mucosa, virus survivability in the face of the host immune response, and the ability of the virus to produce infectious virions for exhalation from the respiratory tract. As an explanation of the increased transmissibility of VARV over MPXV, it is likely that VARV produces more infectious virions in the respiratory mucosa than MPXV.

Treatment

Currently, the public health importance of human monkeypox is minor compared to that of VARV before the 1980s. However, MPXV is becoming a more common infection in

central Africa, where there seems to be a rise in the number of transmission generations observed during outbreaks. MPXV could be controlled in the human population by vaccination against smallpox. However, considering the current poor transmissibility in human populations and zoonotic nature of MPXV, this would need to be weighed carefully against the adverse reactions expected from vaccination. As of 2007, two antiviral drugs with activity against orthopoxviruses are being evaluated in animal models.

Diagnostics

Historically, biological properties have been used to identify and differentiate orthopoxviruses. Growth characteristics in embryonated chick eggs were particularly useful during the smallpox eradication campaign. However, this approach is labor and time consuming and requires a high level of skill. Even today, electron microscopy is a first-line technique, but does not allow for differentiation between orthopoxvirus species. Real-time polymerase chain reaction (PCR) is now regarded as the technique of choice for species differentiation, and several protocols are available specifically to identify and differentiate VACV and MPXV from other poxviruses.

Future Perspectives

VARV has been exterminated from the world's human population and could only be reintroduced by artificial release of clandestinely stored stocks. Such an incident would have devastating ramifications. MPXV is of minor public health significance when compared to VARV, but human MPXV infections are increasing. Elimination of MPXV is not possible because, unlike VARV, the virus is likely to have several animal reservoirs. Lastly, the possibility that terrorist groups or rogue nations might bioengineer VARV or MPXV to enhance virulence and transmissibility is a potential threat. Since the molecular biology of both viruses (and other orthopoxviruses) is fairly well understood, genetic tinkering aimed at enhancing virulence is a possibility, although techniques to increase transmissibility are less well developed.

Glossary

–1 Ribosomal frameshifting Event occurring during translation elongation when the ribosome shifts its frame for reading the mRNA exactly one position in the upstream direction.

Icosahedral particle Spherical viral particle that is a polyhedron having 20 faces.

Leaky scanning mechanism Mechanism during translation initiation for escaping the first start codon, which occurs when the first AUG resides in a very poor context and therefore only some ribosomes initiate translation at that point.

Polycistronic RNA Contains the genetic information to translate more than one protein.

Satellite RNA (satRNA) Subviral agent consisting of RNA that becomes packaged in protein shells made from coat protein of the helper virus and whose replication is dependent on that virus.

***T* = 3 particle** Icosahedral virus particle that contains three chemically identical coat protein monomers in the icosahedral asymmetric unit; *T* = 3 particle contains 180 coat protein molecules.

VPg Protein that is attached to the 5′ end of viral genomic RNA.

Introduction

It was proposed in 1969 that single-component-RNA beetle-transmitted viruses be placed into a southern bean mosaic virus group. Since 1995, this group has been recognized by the International Committee on Taxonomy of Viruses (ICTV) as the genus *Sobemovirus* (sigla from *so*uthern *be*an *mo*saic *virus*) unassigned to any family. The establishment of this virus group was based on similarities in particle morphology, capsid stabilization, sedimentation coefficients, sizes of protein subunits and genomic RNA, features in mode of vector transmission, and distribution of the particles within the cell. In the *Eighth Report of the International Committee on Taxonomy of Viruses*, 13 virus species were accepted as definite species of the genus *Sobemovirus* and four tentative species were proposed (**Table 1**).

In addition, two viruses presently not recognized by the ICTV are closely related to the sobemoviruses. Nucleotide sequence comparison of the polymerase, VPg, and coat protein (CP) genes of papaya lethal yellowing virus (PLYV) shows high homology to sobemoviruses (about 41–51% with lucerne transient streak virus (LTSV), southern bean mosaic virus (SBMV), southern cowpea mosaic virus (SCPMV), and cocksfoot mottle virus (CfMV)). Snake melon asteroid mosaic virus (SMAMV) RNA-dependent RNA polymerase (RdRp) fragment possesses 71% amino acid sequence similarity to rice yellow mottle virus (RYMV) RdRp.

The host range of sobemoviruses is usually narrow; individual viruses can naturally infect plants from one family only. The exception is sowbane mosaic virus (SoMV) that infects plants from the families Chenopodiaceae, Vitaceae, and Rosaceae. Some sobemoviruses (SBMV, SCPMV, SoMV) are distributed throughout the world; others are limited to one continent or even to one country (**Table 1**).

Sobemoviruses are readily transmitted mechanically. RYMV, for example, is efficiently transferred from plant to plant by farming operations, donkeys, cows, grass rats, wind-mediated leaf contacts, soil, etc. In addition, sobemoviruses are transmitted by vectors. The most common vectors are different species of beetles that transmit sobemoviruses in a semipersistent manner. However, blueberry shoestring virus (BSSV) and SoMV are transmitted by aphids, SoMV also by leafminers and leafhoppers, and velvet tobacco mottle virus (VTMoV) by mirids. Several viruses in the genus are seed-transmissible (**Table 1**).

Genome Organization and Replication

The full-length genomic nucleotide sequences have been determined for members of nine sobemovirus species. Their genome sizes vary from 4.0 to 4.5 kb. The genomic (as well as subgenomic) RNA has a viral genome-linked protein (VPg) covalently bound to its 5′ end. The 3′ terminus of the genomic RNA is nonpolyadenylated.

All the sequenced sobemoviruses have a polycistronic positive-sense single-stranded RNA (ssRNA) genome that consists of four open reading frames (ORFs) (**Figure 1**). The genome is compact, as for most viruses all ORFs overlap. ORFs 1, 2a, and 2b are all translated from the genomic RNA. The initiation of translation from the genomic RNA is facilitated at least in case of CfMV by the translational enhancer in the 5′ untranslated region (UTR) of the genome. Translation of ORF1 and ORF2a occurs via a leaky scanning mechanism. ORF2b is expressed as a fusion protein with ORF2a through a 1 ribosomal frameshift mechanism. Previously, it was reported that some sobemoviruses express the RdRp from a single in-frame polyprotein, not via a –1 translational frameshift. Recently, it has been demonstrated, however, that the difference between the two kinds of genomic organization resulted from a single erroneous extra nucleotide in the genomic sequences of these sobemoviruses that RdRp was thought to be expressed without the –1 ribosomal frameshifting mechanism. Thus, all sequenced sobemovirus species possess similar genomic organization.

A genome 3′-proximal ORF is translated from the subgenomic RNA (sgRNA). The sgRNA has been detected in sobemovirus-infected tissues as well as in virus particles. In addition to the genomic and sgRNA, some sobemoviruses (LTSV, RYMV, subterranean clover mottle virus (SCMoV), Solanum nodiflorum mottle virus (SNMoV), VTMoV) encapsidate a circular viroid-like satellite RNA (satRNA). The sizes of these circular satRNAs range from 220 to 390 nt, the 220 nt RYMV satRNA being the smallest known naturally occurring circular RNAs.

The replication of sobemoviruses uses is poorly understood. The genomic RNA of incoming virus particles is probably uncoated by the co-translational disassembly mechanism that is followed by RNA replication. Little is known about the signals needed for the replication. The 5′ terminal nucleotides of the genomic RNA are ACAAAA for SCPMV, ACAA for RYMV, ACAAA for LTSV and ryegrass mottle virus (RGMoV), ACAAAA for SCMoV, CACAAAA for Sesbania mosaic virus (SeMV) and SBMV, and CAAAA for turnip rosette virus (TRoV). For all these viruses, the 5′ ACAAA or ACAAAA sequence is also present upstream from the CP translation initiation codon, indicating the possible 5′ terminus of sgRNA. This sequence is also characteristic of 5′ termini of polero-, diantho-, and barnaviruses. Due to the conservation of this sequence, it or its complementary sequence in ( )-strand has been predicted to function in viral RNA replication by promoting or enhancing the binding of viral RdRp. Different from other sobemoviruses, such motif is present neither at the 5′ end nor upstream from the CP translation initiation codon in CfMV genome. In addition, all sobemoviruses contain a polypurine tract 5′-aAGgAAA near the beginning of their genomic RNA. Nearly nothing is known about signals at the 3′ end of the genomic RNA essential for the initiation of the synthesis of the genomic

Table 1 Viruses of the genus *Sobemovirus* and their biological properties

minus strand. A potential tRNA-like structure has been attributed to the 3′ end of some sobemoviruses, but no experimental data are available on that.

Mutation and recombination rates associated with the replication by sobemoviral RdRps are largely uncharacterized. No intra- or interspecies recombinant sobemoviruses have been described so far. Based on the phylogenetic analysis of RYMV sequences, it has been concluded that RYMV has evolved in the absence of recombination events. No recombinants were also detected between CfMV and RGMoV in doubly infected plants. However, several defective interfering (DI) RNA molecules have been cloned from CfMV-infected plants containing the 5′ end of the genomic RNA linked to 850–950 nt of the 3′ terminus. SatRNAs have several interesting interactions with the replication of the helper sobemoviruses. For example, LTSV supports the replication of satRNA of SNMoV but SNMoV does not replicate LTSV satRNA. At the same time, LTSV satRNA replication is supported by CfMV, SBMV, SoMV, and TRoV, whereas this support is host dependent.

Gene Products and Their Functions

P1

P1 is encoded by the 5′ terminal ORF of the viral genomic RNA and its translation occurs with poor efficiency, as the translation initiation context is suboptimal. The molecular masses of different P1s range between 11.7 and 24.3 kDa and, surprisingly, there is no similarity between the P1 amino acid sequences, making this region the most variable one in the genome of sobemoviruses.

The most-studied P1 proteins are the ones of RYMV, SCPMV, and CfMV. All these proteins are required for systemic infection and are dispensable for viral replication. The P1 of SCPMV has also been shown to be nonessential for viral assembly. In addition, RYMV P1 is described as an important pathogenicity determinant. Both CfMV P1 and RYMV P1 act as suppressors of RNA silencing in *Nicotiana benthamiana*, a nonhost species. P1 of CfMV binds ssRNA in a sequence-independent manner and it does not bind double-stranded small interfering RNAs (siRNAs).

The transient gene expression of ORF1 from CfMV and from SCMoV demonstrated that P1 – as a green fluorescent protein (GFP) fusion protein – is involved in movement. However, the cell-to-cell movement of P1, independent of other viral components, was very limited.

Little is known about the subcellular localization of P1. In the case of CfMV, the P1 is coupled with cellular membranes and/or heavily aggregated when overexpressed in insect cells.

It is worth mentioning that the 5′ terminal half of the genomes of sobemoviruses and poleroviruses is similar in organization. Moreover, poleroviral P0, encoded by the 5′ terminal ORF, shares many features with sobemoviral P1: it acts as suppressor of RNA silencing, it is the

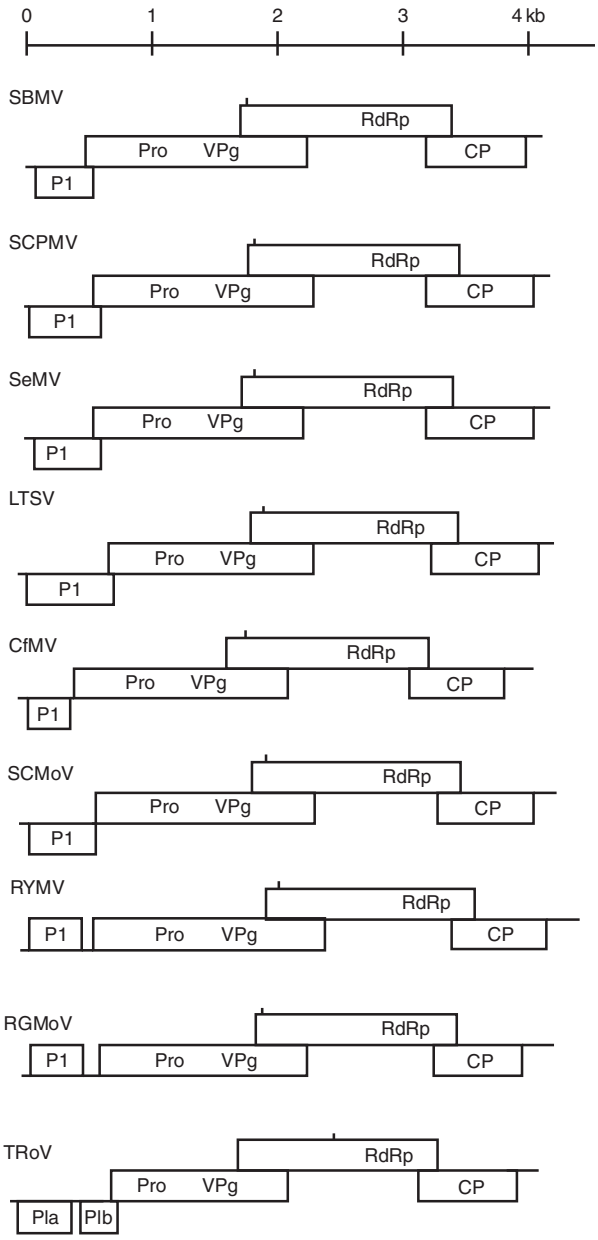

Figure 1 Genome organization of sobemoviruses.

most divergent protein of the viral genome, and it has a poor translation initiation context.

Polyprotein

Translation of the P2a or P2a2b polyprotein takes place from sobemoviral genomic RNA via a leaky scanning mechanism. The comparison of the sequences surrounding the initiation codons for ORF1 and ORF2a/ORF2a2b of sobemoviruses with the consensus sequences established for plant mRNAs shows that the sequence surrounding the ORF2a initiation codon is always in a more favorable context for translation by plant ribosomes.

In vitro translation of sobemoviral RNAs as identified a protein with a molecular mass of about 100–105 kDa. This protein is encoded by partially overlapping ORF2a and ORF2b due to the signal for −1 ribosomal frameshifting. The −1 ribosomal frameshift is needed to regulate the production of sobemoviral RdRp which is encoded by ORF2b. Although no sobemoviral RdRp has been molecularly characterized yet, the presence of the highly conserved GDD motif with its surrounding (characterized as SGSYCTSSTNX$_{19–35}$GDD) feature for RdRps of positive-strand ssRNA viruses has been identified by computer-based sequence analysis of sobemovirus genomes. In the case of CfMV, the consensus signal for −1 ribosomal frameshift event has been shown to consist of a slippery sequence UUUAAAC and a stem–loop structure located 7 nt downstream of it. The slippery sequence UUUAAAC, followed by a simple stem–loop structure, is absolutely conserved for all sequenced sobemoviruses. In a wheat germ extract, CfMV-derived 1 ribosomal frameshifting takes place with an efficiency of *c.* 10%. It has been proposed that the C-terminal processing products of ORF2a-encoded protein regulate the efficiency of the frameshifting.

ORF2a encodes the N-terminal part of the polyprotein that contains at least a viral serine protease and a VPg. The position of the VPg in between the viral protease and replicase (Pro-VPg-RdRp) is unique to sobemo-, polero-, enamo-, and barnaviruses. It is proposed that sobemoviral VPgs exist in a 'natively unfolded state' lacking both secondary and tertiary structures. The only conserved amino acid sequence element observed among sobemoviral VPgs is a WAD or WGD motif followed by a D- or E-rich region.

The proposed consensus amino acid sequence for the catalytic triad of the serine proteases of sobemo-, polero-, enamo-, and barnaviruses is H(X$_{32–35}$)[D/E](X$_{61–62}$)TXXGXSG. The glycine and histidine residues downstream from the catalytic residues (H181, D216, S284 for SeMV) are suggested to be the site for substrate binding. The crystal structure of the protease domain has been determined for SeMV at 2.4 Å resolution. The structure exhibits the characteristic features of trypsin fold.

Mutations of active site residues of H181A, D216A, or S284A render the SeMV protease inactive. The SeMV serine protease domain lacking the N-terminal 70 amino acids is inactive *in trans*. According to *in silico* analysis, the N-termini of the sobemoviral polyprotein sequences (except LTSV that lacks the domain respective to N-termini of other sobemoviral polyproteins) show the presence of high-propensity membrane helices. Interestingly, the presence of the VPg domain at the C-terminus of the SeMV protease domain lacking the N-terminal 70 amino acids restores the protease activity both in *cis* and in *trans*. Furthermore, the substitution of conserved W43 in SeMV VPg to phenylalanine or the deletion of the entire VPg domain abolishes the proteolytic processing of the viral polyprotein.

The N-terminal sequencing of SBMV, CfMV, and SeMV VPgs attached to viral genomes as well as other approaches have indicated that the polyprotein is processed at E/T or E/N sites between the protease, VPg, and RdRp domains. Additionally, A/V cleavage site was identified at the N-terminus of SeMV polyprotein by mass spectrometric analysis. As the alanine and valine residues are small enough to be accommodated in the active site without steric hindrance, it is suggested that the specificity of sobemoviral proteases depends not only on the sequence but also on the conformation of the polypeptide.

Virion Structure and Coat Protein

The virions of members of the genus have an icosahedral capsid roughly the size of 30 nm, which is assembled according to $T = 3$ symmetry. The capsid contains 180 molecules of a single ~30 kDa CP, which is translated from an sgRNA. The single-stranded genomic RNA and sgRNA together with VPg are packaged inside the virion. The three-dimensional structures of SCPMV, SeMV, RYMV, RGMoV, and CfMV virions have been determined utilizing X-ray crystallography. Each icosahedral unit of the virion comprises of three quasi-equivalent subunits A, B, and C, which have minor differences in conformation (**Figure 2(a)**). The A subunits group at fivefold axes while pairs of B and C subunits meet at threefold axes. In addition to protein–protein and protein–RNA interactions each icosahedral unit is stabilized by three calcium-binding sites located between subunits AB, BC, and CA.

The CP is divided into two domains: C-terminal S (shell) domain, which has an eight-strand jellyroll β-sandwich topology, common to nonenveloped icosahedral viruses, and N-terminal R (random) domain, which is disordered in subunits A and B, but is partially structured in subunit C. The S domain is the building block of the virion, whereas the R domain is involved in the regulation of the capsid structure. The primary sequences of CPs among the members of the genus are quite different. However, the three-dimensional structures are nearly identical, for example root mean square difference between RYMV and SCPMV is 1.4 Å. Regardless of that, two different structures of the R domain in C subunit have been found (**Figure 2(b)**). In SCPMV and SeMV the N-terminus of subunit C, makes a U-turn and extends toward the threefold axis nearest to C, where it makes a β-structure together with R domains from analogous C subunits. In RYMV and CfMV there is no U-turn, instead the N-terminal arm of subunit C extends toward subunit B and makes a similar structure at the distal threefold axes closest to subunit B. When the R domain of SCPMV or SeMV CP is removed, only $T = 1$ particles are formed, indicating the importance of the region in $T = 3$ particle formation.

Due to its complex nature, very little is known about the mechanism of capsid formation. Yet, there is evidence suggesting that the virion assembly could be nucleated by AB dimers at icosahedral fivefold axes since pseudo $T = 2$ SeMV particles comprise of groups of A and B subunits. Studies with SCPMV, SeMV, and RYMV particles demonstrate that the stability of the virions depends greatly on pH and the availability of calcium ions. Upon alkaline pH or removal of the cations the virus particles swell and become less stable. Mutation analysis of SeMV CP calcium-binding sites demonstrates that cation-mediated interactions are mainly needed for particle stability. The R domain of all sobemovirus CPs is rich in basic amino acid residues and contains an arginine-rich motif (ARM). Studies with SCPMV and SeMV CP demonstrate that ARM is essential for RNA encapsidation but not for particle formation. However, the presence of RNA enhances the overall stability of capsids. The N-terminus of SCPMV CP withholds a potential to form an α-helix and can interact with membranes *in vitro*. It is proposed that the R domain of all sobemoviral CPs contains a nuclear localization signal.

The functions of sobemoviral CPs in viral life cycle besides capsid formation are not fully understood. Studies with full-length clones of SCPMV and RYMV display that the CP is dispensable for virus replication but systemic virus movement is completely abolished in the absence of CP. Sobemoviral CPs have also been reported to complement the long-distance movement of taxonomically distinct plant viruses.

Subcellular Localization, Short- and Long-Distance Movement

Sobemoviral particles are found mainly in mesophyll and vascular tissues, but also in epidermal, bundle sheath, and guard cells. The quantity of particles present is in correlation with the severity of symptoms. In vascular tissues there are reports of virus particles in both xylem and phloem. CfMV, SCPMV, and SBMV virus particles have been found in phloem companion cells, whereas RYMV particles have been detected predominantly in xylem. RYMV particles accumulated in xylem parenchyma cells and vessels; additionally association with intervascular pit membranes was observed. For RYMV, the common belief is that the virus is transported between xylem cells through pit membranes.

Subcellularly virus particles are found at least in cytoplasm, vacuoles, and nuclei. Virus particles in cytoplasm or vacuoles are known to form crystalline structures, sometimes particles are found in vesicles. No particles have been found in mitochondria and chloroplasts, but the latter are noted to form finger-like extrusions in infected cells. Studies with RYMV suggest that vacuoles of xylem parenchyma cells become the storage compartments for virions in late phase of infection. It is proposed that swollen and less compact virions coexist in

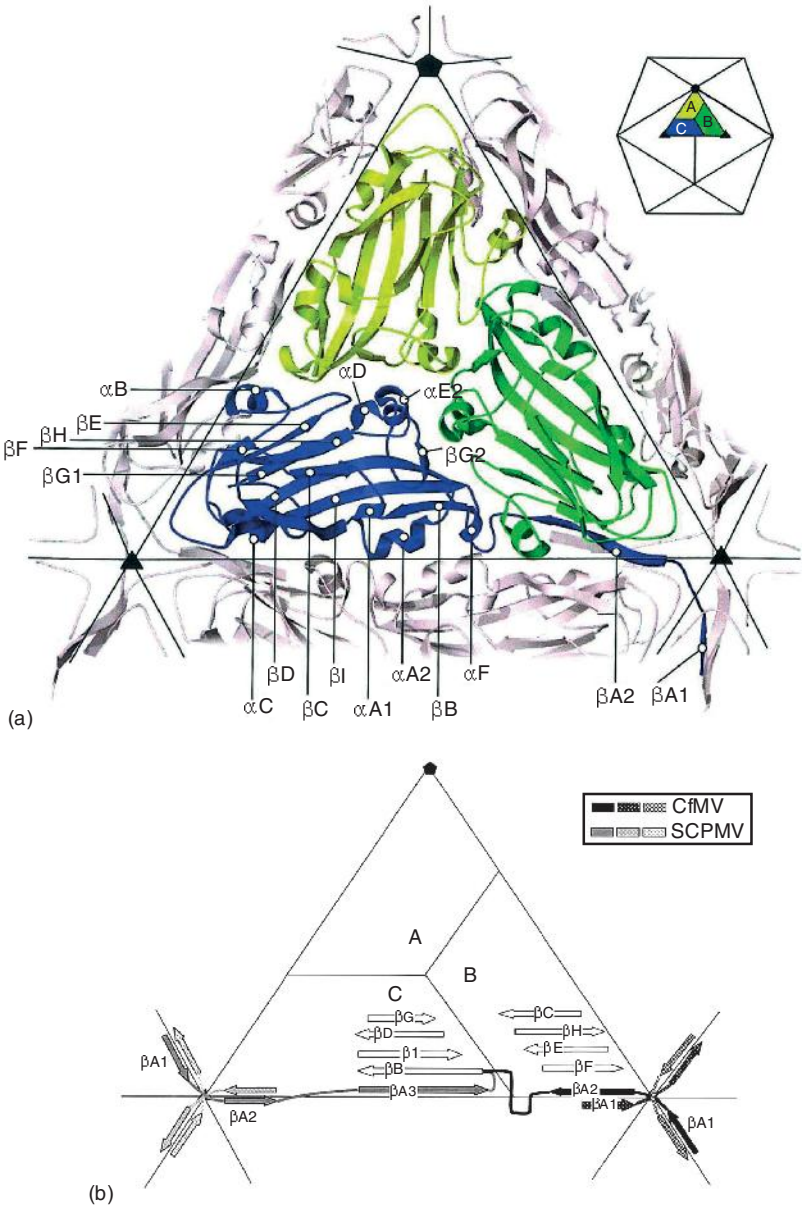

Figure 2 (a) Arrangement of CP molecules in CfMV capsid. (b) A schematic representation of the N-terminal arm in sobemoviruses. Reproduced from Tars K, Zeltins A, and Liljas L (2003) The three-dimensional structure of cocksfoot mottle virus at 2.7 Å resolution. *Virology* 310: 288–289, with permission from Elsevier.

the cytoplasm, whereas vacuoles with their lower pH and higher Ca^{2+} concentration contain compact virions.

Studies with SCPMV, SBMV, and RYMV emphasize that cell-to-cell and vascular movement of sobemoviruses are two distinct processes, whereas the long-distance movement is dependent on the correct capsid formation.

Pathology, Economic Importance, Resistance

Sobemoviral infections can cause a variety of disease symptoms: mild or severe chlorosis and mottling, stunting, necrotic lesions, vein clearing, sterility. Subcellularly, sobemoviruses form crystalline arrays and tubules in the cytoplasm, some of which are enveloped in endoplasmic reticulum-derived vesicles. It has been observed that nucleolus of the RYMV-infected cell enlarges. Probably the most dramatic change induced by RYMV occurs in the cell walls of parenchyma and mature xylem cells, where middle lamellae of the wall are disorganized. RGMoV has been reported to induce apoptotic cell death in oat leaves. The outcomes of these histopathological changes range from symptomless infections of sobemoviruses to severe diseases and death of plants. RYMV infection also causes important changes in the abundance of many host proteins.

For instance, the expression levels of several defense- and stress-related proteins like superoxide dismutase and different heat shock proteins increase several times.

Several sobemoviruses are economically important pathogens. RYMV causes one of the most damaging and rapidly spreading diseases of rice in Africa. Yield losses fluctuate between 10% and 100%, depending on plant age prior to infection, susceptibility of the rice variety, and environmental factors. PLYV, causing serious chlorosis, is responsible for an important disease of papaya in northeast Brazil. SCMoV decreases seed and herbage production in Australia. Over time, SCMoV-infected pastures become weedy and unproductive. SBMV infections in common bean leads to the mosaic and distortion of pods and reduced size and number of seeds.

Natural resistance to sobemoviruses has been detected at least for CfMV in cocksfoot, for CnMoV in *Cynosurus cristatus*, for RYMV in rice and *Oryza glaberrima*, for SBMV in beans, for SCMoV in subterranean clover, and for SCPMV in cowpea. The molecular mechanisms conferring resistance have only been described for RYMV in *Oryza* species. Namely, the recessive resistance gene *Rymv-1* encodes the eukaryotic translation initiation factor eIF(iso)4G whose interaction with viral VPg is responsible for the high-resistance trait. In parallel, a quantitative trait locus (QTL) is described conferring partial resistance against

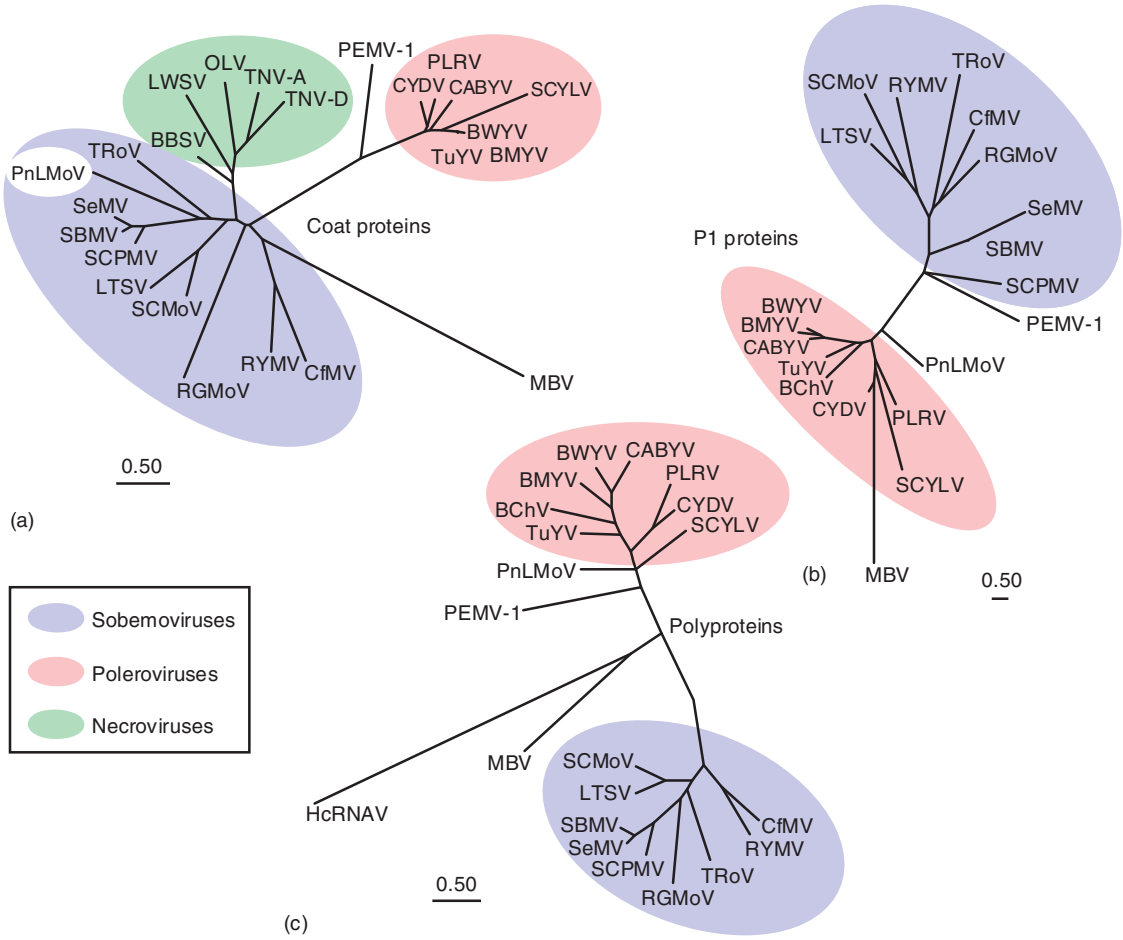

Figure 3 Unrooted phylogram of sobemoviral proteins and the respective proteins of related viruses using maximum-likelihood method. (a) Coat proteins, (b) P1 proteins, and (c) polyproteins. The bar shows the scale of branch length. The protein sequences were aligned with ClustalW and the phylogenetic trees were constructed using PHYLIP PROML 3.6.1 and visualized using Treetool. Viruses (with GenBank accession number) involved in the analyses presented in this figure were the following. Sobemoviruses: CfMV, cocksfoot mottle virus (DQ680848); LTSV, lucerne transient streak virus (U31286); RYMV, rice yellow mottle virus (AJ608206); RGMoV, ryegrass mottle virus (AB040446); SeMV, Sesbania mosaic virus (AY004291); SBMV, southern bean mosaic virus (AF0558871); SCPMV, southern cowpea mosaic virus (M23021); SCMoV, subterranean clover mottle virus (AF208001); TRoV, turnip rosette virus (AY177608). Poleroviruses: BChV, beet chlorosis virus (AF352024); BMYV, beet mild yellowing virus (X83110); BWYV, beet western yellows virus (AF473561); CYDV, cereal yellow dwarf virus (Y07496); CABYV, cucurbit aphid-borne yellows virus (X76931); PLRV, potato leafroll virus (D00530); ScYLV, sugarcane yellow leaf virus (AF157029); TuYV, turnip yellows virus (X13063). Enamovirus: PEMV-1, pea enation mosaic virus 1 (L04573). Barnavirus: MBV, mushroom bacilliform virus (U07551). Necroviruses: BBSV, beet black scorch virus (AF452884); LWSV, leek white stripe virus (X94560); OLV-1, olive latent virus 1 (X85989); TNV-A, tobacco necrosis virus A (M33002); TNV-D, tobacco necrosis virus D (D00942). Unclassified viruses: PnLMoV, poinsettia latent mottle virus (AJ867490); HcRNAV, Heterocapsa circularisquama RNA virus (AB218609).

several RYMV isolates, but the molecular mechanisms responsible for that trait are unknown. Pathogen-derived transgenic resistance against RYMV has been achieved by transforming plants with constructs expressing either RdRp or CP sequences of the virus.

Phylogenetic Relationships

Within the genus *Sobemovirus*, phylogenetic analysis of different proteins indicates that three species – SeMV, SBMV, and SCPMV – are very closely related to each other. Also LTSV and SCMoV as well as CfMV and RYMV cluster into two corresponding subgroups within the genus (**Figure 3**).

When the sobemoviral sequences are compared to all other sequences available, it is evident that the 5′ terminus of the sobemoviral genomes together with ORF1 are unrelated to any other known viral genera (**Figure 3**). The middle part of the genomes (encoding for the successive domains of Pro-VPg-RdRp), however, is similar to those of genera *Polerovirus* and *Enamovirus* from the family *Luteoviridae*. In contrast, the 3′ part of the sobemoviral genomes encoding for the CP is more closely related to CP genes of the genus *Necrovirus* from the family *Tombusviridae* (**Figure 3**). These similarities indicate that possibly early recombination events have played an important role during the evolution of sobemoviruses, luteoviruses, and tombusviruses. This possibility is further supported by the existence of poinsettia latent mottle virus (PnLMoV) whose sequence (AJ867490) shows a close relationship to poleroviruses within the first three quarters of its genome (encoding P1 and polyprotein), but rather to sobemoviruses in the last quarter (encoding CP gene) (**Figure 3**).

A virus belonging to the single species *Mushroom bacilliform virus* of the family *Barnaviridae* (genus *Barnavirus*) has a genomic organization similar to sobemoviruses (except that it lacks ORF1 of sobemoviruses) and its Pro-VPg-RdRp and CP genes are related to the same sequences of different sobemoviruses. In addition, putative protease and RdRp of a positive-sense ssRNA virus infecting a marine dinoflagellate *Heterocapsa circularisquama*, HcRNAV (Heterocapsa circularisquama RNA virus, AB218609), are similar to those of the sobemo- and poleroviruses as well as of PnLMoV and MBV.

Glossary

Bridge vector Vector responsible for carrying virus from the primary cycle to tangential hosts such as humans.
Diapause Insect hibernation.
Gonotrophic cycle Recurrent cycle of blood feeding and egg laying by female mosquitoes.
Maintenance vector Vector responsible for transmission of virus among primary vertebrate host species.

Neuroinvasive Ability of virus to invade the central nervous system.
Vector competence Ability of an insect to become infected with and transmit a pathogen.
Viremia Concentration of virus within peripheral blood.
Viremogenic Ability to elicit an elevated viremia response.

History

St. Louis encephalitis virus (SLEV) probably has been present in the New World within its enzootic cycle for thousands of years. The arrival of European settlers in the 1600s and the extensive agricultural development that followed greatly altered the landscape by clearing and irrigating vast areas of North America and establishing extensive urban centers. These changes probably increased the abundance of peridomestic *Culex* mosquito species and avian hosts such as house finches and mourning doves, introduced new avian hosts such as house sparrows, intensified human–vector mosquito contact, and probably increased the incidence of human infection. However, diagnosis of diseases caused by arbovirus infections such as SLEV assuredly was confounded with other infections causing fever and central nervous system (CNS) disease during summer.

During the summer of 1933, a major encephalitis epidemic with more than 1000 clinical cases occurred in St. Louis, Missouri. These cases occurred during the middle of an exceptionally hot, dry summer and were concentrated within areas of the city adjacent to open storm water and sewage channels that produced a high abundance of *Culex* mosquitoes. A virus, later named St. Louis encephalitis virus, was isolated at autopsy from human brain specimens. Mouse protection assays using convalescent human sera demonstrated that SLEV differed from other viruses causing seasonal CNS disease, such as the equine encephalitides, poliomyelitis, and vesicular stomatitis. The epidemiological features of this epidemic included the late summer occurrence of cases (especially in persons over 50 years of age), exceptionally warm temperatures, and elevated *Culex* mosquito abundance associated with a poorly draining wastewater system. These features remain the hallmark of SLEV epidemics to date.

A multidisciplinary team of entomologists, vertebrate ecologists, epidemiologists, and microbiologists from the University of California subsequently investigated an SLEV epidemic in the Yakima Valley of Washington State during 1941 and 1942 and established the components of the summer transmission cycle, including wild birds as primary vertebrate hosts and *Culex* mosquitoes as vectors. The isolations of SLEV from *Culex tarsalis* and *Culex pipiens* mosquitoes were among the first isolations of any virus from mosquitoes and stimulated the redirection of mosquito control in North America from *Anopheles* malaria vectors and pestiferous *Aedes* to *Culex* encephalitis vectors.

Understanding the basic transmission cycle, an appreciation of the wide range of clinical symptoms, and the development of laboratory diagnostic procedures provided an expanding view of the public health significance of SLEV, with epidemics or clusters of cases recognized annually throughout the US. Wide geographic distribution and consistent annual transmission since 1933 has resulted in >1000 deaths, >10 000 cases of severe illness, and >1 000 000 mild or subclinical infections. The largest documented SLEV epidemic occurred during 1975 in the Ohio River drainage, with >2000 human cases documented. Other substantial human epidemics involving hundreds of cases have occurred in Missouri (1933, 1937), Texas (1954, 1956, 1964, 1966), Mississippi (1975), and Florida (1977, 1990). Smaller outbreaks have been recognized in California (1952), New Jersey (1962), and several other states plus Ontario (1975), Canada. Cases reported annually to the Centers for Disease Control and Prevention (CDC) since 1964 are shown in **Figure 1**.

Distribution

SLEV is distributed from southern Canada south through Argentina and from the west to the east coasts of North America and into the Caribbean Islands. Historically, human cases have been detected in Ontario and Manitoba, Canada, all of the continental US (except the New England States and South Carolina, **Figure 2**), Mexico, Panama, Brazil, Argentina, and Trinidad. The low number of human cases in Canada probably reflects the warm temperature requirements for SLEV replication in the mosquito host, whereas the low numbers of cases from tropical America may reflect inadequate laboratory diagnosis, the circulation of attenuated virus strains, and/or enzootic cycles involving mosquitoes that feed infrequently on humans. Support for this geographic distribution comes from laboratory-confirmed human cases, SLEV isolations from birds, mammals, and mosquitoes, and serological surveys of mammal and avian populations.

Classification

Taxonomically, SLEV is classified within the Japanese encephalitis virus (JEV) complex in the genus *Flavivirus* of the family *Flaviviridae*. Related viruses within this group include Japanese encephalitis, Murray Valley encephalitis, West Nile, and Usutu. SLEV consists of a positive-sense, single-stranded RNA enclosed within a

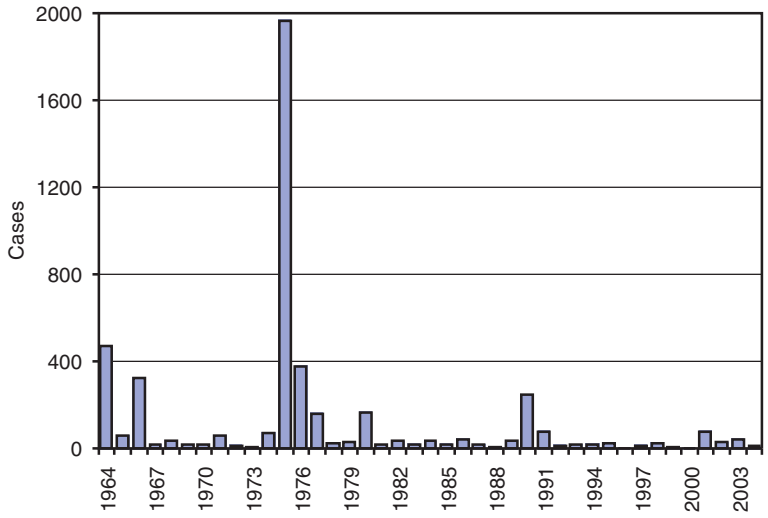

Figure 1 Number of clinical cases of St. Louis encephalitis reported to the US CDC, 1964–2004. Data provided by ArboNet, Center for Disease Control and Prevention, Ft. Collins, CO, USA.

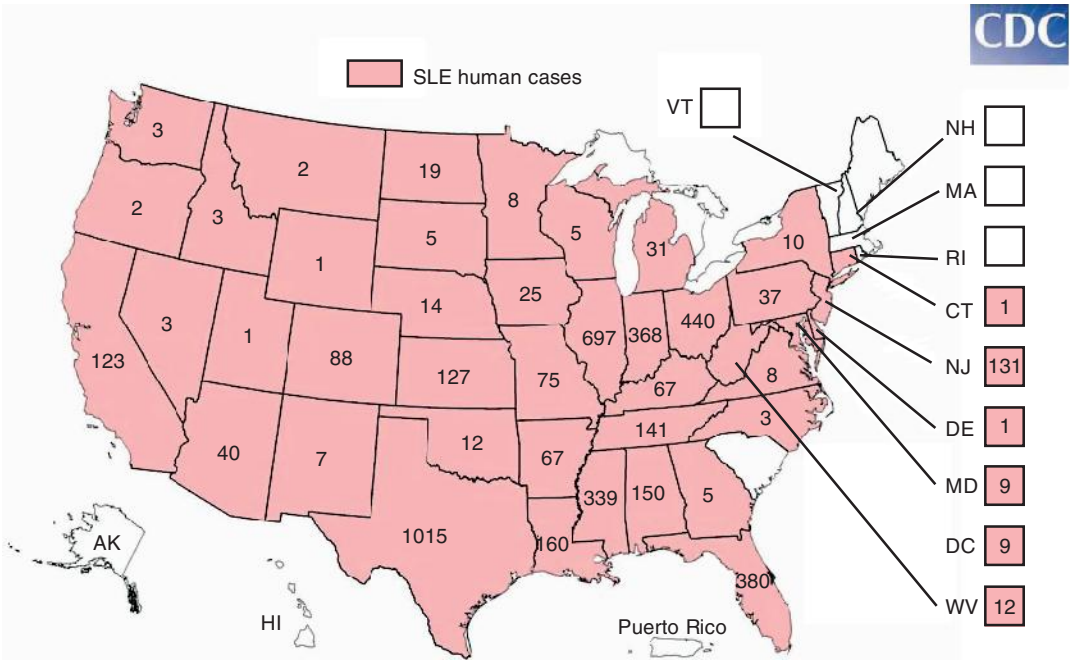

Figure 2 Distribution of human St. Louis encephalitis cases in the US, 1964–2004. Map provided by ArboNet, Center for Disease Control and Prevention, Ft. Collins, CO, USA.

capsid composed of a single polypeptide (C) and surrounded by an envelope containing one glycosylated (E) and one nonglycosylated (M) protein. Marked differences in the severity of SLEV epidemics stimulated interest in possible differences among isolates made over time and space. Detailed studies by the CDC during the 1980s clearly demonstrated geographic variation among 43 different SLEV isolates using oligonucleotide finger printing and virulence in model vertebrate hosts. These strains are grouped into six clusters: (1) east central and Atlantic USA, (2) Florida epidemic, (3) Florida enzootic, (4) eastern USA, (5) Central and South America with mixed virulence, and (6) South America with low virulence. Changes in virulence were attributed, in part, to differences in mosquito vector competence and were supported by the historical presence or absence of human cases. Subsequent genetic sequencing studies extended the understanding of SLEV genetics and provided further insight into patterns of geographical variation. Sequences of the envelope gene from SLEV strains isolated in California

from 1952 to 1995 varied temporally and spatially, but indicated regional persistence in the Central Valley for at least 25 years as well as sporadic introduction and extinction. Studies in Texas using a single-strand conformation polymorphism technique showed that multiple SLEV strains circulate concurrently and remain highly focal, whereas other strains amplify and disseminate aggressively during some summers, but then disappear. Further analyses of sequences from 62 isolates made throughout the known geographical range of SLEV indicated that there have been seven lineages that overlapped somewhat with the six groups the CDC defined previously using oligonucleotide fingerprinting: (1) western USA, (2) central and eastern USA and three isolates from Mexico and Central America, (3) one mosquito isolate from Argentina, (4) five isolates from Panama mosquitoes, (5) South American strains plus an isolate from Trinidad, (6) one Panama isolate from a chicken, and (7) two isolates from Argentina rodents. Collectively, these data indicated that SLEV strains vary markedly in virulence and that the frequency and intensity of epidemics in the US may be related to genetic selection by different host systems. Interestingly, transmission within the Neotropics appears to have given rise and/or allowed the persistence of less-virulent strains that rarely amplify to produce epidemic-level transmission, a scenario duplicated by West Nile virus in the Americas.

Host Range

Arthropods

Although a wide variety of mosquitoes occasionally have been found infected in nature, three avian-feeding species within the genus *Culex* appear to be the most frequently infected and important arthropod hosts: *C. pipiens* (including the subspecies *C. pipiens quinquefasciatus* at southern latitudes, *C. p. pipiens* at northern latitudes, and intergrades) in urban and periurban environments throughout North and South America, *C. tarsalis* in irrigated agricultural settings in western North America including northern Mexico, and *Culex nigripalpus* in the southeastern US, the Carribean, and parts of the Neotropics. Although these species feed predominantly on birds, they also feed on mammals including humans, and therefore function as both maintenance and bridge vectors. Other *Culex* species such as *stigmatosoma* in the west, *restuans* and *salinarius* in the east, and perhaps species in the subgenus *Melanoconion* in the Neotropics also may be important in local transmission. Ticks have been found naturally infected, but their role in virus epidemiology most likely is minimal.

Wild Birds

The importance of avian host species appears to be related to vector *Culex* host-selection patterns as well as to avian susceptibility to the virus. Species can be separated into those frequently, sporadically, and never found infected in nature, and these groupings are related directly to their nocturnal roosting/nesting behavior and the questing behavior of *Culex* vectors. Wild birds do not develop apparent illness following experimental infection, but their viremia response varies markedly, depending upon virus strain, bird species, and bird age. Titers sufficient to infect mosquitoes typically are limited to 1–5 days post-infection. Based on serological surveys during or after epidemics, peridomestic passerifoms (including house finches, house sparrows, cardinals, and blue jays) and columbiforms (including mourning oves and rock doves or domestic pigeons) seem to be infected most frequently. In house sparrows, SLEV strains isolated from *C. pipiens* complex mosquitoes from the central and eastern USA produced elevated viremias, whereas strains isolated from *C. tarsalis* from the western USA were weakly viremogenic. Although host competence studies have been limited, the adults of few bird species seem to develop elevated viremias. However, nestling house finches, house sparrows, and mourning doves produce high viremias that readily infect mosquitoes. Therefore, the nesting period of multibrooded species may be critical for virus amplification. Regardless of their viremia response, most experimentally infected birds produce antibody and, although titers typically decay rapidly, these birds remain protected for life.

Humans

Humans are incidental hosts and do not produce viremias sufficient to infect mosquitoes. Like most arboviruses that cause CNS disease, infection with SLEV does not result in a clear clinical picture in humans and most infections remain unrecognized, unless associated with an epidemic. When presented with such diverse symptoms, few physicians initially suspect SLEV, even in endemic areas. Most SLEV infections, especially in young or middle age groups, fail to produce clinical disease, and infected individuals rarely experience more than a mild malaise of short duration with spontaneous recovery.

Domestic Animals

Although frequently antibody positive during serosurveys, SLEV infection does not produce elevated viremias or cause clinical illness in domestic animals, including equines, porcines, bovines, or felines. In a single experiment, dogs (purebred beagles) produced a low-level viremia, with only two of eight dogs developing clinical illness. Similar to wild birds, immature fowl <1 month old (including chickens and ducks) consistently developed sufficient viremia to infect mosquitoes, but did not develop clinical illness. Adult chickens (>22 weeks old)

usually failed to develop a detectable viremia, and along with immature birds, developed long-lasting antibodies.

Wild Mammals

The response of wild mammals to natural or experimental infection varies. Serosurveys occasionally have shown higher SLEV prevalence in mammals than in birds, but these data could be confounded because mammalian hosts typically live longer than avian hosts and therefore have a longer history of exposure. Rodents in the genera *Ammospermophilus* and *Dipodomys* were susceptible to infection after subcutaneous (s.c.) inoculation, whereas *Spermophilus*, *Rattus*, *Sigmodon*, and *Peromyscus* were refractory. Similarly varied were lagomorphs: *Lepus* was susceptible, whereas four species within *Sylvilagus* ranged from refractory to susceptible. Raccoons and skunks were refractory, whereas opossums and woodchucks were susceptible. Like birds, susceptible mammals produced an immediate viremic response that generally persisted for <1 week, and all species produced detectable antibodies regardless of their viremia response. SLEV frequently has been isolated from bats (*Tadarida*, *Myotis*, etc.), and many populations exhibit a high prevalence of neutralizing antibody. Overall, the role of mammalian infection in SLEV epidemiology is complex and difficult to interpret. All reputed *Culex* vectors feed most frequently on avian hosts, occasionally on large mammals and lagomorphs, rarely on rodents, and almost never on bats.

Pathogenicity

In humans, clinical disease due to SLEV infection may be divided into three syndromes in increasing order of severity: (1) 'Febrile headache' with fever, headache possibly associated with nausea or vomiting, and no CNS illness; (2) 'Aseptic meningitis' with high fever and stiff neck; and (3) 'Encephalitis' (including meningoencephalitis and encephalomyelitis) with high fever, altered consciousness, and/or neurological dysfunction. The onset of illness may be sudden (<4 days after infection) and acute, leading rapidly to encephalitis, or insidious, progressing gradually through all three syndromes. Symptoms may resolve spontaneously during any stage of the illness, with full recovery. Acute illness may be followed by 'convalescent fatigue syndrome' in <50% of patients, with complaints of general weakness, depression, and the inability to concentrate that generally resolve within 3 years. Other sequelae include headache, disturbances in gait, and memory loss.

Pathogensis in SLEV follows a course similar to other flaviviruses in the JEV complex. The extent of illness usually is dependent upon viremia level and duration. Virus replication occurs within the lymphatic system soon after infection, and resulting viremias reflect the balance between virus production and release by the lymphatic system and clearance mediated by phagocytes of the liver and spleen. The probability of CNS involvement is directly correlated with the extent and duration of the viremia, although the mechanism of neuroinvasion remains unclear. Movement from peripheral to central nervous tissue most likely is by passive transport through neuron cytoplasm and then by transport across associated membranes after cell lysis. CNS pathology consists of necrosis of neurons and glia cells and inflammatory changes. Inflammatory changes typically are most important in slowly progressing or sublethal CNS disease and sequelae. Viral clearance is dependent upon a functional immune system and the rapid production of neutralizing antibody, which usually appears within 7 days after infection.

Epidemiology

Transmission of SLEV is complex and requires that the virus replicate in and avoid the immune responses of alternating insect and vertebrate hosts under temperatures ranging from below 0 °C in diapausing mosquitoes to more than 40 °C in febrile avian hosts. Annual transmission activity may be divided into overwintering, vernal and/or summer amplification, and autumnal subsidence periods.

Overwintering

Three possible mechanisms may explain the persistence of SLEV at temperate latitudes; however, few supportive field data are available.

Persistence in mosquito populations

Three mechanisms may explain SLEV overwintering within vector mosquito populations. First, low-level vertical passage of SLEV from infected females to F1 progeny has been demonstrated repeatedly in laboratory experiments. Although not detected for SLEV in nature, vertical transmission has been documented for other viruses in the JEV complex, including JEV and West Nile virus (WNV). Second, *C. p. pipiens* females destined for diapause have been shown to take small blood meals during late summer and early fall without ovarian development. Two isolations of SLEV made from diapausing *C. p. pipiens* females collected resting during winter in Maryland were considered to have been infected by this mechanism, although infection by vertical transmission also was possible. Third, *Culex p. quinquefasciatus* and *C. nigripalpus* do not enter reproductive diapause, remain reproductively active throughout winter at southern latitudes and, depending upon ambient temperature, could maintain SLEV by continued, infrequent transmission among resident birds. Experimentally infected, reproductively active *C. p. quinquefasciatus* females have been shown

to survive winter as gravid females and to then transmit SLEV to recipient birds throughout the following spring.

Persistence in vertebrate populations

SLEVs may also persist over winter within vertebrate host populations. Passeriform birds infrequently develop chronic infections that persist as long as a year following experimental infection. However, attempts to demonstrate natural relapse or to trigger relapse experimentally have not been successful. Flaviviruses, including SLEV, have also been isolated repeatedly from bats, and experimental infections in bats destined for hibernation have been maintained for 20 days at 10 °C. When returned to room temperature, SLEV was detected in the brown fat and at low levels in the blood. These data indicated that bats could function as an overwintering host. However, studies of mosquito host-selection patterns indicated that bats rarely, if ever, were fed upon by host-seeking mosquitoes.

Reintroduction of virus

An alternative hypothesis to local persistence involves annual or periodic reintroduction of virus into northern latitudes from southern refugia. Long-distance movement of SLEV has been indicated indirectly from genetic evidence as well as by the reappearance of SLEV after years of absence. Two possible hypotheses address reintroduction, but neither is well supported by field evidence. Many species of birds and some bats have long-distance annual migrations that could allow the transport of virus from foci active during winter in southern latitudes or south of the equator to receptive areas north of the equator during spring. These vertebrate migrations typically are very consistent in their summer and winter destinations, and this would allow the same or similar genetic strains to reappear each summer at the same locality. However, molecular genetic studies of North, Central, and South American isolates indicate that they are relatively distinct, thereby implying infrequent genetic exchange. In addition, migratory birds do not seem to be frequently involved in transmission because they infrequently are found positive for virus or antibody.

Amplification

Regardless of the persistence mechanism, summer enzootic amplification transmission in North America involves *Culex* mosquitoes and primarily birds in the orders Passeriformes and Columbiformes. Humans become infected tangentially to the primary cycle, do not develop viremias sufficient to infect mosquitoes, and are considered to be 'dead end' hosts (**Figure 3**). Transmission appears to be initiated after the *Culex* vectors resume blood-feeding and reproductive activity, and ambient temperatures warm sufficiently to allow the replication of virus in the mosquito host. Infection is acquired when a female *Culex* blood feeds on a viremic avian host. Virus imbibed within infectious blood meals taken in early in spring when ambient temperatures average <17 °C may lay dormant until warm conditions or changes in mosquito physiology stimulate replication. Under warm temperatures, virus replicates rapidly, disseminates within the mosquito during the ensuing extrinsic incubation period, and then may be transmitted by bite after the female oviposits and attempts to imbibe a subsequent blood

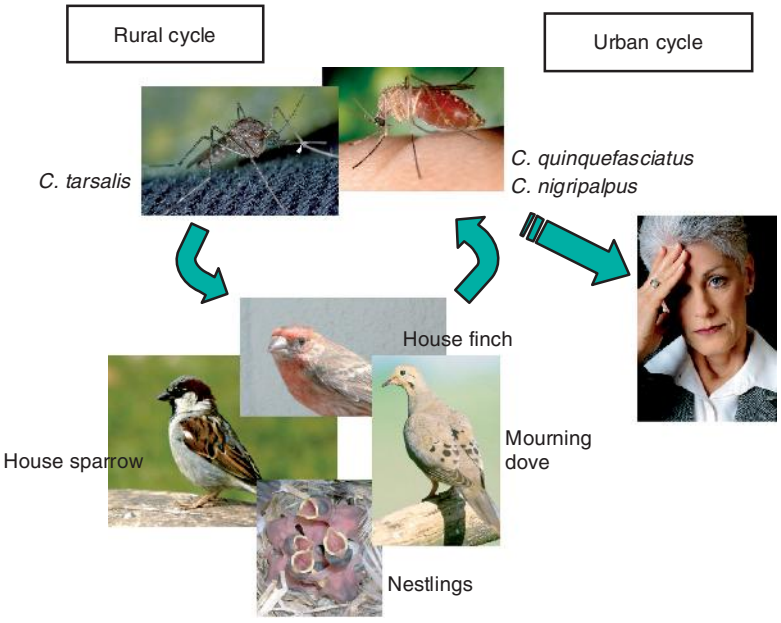

Figure 3 Amplification transmission cycle of St. Louis encephalitis virus in North America.

meal. The duration of the extrinsic incubation period is temperature dependent and requires >10 days and perhaps two mosquito gonotrophic cycles when temperatures average 22 °C. In contrast, the viremia response in susceptible avian hosts typically is of short duration, lasting 2–4 days.

Four distinct transmission cycles of SLEV are defined by differences in the biology of the primary vector mosquito species and their distribution, and include: (1) rural North America, west of the Mississippi River transmitted by *C. tarsalis*; (2) rural and urban central and eastern North America transmitted by members of the *C. pipiens* complex; (3) Florida, Caribbean, and parts of Central America transmitted by *C. nigripalpus*; and (4) urban and rural South America transmitted by *C. pipiens* complex and mosquitoes of other taxa.

Subsidence

Intensity of enzootic transmission and occurrence of new human cases always subsides rapidly during autumn. Cool evening temperatures slow the replication of SLEV within infected mosquito hosts, decreasing the efficiency of transmission and, concurrently, the combination of cool water temperature and shortening days during larval development initiates reproductive diapause (*C. tarsalis, C. p. pipiens*) or quiescence (*C. p. quinquefasciatus*, *C. nigripalpus*) in vector females emerging during fall. The fall mosquito population declines in abundance and divides into newly emerged females that do not routinely bloodfeed and survive the winter, and remnants of the summer population that continue reproductive activity, but fail to survive winter. The critical day length that triggers the onset of diapause in *C. p. pipiens* may occur in late summer at northern latitudes, markedly shortening the SLEV transmission season. During warm days, however, females may become infected when taking partial blood meals from viremic birds, survive winter, and then transmit the virus after diapause is terminated by warm spring temperatures. *Culex p. quinquefasciatus* does not undergo diapause, so that reproductive activity may continue through winter, albeit at a rate slowed by winter temperatures. Populations exploiting underground storm water systems for resting or for larval development may be exposed to relatively warm temperatures throughout winter.

Risk Factors for Human Infection

Five factors have been associated with human risk of SLEV infection.

Residence

Clearly, place of residence markedly affects the risk of infection, with geographic regions in the southern USA having the greatest numbers of human cases and greatest incidence of disease (**Figure 2**). Based on experimental infection patterns in laboratory mice, virus strains from this geographical area also exhibit greater neurovirulence than strains from the western USA or South America. Because of mosquito abundance relative to humans and host-selection patterns, urban residents seem to be at greater risk for SLEV infection than rural residents. However, these conclusions may be confounded by protective immunity acquired early in life that may be greater among rural residents and by low apparent: inapparent case ratios that require a substantially large population to produce recognizable clusters of human cases.

Age

In the absence of acquired immunity, clinical illness and fatality rates, but not necessarily infection rates, increase dramatically with age. Infection seems to occur equally among different age classes as indicated by the increase in antibody as a function of age in endemic areas and by cohort seroconversion rates determined after epidemics in previously unexposed populations. For example, using data following the 1964 Houston (Texas) epidemic, seroprevalence rates remained similar among cohorts, whereas the case–incidence rates increased from 8.2 per 100 000 for the 0–9-year-old cohort to 13.5–27.6 for the 10–59-year-old cohorts and to 78.0 for the >60-year-old group; apparent to inapparent ratios decreased concomitantly from 1:806 to 1:490–1:239 and to 1:85, respectively. Case–fatality rates among 2288 cases reported to the CDC from 1971–83 increased from <6.7% for 0–64-year-old age classes to 9.5% for the 65–74-year-old class to 18% for the >75-year-old class.

Occupation

In the West, where SLE historically was a rural disease, infection risk was greatest among male agricultural workers who frequently lived in suboptimum housing and worked at night. However, infection patterns during recent urban outbreaks indicated that attack rates were highest among elderly women. These data indicated that there may be differences in risk related to vector species, with elderly women infected most readily during urban outbreaks associated with the *C. pipiens* complex, and men working outdoors at greatest risk during rural outbreaks associated with *C. tarsalis*.

Socioeconomic status

Historically, socioeconomic status has been related closely to the distribution of cases during urban epidemics. Homes and municipal drainage systems frequently were not well maintained in low-income neighborhoods, and this was related to the distribution of human cases, but not necessarily the occurrence of virus within the enzootic transmission cycle. TV and air conditioning ownership that brought people indoors during the evening *Culex* host-seeking period was found to reduce risk.

Weather

Climate variability affects temperature and precipitation patterns, mosquito abundance and survival, and therefore SLEV transmission. Annual temperature changes based on the El Niño/southern oscillation in the Pacific alter precipitation and temperature patterns over the Americas and cycle with varying intensity at 3–5 year intervals. These cycles alter storm tracks that affect mosquito and avian abundance, the intensity and frequency of rainfall events, and groundwater depth, all related to SLEV risk. Above-normal temperatures have been especially necessary for northern latitude SLEV epidemics, because elevated temperatures are required for effective SLEV replication within the mosquito host.

Prevention and Control

Effective vector control remains the only approach available to suppress summer virus amplification and prevent human infections. Best results are achieved using an integrated management approach that focuses on mosquito vector population suppression through habitat inspection and larviciding. Failure of larval management can be followed by emergency adult control focusing on reducing the force of transmission and preventing human infection. Protection of the human population by vaccination does not seem cost-effective or prudent, because there is no human-to-human transmission, few human infections produce disease, and infection rates remain relatively low, even during epidemics. However, if regional infection rates were to become high, thereby placing selected cohorts at high risk for disease, then selective vaccination may be warranted. There currently is no approved commercial vaccine for SLEV, although vaccination against other flaviviruses such as JEV may impart some protection. Control of avian hosts such as house sparrows and pigeons in urban situations could be done, but this approach is not generally acceptable to the public. Notification of the public of infection risk through the media and the wide scale use of personal protection through changes in behavior (staying indoors after sunset) and/or repellent application were credited with reducing the number of infections during the 1990 epidemic in Florida.

Glossary

Cultivar decline A vegetatively propagated cultivar suffering from reduced vigor as a result of a chronic (but often symptomless) disease.

Differential hosts Special species of plants varying in susceptibility to a given disease agent, such that their distinctive symptoms facilitate a presumptive identification of the causal agent.

Indexing Any procedure for demonstrating the presence of a pathogen(s) in susceptible plants. The virus indexing combines information on viruses with methodologies for their detection to assure effective safe movement of sweetpotato germplasm.

Introduction

Sweetpotato

Sweetpotato (*Ipomoea batatas* (L.) Lam.) is a dicotyledonous, perennial plant, producing edible tuberous roots. It belongs to the family Convolvulaceae, the morning glory.

This family contains about 55 genera. The genus *Ipomoea* is thought to contain over 500 species with ploidy levels ranging from $2x$ to $6x$. Sweetpotato is the only *Ipomoea* species of economic importance as a food crop, and has both $4x$ and $6x$ forms ($2n = 4x = 60$ or $2n = 6x = 90$). Thousands of cultivars of sweetpotato are grown throughout the tropics and subtropics. With an annual production of more than 133 million tons globally, sweetpotato currently ranks as the seventh most important food crop on a fresh-weight basis in the world, and fifth in developing countries after rice, wheat, maize, and cassava. The production is concentrated in East Asia, the Caribbean, and tropical Africa, with the bulk of the crop (88%) being grown in China (**Figure 1**). Sweetpotato performs well in relatively poor soils, with few inputs, and has a short growing period. Among the major starch staple crops, it has the largest rates of production per unit area per unit time: in some areas up to three harvests per year can be achieved. Sweetpotato roots are rich in vitamin C and essential mineral salts. Due to the high beta-carotene content of yellow and orange-fleshed storage roots, they are being promoted to alleviate vitamin A deficiency in East Africa and Eastern India.

Viruses of Sweetpotato

Until recently, viruses of sweetpotato have been relatively poorly studied as compared to viruses of other crops. Still, more than 20 different viruses have been described infecting sweetpotato worldwide, but only 15 of these are currently recognized by the International Committee on Taxonomy of Viruses (ICTV; **Table 1**). This number, however, will most likely increase by additional surveys (**Figure 2**) and by indexing germplasm collection (**Figure 3**).

Vegetative propagation, usually by taking cuttings from a previous crop, increases the risk of a buildup of viruses. The importance of virus diseases and their buildup in farmers' planting materials has been shown convincingly in China, where sweetpotato cultivars planted using pathogen-tested materials yielded 30–40% more, on average, than those grown from farm-derived planting materials. Next to weevils, virus diseases form the most important biotic production constraint in sweetpotato. Most sweetpotato-infecting viruses, however, show only mild or no symptoms when in single infection and the damages caused by sweetpotato viruses are mostly through synergistic mixed infections. Viruses of the families *Potyviridae* and *Geminiviridae* as well as sweetpotato chlorotic stunt virus (SPCSV) are particularly significant in relation to sweetpotato cultivar decline.

Due to low virus titers and absence of symptoms from single infections in sweetpotato by most viruses, grafting and in some cases sap transmission onto indicator plants is often required to increase virus concentration and detect viruses reliably (**Figure 3**). Commonly used indicator plants are *Ipomoea setosa*, *I. nil*, *I. purpurea*, *I. aquatica*, and in some cases *Nicotiana benthamiana* and *N. clevelandii*.

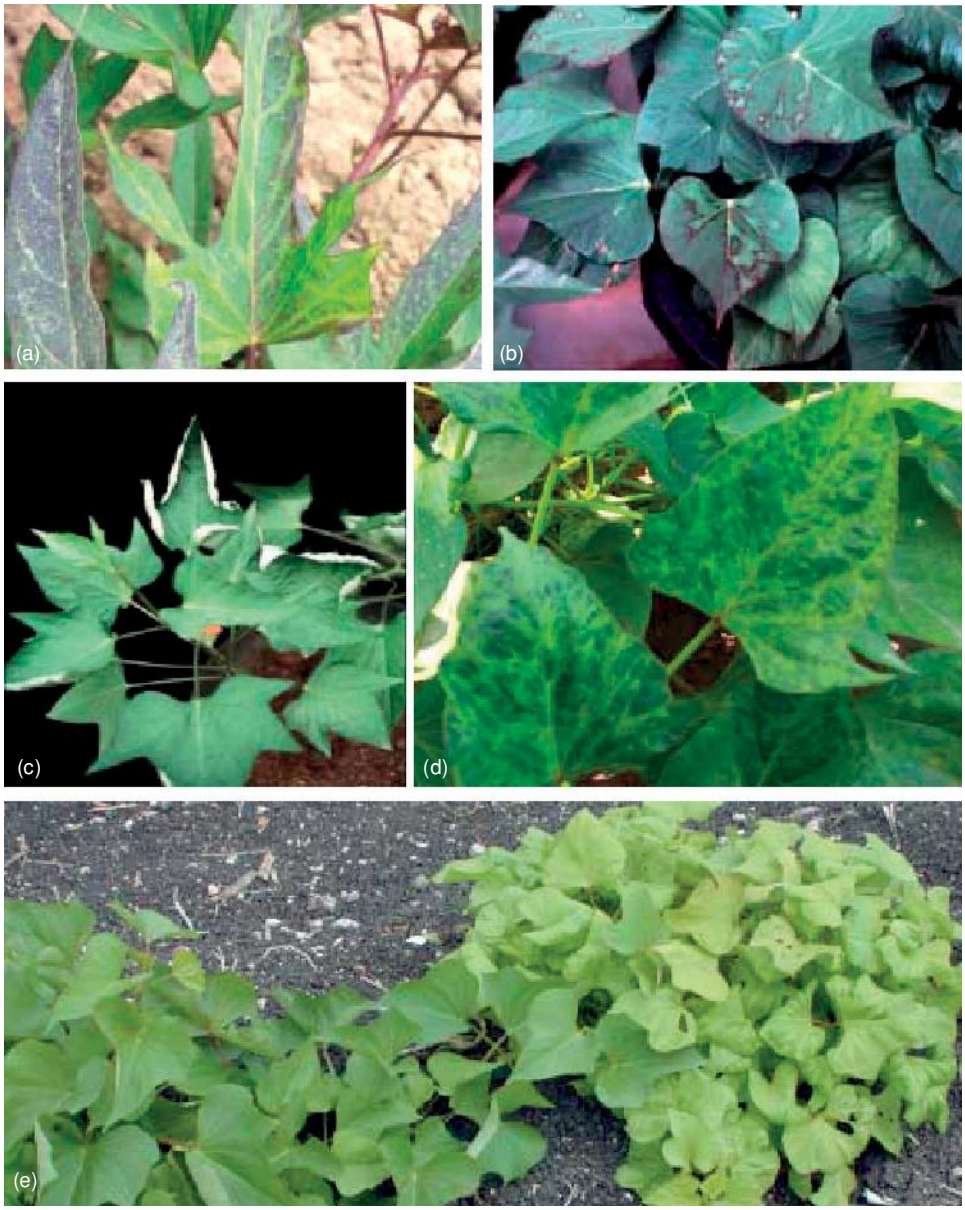

Figure 2 Sweetpotato plants showing symptoms of vein clearing (a and b), leaf curling (c), mosaic (d), and chlorosis, stunting, and leaf deformation. Some times the vein clearing is surrounded by purple pigmentation.

Potyviruses

Several potyviruses infect sweetpotato and usually only cause transient, mild, or no symptoms when infecting sweetpotato by themselves. The most widespread of these, and the one studied in most detail is sweetpotato feathery mottle virus (SPFMV, genus *Potyvirus*, family *Potyviridae*) that occurs wherever sweetpotato is grown. In many cases infection of sweetpotato plants with SPFMV causes mild or no symptoms, although certain strains can cause qualitative damage due to internal cork or cracking of the tuberous roots. However, quantitative losses due to reduced plant vigor associated with chronic infection with SPFMV have also been experienced. Yet, it is as a component of complex virus diseases that SPFMV probably causes the greatest damage.

Sweetpotato Feathery Mottle Virus

SPFMV has flexuous filamentous particles measuring 830–850 nm in length. They contain a single-stranded, positive-sense RNA genome of about 10.6 kb, which is

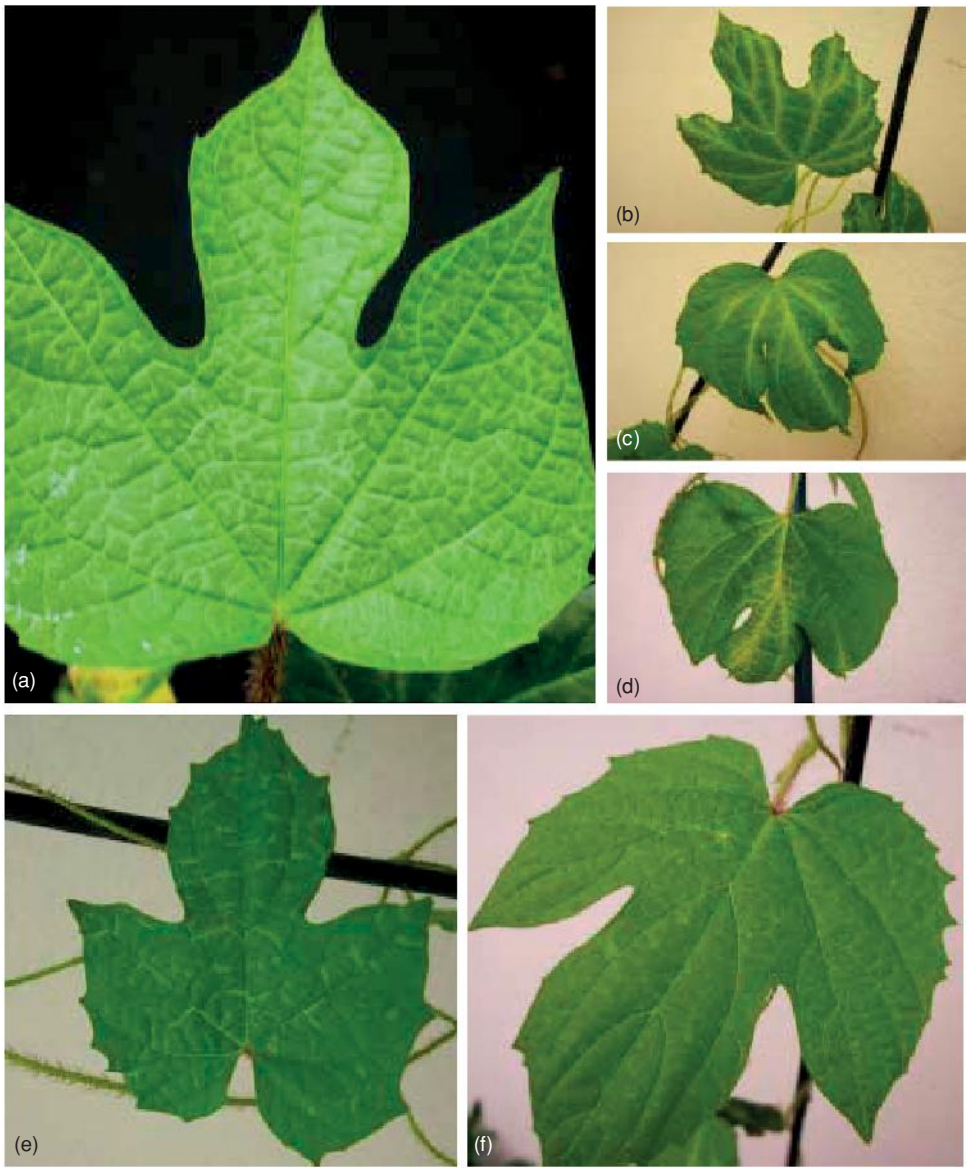

Figure 3 *Ipomoea setosa* graft-inoculated with scions from sweetpotato plants collected in farmer's fields in Peru. Infected with sweetpotato feathery mottle virus (a–d) and sweetpotato virus G (e). Faint chlorotic spots (f) induced by an unknown virus. The causal virus tested negatively to available antisera in NCM-ELISA.

larger than the average size (9.7 kb) of a potyvirus genome. The coat protein (CP) of SPFMV is also exceptionally large (38 kDa) as compared to other potyviruses, which is largely due to the insertion of a contiguous sequence at the 5′-end of the CP cistron. SPFMV is transmitted by several aphid species (i.e., *Aphis gossypii*, *A. craccivora*, *Lipaphis erysimi*, *Myzus persicae*) in a non-persistent manner. However, these aphids rarely colonize sweetpotato under field conditions and therefore itinerant alate aphids are probably the most efficient vectors of SPFMV. The experimental host range of SPFMV is narrow and mostly limited to plants of the family Convolvulaceae, and especially to the genus *Ipomoea*, although some strains have been reported to infect *N. benthamiana* and *Chenopodium* spp. Symptoms, host range, and serology have been used to group SPFMV isolates into two strains, the common strain (C) and the more severe russet crack (RC) strain. However, based on phylogenetic analysis of 3′ nt sequences of an extensive number of isolates it is now clear that SPFMV can be distinguished in four phylogenetic lineages RC, O (ordinary), EA (East Africa), and C (**Figure 4**). Based on molecular data the C strain is rather distantly related to the remaining strains and may in the future be classified as a separate virus.

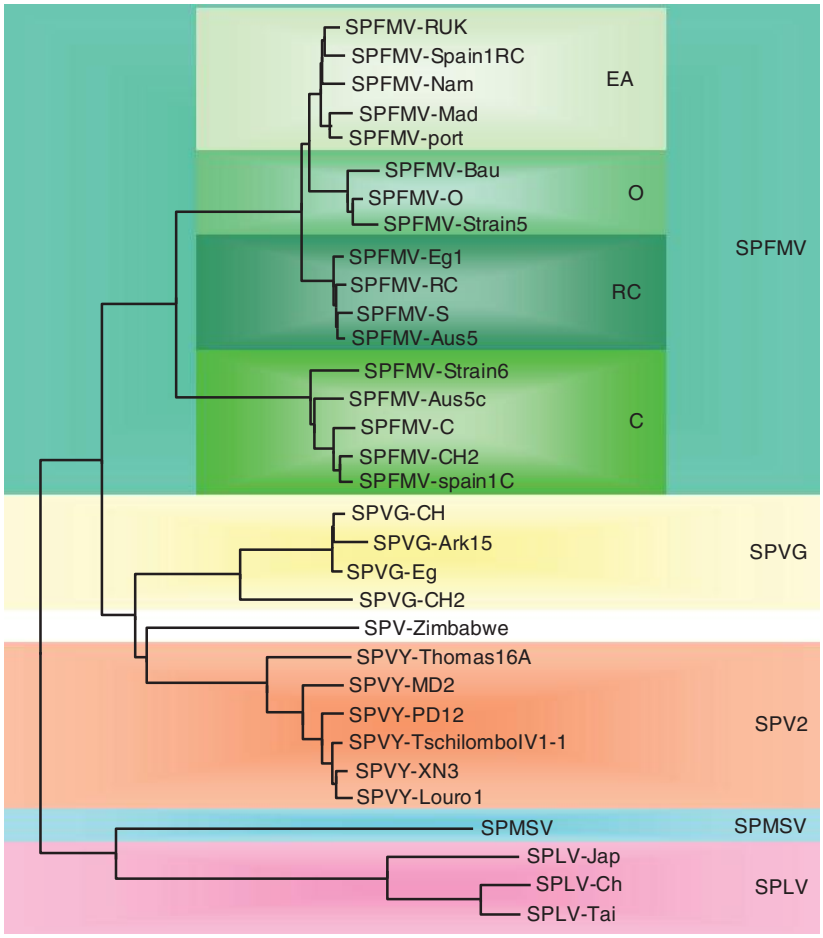

Figure 4 Phylogeny of representative isolates of sweetpotato-infecting potyviruses based on complete CP sequences. Clades corresponding to described virus species are shaded in different colors. The four recognized strain groups of SPFMV are also indicated and shaded in different colors of green. One sequence, originally described as SPFMV from sweetpotato in Zimbabwe, is distinct from all other named species.

Other Potyviruses

Several other potyviruses are known to infect sweetpotato, some of which are distributed widely. They have in common that they are mostly symptomless and in low titers when infecting sweetpotato by themselves, but can be distinguished by their symptoms induced in indicator plants such as *I. nil* and *I. setosa* (**Figure 3**), or by symptoms induced through synergism with SPCSV. With the exception of sweetpotato vein mosaic virus (SPVMV) sequence information is available for these viruses and their phylogenetic relationships are depicted in **Figure 4**.

Sweetpotato virus G (SPVG) was first reported from China, but is now known to occur also in the Americas and Africa. Another virus, originally identified as sweetpotato virus 2 in Taiwan, was recently further characterized simultaneously by two groups suggesting the species names sweetpotato virus Y and ipomoea vein mosaic virus, respectively, and has been reported from Taiwan, China, USA, South Africa, Australia, and Barbados. The name SPV2 is currently being considered for this virus by the ICTV. Sweetpotato latent virus (SPLV) was also first reported from China, but is now known to occur in most major sweetpotato-growing areas in Asia. The two remaining potyviruses reported were first described from Argentina and are SPVMV and sweetpotato mild speckling virus (SPMSV). Whereas SPMSV has also been detected in Peru and Indonesia, neither antibodies nor sequence information are available for SPVMV, and the virus has not been reported from elsewhere. The number of sweetpotato-infecting potyvirus species will certainly still increase through future surveys, for example, a potyvirus distinct from any of the above mentioned was isolated from infected sweetpotato in Zimbabwe and remains to be characterized in more detail (**Figure 4**).

Sweetpotato mild mottle virus (SPMMV, genus *Ipomovirus*) is transmitted by whiteflies in a nonpersistent

manner. It should be noted, however, that since the initial report, it has not been possible to confirm independently the whitefly transmissibility of SPMMV. A study of the variability of SPMMV in Uganda using 3′ nt sequences showed the virus consisted of a population of distinct sequence variants (>85.9% nt identity in the CP), which however did not show any particular clustering. A distinct feature of SPMMV as compared to other sweetpotato-infecting viruses is its exceptionally broad host range including species in 14 families. SPMMV has serologically been detected throughout Africa, Indonesia, China, Philippines, Papua New Guinea, India, Egypt, and New Zealand. Another whitefly-transmitted potyvirus with properties distinct from SPMMV was described in Taiwan and named sweetpotato yellow dwarf virus (SPYDV). The relationship between these two viruses is however unclear as no sequence information is available for SPYDV.

Begomoviruses

Sweetpotato leaf curl diseases typical of geminivirus infection (**Figure 2(c)**) have been reported from Peru, Japan, Taiwan, Korea, China, Puerto Rico, Costa Rica, Spain, United States, Africa, and other countries. The host range of the *Ipomoea*-infecting begomoviruses (family *Geminiviridae*) is narrow and mostly restricted to species in the family Convolvulaceae (especially to the genus *Ipomoea*), but *N. benthamiana* (Solanaceae) can also be infected. They cause leaf curl on some hosts, and yellow vein or leaf distortion and chlorosis symptoms on others. Some sweetpotato cultivars are symptomless. As they induce mild, transient symptoms in the standard virus indicator, *I. setosa,* a universally reliable biological indicator is lacking. Some *Ipomoea* species (*I. aquatica, I. cordatotriloba, I. purpurea*) can however be used as differential hosts to distinguish *Ipomoea*-infecting begomoviruses.

Only three sweetpotato-infecting begomovirus species have been officially recognized by the ICTV (**Table 1**): *Sweetpotato leaf curl virus* (SPLCV), *Sweetpotato leaf curl Georgia virus* (SPLCGV), and *Ipomoea yellow vein virus* (IYVV). DNA B components have not been identified for any of these viruses indicating they are monopartite begomoviruses. Sequences of AC1 gene fragments from isolates obtained from infected *Ipomoea* spp. from USA, China, Taiwan, Korea, Puerto Rico, Spain, and Italy all fall into two groups corresponding to SPLCV/IYVV and SPLCGV. A third phylogenetically distinct group of begomoviruses was identified from infected sweetpotato in Spain, representing a putative fourth species. Similarly the sequence of a SPLCV isolate from China shows <83% identity to other published sequences indicating yet another virus species. Another virus, proposed to be named ipomoea crinkle leaf curl virus (ICLCV) and reported from Israel, differed in host range from SPLCV but its exact relationship to other identified viruses remains unclear.

From a taxonomic point of view, the *Ipomoea*-infecting begomoviruses are a curiosity; phylogenetic analysis of IYVV and several strains of SPLCV and SPLCGV revealed that these viruses form a separate unique cluster within the genus *Begomovirus*, dissimilar to both the New World and Old World begomoviruses. Additionally, the relatively poor transmission rates of the *Ipomoea*-infecting begomovirus by *Bemisia tabaci* may be a reflection of the low CP amino acid sequence identity (46%) between them and the other begomoviruses.

Sweetpotato Leaf Curl Virus

The virus has geminate particles of *c.* 18×30 nm with a genome of 2828 nt. Its genomic DNA and organization is similar to that of monopartite begomoviruses. SPLCV virus was first reported from Japan and Taiwan but now it is known to occur in several countries on different continents. SPLCV can cause up to 30% reductions in yield of storage roots. Various *Ipomoea* species are susceptible to SPLCV, such as *I. purpurea* causing leaf curl and stunt, *I. aquatica* causing yellow vein symptoms, *I. nil*, *I. setosa,* and *N. benthamiana* causing leaf curl symptoms. Co-infections of SPFMV and SPLCV in *I. setosa* and *I. nil* induce severe leaf distortion, general chlorosis, and stunting.

Ipomoea Yellow Vein Virus

IYVV was first found in Spain infecting *I. indica* plants showing yellow vein symptoms, but has since then been found infecting cultivated sweetpotato as well. Its properties, including typical geminivirus symptoms, detection of geminate particles by electron microscopy, and complete nucleotide sequence confirmed its begomovirus nature. Based on nucleotide sequence similarity of >89% over the entire genome, IYVV should be considered a strain of SPLCV, and will probably be revised accordingly in the future. However, contrary to SPLCV which is transmitted by *B. tabaci* biotype B, IYVV-[Spain] was not transmitted by biotypes Q, S, or B of *B. tabaci*.

Sweetpotato Leaf Curl Georgia Virus

SPLCGV, previously called ipomoea leaf curl virus, has a genome of 2773 nt with an organization typical of other Old World monopartite begomoviruses. The complete nucleotide sequence of SPLCGV is 82–85% identical to those of SPLCV and IYVV, which is below the species threshold of 89% nucleotide sequence identity for begomoviruses. Like SPLCV, SPLCGV is transmitted by *B. tabaci* biotype

B and induces similar symptoms in most *Ipomoea* species (various degrees of leaf curling). The means to distinguish SPLCGV from SPLCV are the use of *I. aquatica* and *I. cordatrotiloba* as differential hosts and a combination of polymerase chain reaction (PCR) and restriction enzyme digestion.

Sweetpotato Chlorotic Stunt Virus

Due to its ability to mediate severe synergistic viral diseases with several other sweetpotato-infecting viruses including potyviruses, cucumoviruses, and carlaviruses, SPCSV is probably the most devastating virus of sweetpotato worldwide. In single infection, this virus causes no symptoms at all or usually only mild stunting combined with slight yellowing or purpling of older leaves, symptoms which are easily confused with nutritional deficiencies.

SPCSV belongs to the genus *Crinivirus* of the family *Closteroviridae*. The particles of SPCSV are 850–950 nm in length and 12 nm in diameter. The size of the major coat protein is 33 kDa, which is similar to other criniviruses. SPCSV is transmitted by whiteflies (e.g., *B. tabaci*, *B. afer*, and *Trialeurodes abutilonea*) in a semipersistent, noncirculative manner, and is not mechanically transmissible. Similar to most other sweetpotato-infecting viruses, the host range of SPCSV is limited mainly to the family Convolvulaceae and the genus *Ipomoea*, although *Nicotiana* spp. and *Amaranthus palmeri* are reportedly susceptible. SPCSV has also been detected in the ornamental species Lisianthus (*Eustoma grandiflorum*). SPCSV can be serologically divided into two major serotypes. One of the serotypes (EA for East Africa) was first identified in East Africa, and also occurs in Peru, while the other serotype (WA for West Africa) was first identified in West Africa and occurs additionally in the Americas, and the Mediterranean, but not in East Africa. The two serotypes correlate to two genetically distantly related strain groups based on coat protein as well as Hsp70h gene similarities.

The genome of an SPCSV isolate from Uganda has been entirely sequenced and consists of two RNA segments of 9407 and 8223 nt. The SPCSV genome encodes two unique proteins, p22 and RNase3, not known to occur in any other RNA viruses. mRNAs corresponding to these proteins are transcribed early during infection and they are cooperatively able to suppress RNA silencing, a process that requires the RNA binding and double-stranded RNase activity of the RNase3 protein.

Other Viruses

Some viruses recognized by ICTV that affect other crops (i.e., cucumber mosaic virus, tobacco mosaic virus, and tobacco streak virus), are sporadically found infecting sweetpotato. Information on these viruses is extensively available. Other sweetpotato-specific viruses have not yet being assigned to a genus (i.e., sweetpotato leaf speckling virus – SPLSV) or recognized as a species (i.e., sweetpotato chlorotic fleck virus – SPCFV; C-6 virus; sweetpotato caulimo-like virus – SPCaLV) by the ICTV (**Table 1**).

Sweetpotato Leaf Speckling Virus

SPLSV has isometric particles *c.* 30 nm in diameter. The virus is transmitted by *Macrosiphon euphorbiae* in a persistent manner. It has a restricted geographical distribution. The sequence of the CP and 17K encoding region has been determined and is characteristic of luteo- and poleroviruses sequences, with highest similarity to potato leafroll virus (PLRV). Although these two viruses can be detected with heterologous CP probes, they are not serologically related.

Sweetpotato Chlorotic Fleck Virus

SPCFV has filamentous particles measuring about 800 nm in length consisting of its genome encapsidated by polypeptide subunits of 33.5 kDa. The virus appears to have a wide geographic distribution in sweetpotato crops in South America, Africa, and Asia. SPCFV has a narrow host range in the families Convolvulaceae and Chenopodiaceae, but some strains/isolates infect *N. occidentalis*. SPCFV is mostly symptomless in its natural host; hence, it was also referred to as sweetpotato symptomless virus in Japan.

Sequence analysis of the entire genome of SPCFV (9104 nt) provides unambiguous evidence for the assignment of SPCFV as a distinct species in the genus *Carlavirus*. The RNA of SPCFV is larger than that of the other carlaviruses due to its considerably larger replicase (238 vs. 200–223 kDa) and a long untranslated region of 236 nt between ORF4 and ORF5. Phylogenetic analysis of CP sequences suggests that there is some geographically associated variation among SPCFV isolates.

Complex Virus Diseases of Sweetpotato

Multiple virus infections are common in sweetpotato and synergistic interactions are often involved. The most common of these disease complexes, known as sweetpotato virus disease (SPVD), is caused by simultaneous infection with SPFMV and SPCSV (**Figures 5** and **6**). This disease is characterized by chlorosis, small, deformed leaves, and severe stunting, and can reduce yields of infected plants by up to 99%. Despite the apparent broad meaning of the name SPVD, the symptoms are so characteristic that the name has become restricted to the disease

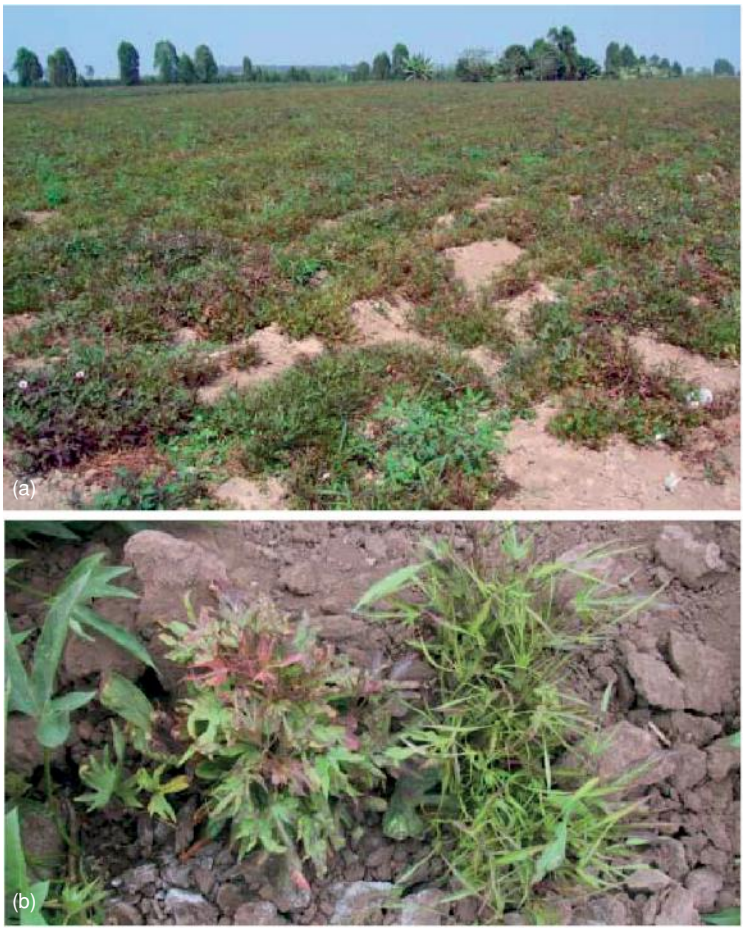

Figure 5 Sweetpotato plants affected by viruses in Peru. Sweetpotato field with a large number of plants affected by sweetpotato virus disease complex (a) and a close up of an affected plant showing stunting, mosaic, and leaf deformation (b).

with these symptoms and caused by these viruses. SPVD is the most serious disease of sweetpotato in Africa and Peru, and may be the most important virus disease of sweetpotato globally.

Other viral disease complexes have also been described, which invariably seem to involve SPCSV. In Israel and Egypt cucumber mosaic virus (CMV, genus *Cucumovirus*, family *Bromoviridae*) is found infecting sweetpotato together with SPCSV and usually also SPFMV, producing symptoms similar to SPVD and causing up to 80% reduction in yield. It was shown that CMV could only infect sweetpotato if the plants were first infected with SPCSV. Interestingly, this seems not to be the case for CMV in Egypt, where it is found infecting sweetpotato with or without SPCSV. In Argentina, a disease locally known as chlorotic dwarf is caused by infection with SPCSV and SPFMV and/or SPMSV, and is the most important disease of sweetpotato in the country. Once again, the symptoms resemble those of SPVD and are most severe when all three viruses infect sweetpotato simultaneously. In the Philippines SPCSV together with several other viruses causes a disease locally known as Camote Kulot.

In all the mentioned disease complexes, infection with each virus separately causes only mild or no symptoms in sweetpotato. They are thus caused by a synergistic interaction between the viruses. As both SPFMV and SPCSV are involved in all these diseases, the variation in the strains of these viruses should be important factors determining the disease severity.

Experimentally SPCSV can induce synergism with all tested potyviruses (including SPMMV), CMV as well as carlaviruses, and is always associated with an increase in the titers of the co-infecting virus and reduced yield of storage roots. For instance, the dual infection of SPCSV and SPMMV has been named 'sweetpotato severe mosaic disease (SPSMD)'. Yet there are reports indicating that strains of SPFMV and SPV2 may differ in their ability to cause synergism with SPCSV. Triple infections involving SPCSV, SPFMV, and an additional virus are even more severe, leading to further increase of the SPFMV

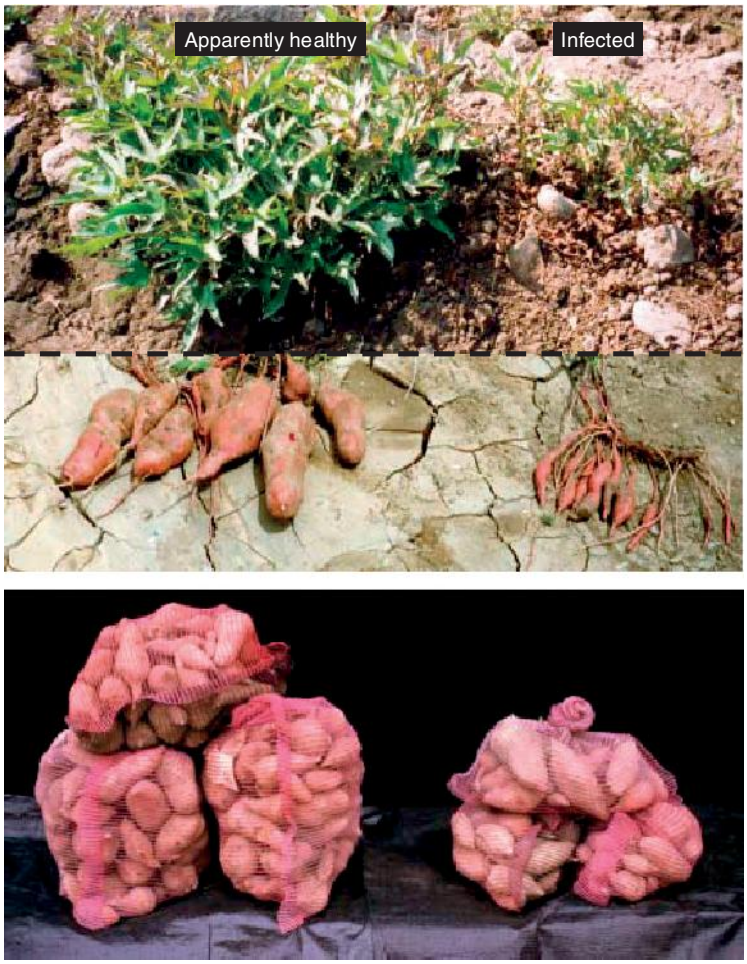

Figure 6 Effect of viruses on sweetpotato plants (top) and yield of storage roots (bottom). Observe yield reduction on sweetpotato variety Costanero (30 plants each treatment).

titers, whereas the titers of the third virus may either increase or decrease. It is thought the synergistic effects of SPCSV on other viruses may be due to interference with RNA silencing, because they are associated with substantially increased accumulation of co-infecting viruses.

Taura Syndrome Virus

A K Dhar, Advanced BioNutrition Corp, Columbia, MD, USA
F C Thomas Allnutt, National Science Foundation, Arlington, VA, USA

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Internal ribosomal entry site (IRES) The sequence in a RNA transcript that allows internal entry of the ribosomal assembly for translation in a cap-independent manner.
Quasispecies Due to the error-prone replication of RNA, a specific RNA virus exists as a steady state or equilibrium mixture of mutant sequences clustered around a master sequence or sequences.
Specific pathogen free (SPF) Shrimp lines that have been bred in captivity and certified to be free of a specific disease or diseases.

Introduction

Taura syndrome disease (TSD) was first described as a shrimp disease in 1992 from Pacific white shrimp (*Penaeus vannamei*) farms located along the mouth of the Taura River basin in Guayas Province, Ecuador. Initially the disease was incorrectly attributed to the toxic effects of fungicides used in a near by banana plantation. The etiologic agent was later proven to be of viral origin. The virus was named Taura syndrome virus (TSV) based on the location where the disease was first recorded. Movement of TSV-contaminated shrimp stocks led to the rapid spread of the disease throughout the Americas between 1992 and 1996. Since the initial discovery of TSD, the economic losses to the shrimp farming industry in the Western Hemisphere have been enormous. From the Americas, the disease spread to Taiwan in 1999, and subsequently TSV epizootics have been recorded in China, Thailand, Korea, and Indonesia.

TSV particles are nonenveloped and icosahedral, measuring 31–32 nm in diameter (**Figure 1**), and have a buoyant density of 1.338 g ml^{-1}. The viral capsid contains three major (VP1, VP2, and VP3) and one minor (VP0) polypeptide. TSV genome is a linear, positive-sense, single-stranded RNA of approximately 10.2 kb. Nascent viral RNA synthesis occurs in intracellular vesicle-like membranes within the cytosol of the host cells. In infected cells, mature virions are also seen in close association with proliferating membranes. Currently, TSV has been classified as an unassigned member of the family *Dicistroviridae*.

History and Classification

TSD, caused by the TSV, is listed as a reportable disease by the Office Internationale des Epizooties (OIE), the international organization responsible for ensuring worldwide information transparency by dissemination of the current status of important animal diseases. TSD etiology was initially very controversial causing uncertainty that contributed to TSV spread through the Western Hemisphere between 1992 and 1996. The resulting epizootic cost the shrimp farming industry in the Americas an estimated US$1.2–2 billion. In 1999, TSD was reported from Taiwan and since then, the disease has spread to China, Thailand, Korea, and Indonesia. The disease has already caused considerable economic losses in Asia.

Based on clinical and histological data, researchers from Ecuador recognized a new syndrome in *P. vannamei* shrimp farms located along the mouth of the Taura River basin (Guayas Province, Ecuador) during the summer of 1992. The cause of TSD was initially attributed to toxicity by two systemic fungicides, Tilt (Propiconazole, Ciba-Geigy) and Calixin (Tridemorph, BASF) that were being sprayed on local banana plantations to control black leaf wilt disease or Singatoka negra. It was hypothesized that fungicide-contaminated runoff resulted in mortalities in shrimp farms. During the 2 years following its discovery, TSD spread west through Ecuador's most concentrated

shrimp-farming region, southward into Northern Peru, and northward to the Pacific Coast of Colombia. These latter regions had neither banana plantations nor application of the suspected fungicides. Meanwhile, attempts to induce TSD experimentally by waterborne, oral, or injection delivery of Tilt, Calixin, or Benlate O.D. (Benomyl, DuPont, a widely used banana fungicide in Ecuador) failed. During May 1994, two separate outbreaks of TSD occurred among cultured *P. vannamei* in Oahu (Hawaii, USA), representing the first TSD incursion into the United States. Subsequently, the induction of TSD clinical signs and histological lesions was demonstrated by experimental challenge of healthy shrimp *per os*, and the viral etiology was established. The virus was named Taura syndrome virus.

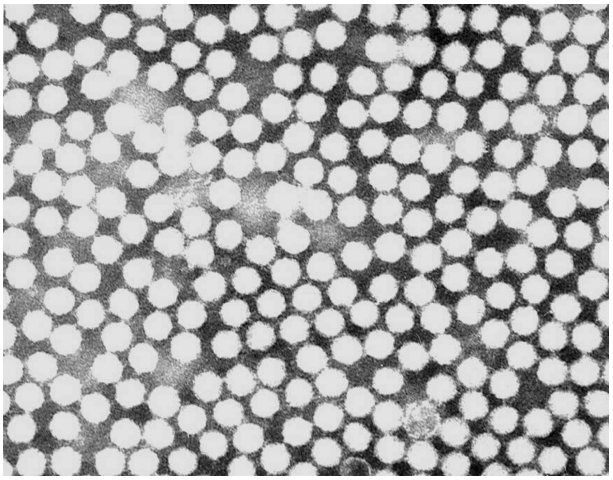

Figure 1 Transmission electron micrograph of CsCl gradient-purified and negatively stained (with 2% PTA) TSV particles. The virus particles are nonenveloped and icosahedral, measuring 31–32 nm in diameter.

Based on morphology and biophysical properties, TSV was then presumed to be a member of the family *Picornaviridae*. Availability of TSV genome sequence data and phylogenetic analysis using the capsid gene sequence of TSV and picornavirus superfamily viruses, revealed two major clusters (**Figure 2**). One cluster contains mammalian picornaviruses and picornavirus superfamily viruses infecting insects while the other cluster contains the plant picornaviruses. Within the first cluster, there were two subclusters. First subcluster contains insect picornavirus superfamily viruses with a dicistronic genome. The second subcluster contains two groups: one group includes sacbrood virus (SBV) of honeybee and infectious flacherie virus (IFV) of silkworm that share more similarities with mammalian than insect picornaviruses and the

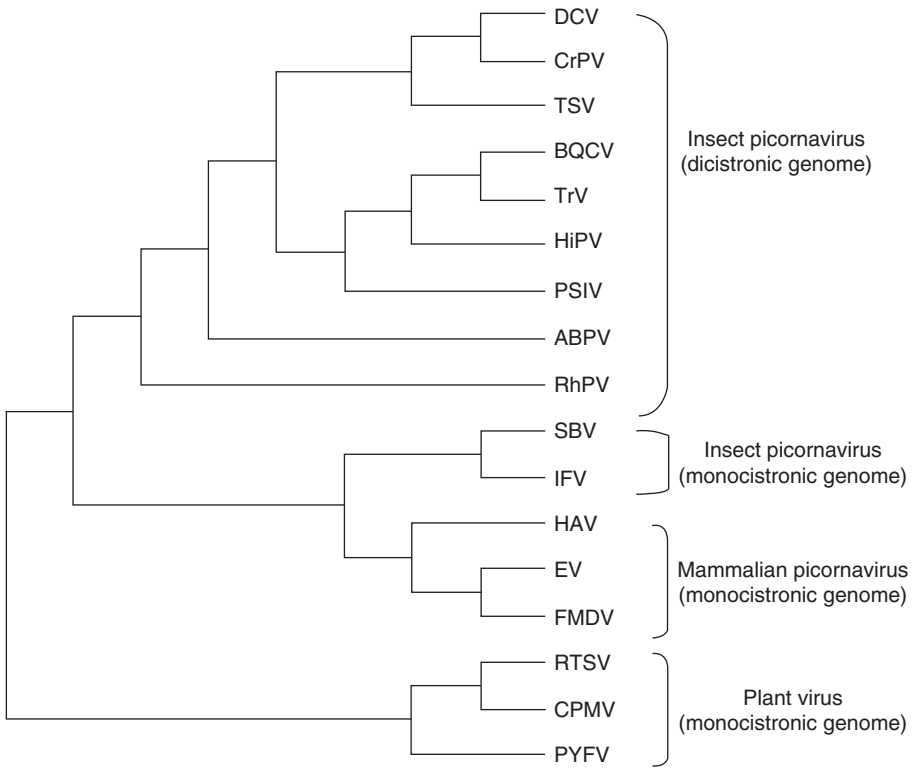

Figure 2 Phylogenetic analysis of TSV and other RNA viruses infecting insects, plants, and mammalian hosts. Reproduced from Dhar AK, Cowley JA, Hasson KW, and Walker PJ (2004) Genome organization, biology and diagnosis of Taura syndrome virus and yellowhead virus of penaeid shrimp. *Advances in Virus Research* 63: 353–419, with permission from Elsevier.

other group is the mammalian picornaviruses (**Figure 2**). The picornavirus superfamily viruses with dicistronic genomes were subsequently classified under a new family, *Dicistroviridae*, of which TSV is a new but unassigned member.

To date, the genomes of RNA viruses infecting a wide range of insect species have been sequenced. These include cricket paralysis virus (CrPV, AF218039), drosophila C virus (DCV, AF014388), acute bee paralysis virus (ABPV, NC002548), black queen cell virus (BQCV, AF183905), sacbrood virus (SBV, AF092924), rhopalosiphum padi virus (RhPV, AF022937), plautia stali intestine virus (PSIV, AB006531), triatoma virus (TrV, AF178440), himetobi P virus, (HiPV, AB017037), infectious falcherie virus (IFV, AB000906), homalodisca coagulata virus-*1* (HoCV-1, DQ288865), aphid lethal paralysis virus (ALPV, AF536531), Kashmir bee virus (KBV, AY275710), solenopsis invicta virus-1 (SINV-1, AY634314), and TSV of shrimp (AF277675). The genome organization of IFV and SBV is similar to mammalian picornaviruses. They contain a single open reading frame (ORF) with the capsid genes located at the 5′ end and nonstructural genes at the 3′ end. In contrast, the genomes of CrPV, DCV, ABPV, BQCV, RhPV, PSIV, TrV, HiPV, HoCv-1, ALPV, KBV, SINV-1, and TSV contain two ORFs (ORF1 and ORF2) separated by an intergenic region (IGR). At the 5′ end, ORF1 encodes the nonstructural genes, and at the 3′ end ORF2 encodes the capsid proteins (as seen for TSV in **Figure 5**). All show greater sequence similarity to each other than to mammalian picornaviruses. To date, eight of these viruses (ALPV, BQCV, CrPV, DCV, HiPV, PSIV, RhPV, and TrV) have been assigned into the newly created family *Dicistroviridae*, genus *Cripavirus,* with CrPV as the type species. SINV-1 is tentatively assigned to this genus, while APBL and TSV are net assigned to any genus but placed in the *Dicistroviridae* family.

Host Range and Clinical Signs

Species of penaeid shrimp differ in their susceptibility to TSV. *Penaeus vannamei*, the principal penaeid species cultivated in the Americas, and *P. schmitti* are highly susceptible to TSV. TSV causes serious disease in postlarval (PL), juvenile, and adult *P. vannamei*, but has not been reported in PL smaller than the PL11 stage (11 day old). Other American penaeid species, such as *P. stylirostris*, *P. setiferus*, *P. duorarum,* and *P. aztecus*, are generally less susceptible to TSV. Among the Eastern Hemisphere penaeid species, TSV infection has been reported in *P. monodon*, *P. japonicus*, and *P. chinensis*.

To combat catastrophic losses caused by TSV in *P. vannamei*, TSV-resistant lines of specific pathogen-free (SPF) *P. vannamei* have been developed by selective breeding. However, due to the ability of the virus to mutate rapidly, less susceptible or resistant species and selected breeding lines may succumb to TSD as more virulent strains emerge. This was observed during TSV epizootics in Mexico, in 1999, when TSV-tolerant *P. stylirostris* showed high mortality due to emergence of a virulent strain of TSV.

The clinical signs of acute-phase TSV infection in *P. vannamei* include lethargy, anorexia, opaque musculature, ataxic swimming behavior, flaccid bodies, soft cuticles, and chromatophore expansion resulting in reddening of the uropods, appendages, and body. These shrimp are typically in late pre-molt or early post-molt stage. Cumulative mortalities during acute-phase infection may reach 95%. In a pond where a TSV outbreak occurs, dead or dying shrimp float on the watersurface, attracting predatory birds (seagulls, cormorants, terns, etc.). Individuals that survive acute-phase infection develop grossly visible, multifocal, melanized lesions on the cephalothorax, tail, and appendages (**Figure 3**). These lesions are characteristic of the transition phase of infection. Chronically

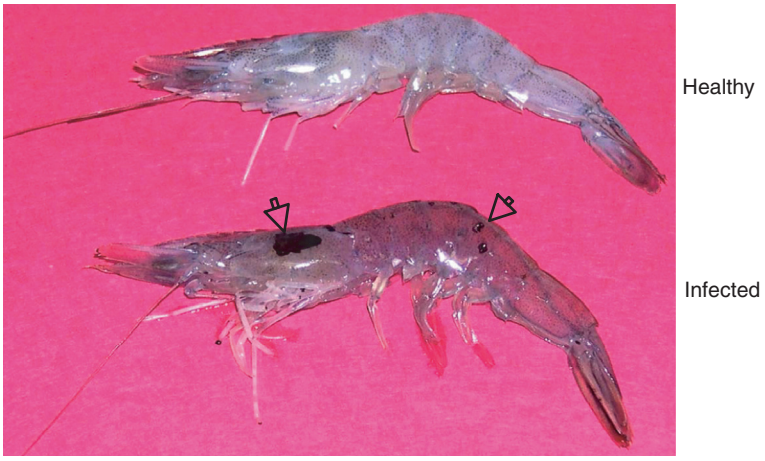

Figure 3 *Penaeus vannamei* shrimp displaying typical clinical signs of Taura syndrome disease at the end of the acute phase. Multifocal, melanized lesions on the thorax and tail are visible (indicated by arrows) in TSV-infected shrimp.

infected shrimp shed the cuticle with melanized foci and display normal behavior but can remain asymptomatic carriers of TSV.

Pathogenesis

TSD pathogenesis consists of three overlapping yet clinically and histologically distinct phases: a peracute to acute phase, a short transition phase, and a persistent chronic phase.

Acute Phase

The acute phase begins approximately 24 h post exposure and persists for approximately 7 days. The acute phase is characterized by the rapid development of severe, multifocal cuticular epithelial necrosis and high mortalities (**Figure 4**(**b**)). Target tissues of TSV infection include the cuticular epithelium of the foregut, gills, appendages, hindgut, and general body cuticle. Lesions sometimes extend into underlying subcuticular connective tissue and striated muscle. In severe cases, the antennal gland, hematopoietic tissue, testes, and ovaries may also be infected. Acutely infected epithelial cells detach from the underlying stroma, assume a spherical shape, and this is followed by cell lysis and release of virions into the circulatory system. Infected cells display highly basophilic pyknotic and karyorrhectic nuclei and marked cytoplasmic eosinophilia, with variably staining and sized cytoplasmic inclusion bodies. These histological lesions are collectively called 'peppered' or 'buckshot-laden' lesions, and are considered pathodiagnostic for acute phase of TSD (**Figure 4**(**b**)).

Transition Phase

Shrimp surviving acute-phase infection enter a brief transitional phase for approximately 5 days before entering into chronic phase. Appearance of multifocal melanized lesions on the cephalothorax and tail, with declining mortalities, are characteristic of the transition phase (**Figure 3**). Histologically, transition-phase animals present infrequent, scattered, epithelial lesions, normally appearing lymphoid organ (LO) arterioles (tubules) that display a TSV-positive signal by *in situ* hybridization (ISH), and the onset of spheroid development within the LO. Transition-phase animals are lethargic, anorexic, start molting, and shed melanized exoskeleton.

Chronic Phase

During the chronic phase, mortality ceases and animals resume normal behavior. The chronic phase may last for 8–12 months in experimentally infected *P. vannamei*. The histological hallmark of chronic phase infection is the appearance of LO spheroids (**Figure 4**(**d**)). Occasionally, ectopic spheroids are also found associated with tegmental glands located within connective tissues of the cephalothorax and appendages. Spheroids consist of phagocytic semigranular and granular hemocytes undergoing apoptosis.

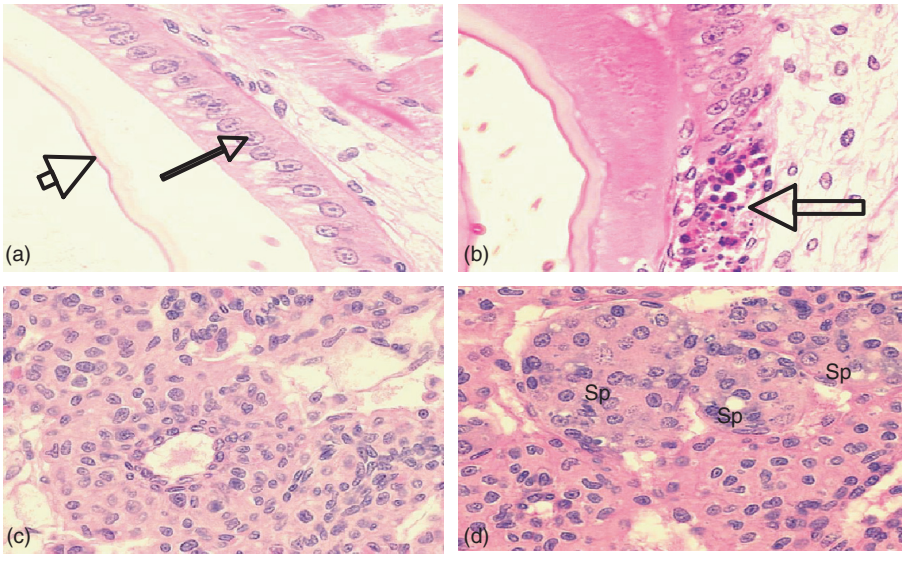

Figure 4 Histopathology by H&E staining of juvenile *Penaeus vannamei* infected with Taura syndrome virus. (a) Normal stomach cuticular epithelium (thin arrow) and cuticle (thick arrow); (b) acute-phase TSV infection evident within the stomach cuticular epithelium (arrow) with nuclear pyknosis, karyorrhexis, and cytoplasmic eosinophilia clearly visible; (c) normal lymphoid organ (LO) showing a prominent arteriole with centralized lumen; and (d) chronic TSV infection visible inside the LO, displays prominent spheroids (Sp). All panels are at ×600 magnification.

Genetics

Genome Organization and Gene Expression

The TSV genome consists of a linear, positive-sense, single-stranded, polyadenylated RNA of 10 205 nucleotides (nt). It has a 417 nt 5′ untranslated region and a 224 nt 3′ untranslated region. There are two ORFs. ORF1 encodes nonstructural proteins, while ORF2 encodes structural proteins (**Figure 5**). ORF1 is 6324 nt long, encoding a 2107 amino acid (aa) polyprotein with a molecular mass of 234 kDa. ORF2 is 3036 nt long, encoding a 1011 aa long polypeptide with a molecular mass of 112 kDa. Nonstructural ORF1 proteins contain conserved helicase (NTP-binding protein), protease, and RNA-dependent RNA polymerase (RdRp) motifs. The RNA helicase consensus sequence (Gx_4GK) is at aa 752–758 and has similarity with the cognate domains of other *Dicistroviridae* and insect picornaviruses. The protease domain in the TSV ORF1-encoded polypeptide, located between aa 1380 and 1570, shows similarity with the 3C proteases of the *Dicistroviridae*, *Picornaviridae*, *Sequiviridae,* and *Comoviridae*. The TSV protease motif is partially conserved, with glycine replaced by cysteine. Similar to picornaviruses, the His-Asp-Cys catalytic triad in the protease domain is conserved in TSV. The RdRp domain, located at the 3′ end of ORF1, contains eight conserved motifs analogous to those in picornaviruses of insects, mammals, and plants.

The N-terminal region of the ORF1-encoded polypeptide contains a stretch of 65 aa (166–230) that shows similarity to the 'inhibition of apoptosis' proteins (IAP) found in mammals, yeast, insects, and some DNA viruses. No other RNA viruses are known to encode polypeptides containing such a motif. It is unknown if this IAP motif of TSV plays a role during the long-term chronic-phase infection in evading the host immune system or facilitates virus replication.

There is an IGR of 207 nt between the two ORFs in the TSV genome. The IGR region contains an internal ribosomal entry site (IRES) that allows cap-independent translation of the ORF2 capsid proteins. Functional IRES elements have also been identified in the IGRs of CrPV and PSIV. In mammalian cells infected with picornaviruses, structural and nonstructural proteins are produced in equimolar amounts. However, in insect viruses, like DCV, structural proteins are produced in excess. This is due to IRES-mediated translation of DCV coat proteins. Translation of the two distinct polyproteins in DCV (ORF1 and ORF2) appears to be independently controlled. This is in contrast to picornaviruses encoding a single ORF in which a single polyprotein is processed post-translationally to generate both the structural and nonstructural proteins. The cap-independent translation in PSIV ORF2 has been demonstrated *in vitro* using a rabbit reticulocyte lysate system. In CrPV, the initiation codon for IRES-mediated translation has been identified as CCU, whereas, the initiation codon in PSIV and RhPV is CUU. The CCU/CUU triplets have been identified as part of the inverted repeat sequence of the IRES elements that form RNA pseudoknot structures essential for IRES activity. In TSV, there is an in-frame methionine upstream of ORF2 although N-terminal sequencing of the VP2 capsid protein has revealed alanine at the terminal position (ANPVEIDNFDTT). The alanine codon is preceded by proline (CCU) and methionine (AUG) codons (MPANPVE). Site-specific mutation in TSV has demonstrated that conversion of the AUG to UUG has no effect on capsid protein expression. Additionally, cell-free expression in the absence of initiator methionine tRNA or in the presence of ribosome inhibitor is possible with TSV. These results indicate that the IRES element in TSV IGR is functional and that the TSV intergenic AUG codon does not act as a translation initiation site. TSV has an unusual side stem–loop structure in its IGR-IRES region that is involved in this cap-independent translation. The presence of a methionine codon in the IGR-IRES has been shown to be unimportant to translation; that is, TSV translation of ORF2 does not require initiator tRNA and relies instead on the IRES element for translation initiation.

The TSV genome is transcribed as a single ~10 kb transcript and does not produce subgenomic RNA for translation of the capsid genes. This distinguishes TSV from many positive-strand RNA viruses (e.g., *Calciviridae* and *Togaviridae*) in which capsid proteins encoded in the 3′ end of the genome are generally translated from subgenomic RNA.

Genetic Diversity

The isolate that caused the first TSV epizootics in the USA (Hawaii) was subsequently characterized using biological, serological, and molecular data as Serotype A. In 1999, significant mortalities in a TSV-tolerant strain of the Western blue shrimp (*P. stylirostris*) occurred at shrimp farms in México and there were concerns that a new TSV

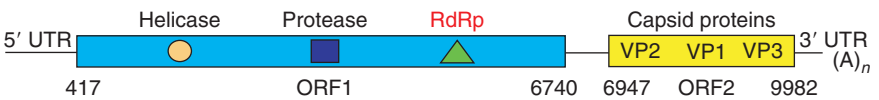

Figure 5 Genome organization of Taura syndrome virus (TSV). The conserved helicase, protease, and the RNA-dependent RNA polymerase (RdRp) domains are indicated in open reading frame 1 (ORF1). IGR, intergenic region; UTR, untranslated region.

strain might have emerged. These shrimp showed acute- or chronic-phase TSV infections by staining with H&E, and were virus-positive by reverse transcriptase polymerase chain reaction analysis (RT-PCR) and by ISH. However, these animals were TSV-negative by immunohistochemical (IHC) analysis using a TSV-specific monoclonal antibody (mAb) specific to the VP1 capsid gene.

Nucleotide sequences of capsid genes (VP1 and VP2) of the Mexican isolates revealed nonconservative amino acid replacements (such as S→A, polar uncharged to non-polar hydrophobic in VP1, and Q→K, polar uncharged to positively charged in VP2) compared to the Hawaiian isolate. Phylogenetic analysis showed that the Mexican isolate falls into a different clade. The Mexican isolate was classified as TSV serotype B.

In 2001, significant mortalities of *P. vannamei* occurred at shrimp farms in Belize, resulting from TSV epizootics. Using OIE diagnostic methods and sequence analysis, the Belize isolate was shown to represent a new serotype, TSV serotype C (**Table 1**).

In 2004, a TSV epizootic occurred in some farms in Texas, USA, near shrimp-processing plants that process frozen shrimp from Southeast (SE) Asia. Phylogenetic analysis using the VP1 capsid gene sequence revealed that TSV Texas isolate groups with the isolates from SE Asia (Thailand, Taiwan, and China, **Figure 6**). The spread of TSV to Asia most likely resulted from the introduction of TSV-infected *P. vannamei* from South America. The first TSV epizootic in Asia occurred in Taiwan in 1998, and subsequently spread to other Asian countries. It is possible that the Texas isolate was introduced through imported shrimp from SE Asia. Based on the phylogenetic analysis, the Asian isolates have been grouped tentatively as serotype D (**Figure 6**). Further characterization (biological and serological) might reveal that this group represents more than one serotype.

Overall, the TSV isolates show very high similarity (~95%) in nucleotide sequence of the VP1 gene among the isolates and most of the variations are located in the C-terminal end of the VP1 capsid gene. In CrPV, the type species of the genus *Cripavirus*, family *Dicistroviridae*, the crystal structure of the capsid gene has revealed that the C-terminal end of the VP3 gene (homologous to TSV VP1) is a helical extension on the virion surface. Therefore, this region is less constrained by structural requirements allowing mutations to accumulate. These mutations have serious implications for antibody-driven diagnosis and potentially modulate the virulence of the newly evolved strain(s).

Evolution and Spread

RNA viruses exist as 'quasispecies' in nature due to the high mutation frequency caused by the lack of effective proofreading activity of RdRp. The presence of a large array of related genotypes in the population allows an RNA virus to evolve and adapt to changes in the host and the environment. The spread and evolution of TSV appears to provide an example of this process. In México, until about the mid-1990s, *P. vannamei* was the principal species for shrimp farming. When TSV epizootics in México reached a peak in 1996, farmers started switching from TSV-susceptible *P. vannamei* to TSV-tolerant *P. stylirostris*. This resulted in the decline of TSV epizootics and, by 1998, shrimp production in México stabilized. In 1999, a new strain of TSV evolved in México that caused significant mortalities in previously tolerant *P. stylirostris*. The replacement of *P. vannamei* with *P. stylirostris* in shrimp farms in México might have contributed to the development of a virulent strain of TSV as the virus adapted to a new host species.

The transportation of live postlarval and adult shrimp (*P. vannamei*) from South America to Asia facilitated TSV dissemination in Asia and in 1998, the first TSV outbreak was reported in Taiwan. From Taiwan, TSV spread to other Asian countries. In Thailand, *P. vannamei* cultivation commenced in late 1990. Due to the ban on cultivation of native *P. monodon* species in freshwater areas in Thailand in 2000 and widespread slow growth in cultivated *P. monodon* in 2001 and 2002, farmers adopted *P. vannamei* as an alternative species. During this time, almost 70% of the broodstock in Thailand was imported from China. In 2003, the first TSV outbreak was confirmed in Thailand. In 2004, TSV epizootics occurred in farms in Texas, USA, located proximal to shrimp-processing plants that import frozen and bait shrimp from SE Asia. Phylogenetic analysis, using nucleotide sequence data from the TSV capsid gene VP1, showed that the isolates from Thailand, China, Taiwan, and Texas formed a single clade (**Figure 6**). As naïve shrimp populations are exposed to TSV, virus/host selection results in the emergence of more virulent strain(s) with devastating consequences. The

Table 1 List of TSV serotypes identified based on biological, genomic, and serological properties

Serotype	*Place of origin*	*Year*	*Species of origin*
TSV serotype A	Hawaii, USA	1994	*Penaeus vannamei*
TSV serotype B	Sinaloa, México	1998	*Penaeus stylirostris*
TSV serotype C	Belize	2001	*Penaeus vannamei*
TSV serotype D	Asia	1999–2005	*Penaeus vannamei, Penaeus monodon, Metapenaeus ensis*

The origin and the year of collection of these isolates are indicated.

availability of TSV genomic information has provided valuable insight into the origin, evolution, and spread of TSV worldwide.

Dissemination

TSV is transmitted by cannibalism of infected moribund or dead shrimp by healthy shrimp in a pond or in an experimental tank. The virus can remain infectious in decaying shrimp carcasses for up to 3 weeks and these may serve as a source of infection. In addition, chronically infected shrimp harbor infectious TSV within the LO and hemolymph for 8–12 months post infection, representing a source for renewed outbreaks in ponds, canals, or adjacent estuaries. In experimentally induced TSV epizootics, waterborne transmission has been reported to occur up to 48 h following peak mortality.

Mechanical transmission of TSV can occur via an aquatic insect (water boatmen, *Trichocorixa reticulate*) living in ponds and via seagulls (*Larus atricilla*). Infective TSV has been demonstrated in the seagull feces collected from the banks of ponds where TSV outbreaks have occurred.

Since the initial outbreak of Taura syndrome in Ecuador, the geographic range of the disease has spread and TSV is now considered endemic along the mid-American Pacific Coast, ranging from northern Peru through to México. Wild postlarvae and broodstock showing acute and/or chronic disease have been collected in Ecuador, Honduras, El Salvador, and Southern México. Therefore, wild postlarvae and broodstock are potential sources of dissemination for TSV. The movement of TSV-infected live postlarvae and adult shrimp has been the principal means by which TSV spread into shrimp farming nations within the Western Hemisphere and Asia. Export of frozen commodity shrimp and bait shrimp from infected areas also may have contributed to the spread of TSV across the continents.

Diagnosis

Taura syndrome diagnosis and the detection of TSV can be conducted by observation of clinical signs, bioassay, histopathology, enzyme-linked immunosorbent assay (ELISA), ISH using nonradiolabeled probes, and reverse transcription-polymerase chain reaction (RT-PCR).

As no immortalized shrimp cell lines are currently available, detection of infectious virus relies on *in vivo* bioassays. The bioassay protocol involves exposing SPF juvenile *P. vannamei* to TSV-suspect shrimp either by *per os* challenge or by injection of a tissue extract.

TSV-positive shrimp are identified by gross signs and histopathology.

A standard diagnostic tool for identifying TSV-induced pathology involves H&E histology of Davidson's alcohol formalin acetic acid fixative (AFA)-preserved shrimp. The presence of acute-phase lesions in cuticular epithelia is considered to be a definitive diagnosis of TSV infection (**Figure 4**).

Digoxigenin-labeled cDNA probes have been developed for TSV detection by ISH. Positive ISH reactions are identified by the presence of a blue-black precipitate within the cytoplasm of TSV-infected cells. ISH has greater sensitivity than H&E staining, as TSV can be detected in shrimp with mild acute infections and in asymptomatic carriers.

ELISA-based dot blot detection of TSV capsid protein using a TSV-specific monoclonal antibody is available and has been modified for application to IHC detection of TSV in histological sections. IHC has advantages over ISH in that it is a more economical and rapid assay with similar sensitivity. However, IHC using monoclonal antibodies can fail to detect some TSV strains due to epitope drift, as discussed above.

An RT-PCR method has been described for TSV detection in hemolymph, providing a nonlethal diagnostic method that is rapid and has a greater sensitivity than other methods. Recently, real-time RT-PCR methods using SYBR Green dye and TaqMan probes have been developed for rapid detection and quantification of TSV. The real-time RT-PCR is highly sensitive, specific, detects subclinical infections, and has a high throughput potential. The drawback with the real-time RT-PCR is its high cost and the need for significant technical expertise. However, combining real-time PCR with conventional diagnosis might be acceptable for large-scale shrimp farm operations to screen broodstock and field samples for TSV.

Control/Prevention

The current TSV control methods emphasize biosecurity at the farm level and the utilization of SPF, TSV-resistant shrimp for stocking. This approach is preventative and has considerable success in the control of TSD on carefully managed farms. Since the immune system of shrimp is relatively primitive, the development of a traditional vaccination procedure for control of TSV is not likely. Experimentation with RNA interference and the expression of antisense RNA against the TSV capsid gene in transgenic shrimp show promise in the control of the disease but currently have only been tested at the laboratory level. Also, disease protection by nonspecific dsRNA indicates that shrimp have a fairly strong innate immune response that could be exploited.

Acknowledgment

The authors thank Dr. Kenneth W. Hasson, Texas Veterinary Medical Diagnostic Laboratory (TVMDL), College Station, Texas for providing the histopathology and electron microscopy photographs.

Taxonomy, Classification and Nomenclature of Viruses

C M Fauquet, Danforth Plant Science Center, St. Louis, MO, USA

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Classification The categorization of organisms into defined groups on the basis of identified characteristics.
Family A category in the virus taxonomic classification of related organisms, comprising one or more genera.
Genus A category in the virus taxonomic classification of related organisms, comprising one or more species.
Nomenclature The assigning of names to organisms in a scientific classification system.
Order A category in the virus taxonomic classification of related organisms, comprising one or more families.
Species A virus species is a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecological niche.
Taxonomy The science of classifying plants, animals, and microorganisms into increasingly broader categories based on shared features. The practice or principles of classification.

Introduction

Virus taxonomy is a very important but controversial field of science. It was ranked as the first constraint for the modern development of virus databases, and the exponential increase in virus sequencing is worsening the situation. However, substantial progress has been made particularly in the last 20 years, both on the conceptual framework and practical implication of virus taxonomy. The International Committee on Taxonomy of Viruses (ICTV) is the only committee of the Virology Division, of the International Union of Microbiological Societies (IUMS), in charge of that task since 1966, for the international virology community. Virus Taxonomy Reports have been published regularly by ICTV and they became the reference in virus taxonomy and nomenclature. This article aims at providing some historical information about the establishment and changes in virus taxonomy and describes the current status of virus classification, nomenclature, and orthography.

There is no such thing as a 'natural' or a 'biological' classification; by essence any classification is an arbitrary human invention and viruses are no exception. The question really is: "How can we classify viruses in such way that it makes sense and is useful to many scientists?" The need for virus classification is not only supported by the common human need for organization, but also as a scientific tool to compare viruses and extrapolate useful information from one virus to another and from one family to another. Crucial biological information can be extrapolated directly from human viruses like picornaviruses to plant comoviruses and vice versa, when the classification indicates many structural and genomic common characteristics. When a newly discovered virus is assigned to a particular taxon, this virus can immediately be granted a number of *a priori* properties that only need confirmation and that have an immediate impact on specific virological studies. Furthermore, although it is not clearly stated by ICTV that the current classification is thought to reflect virus evolution, it is accepted that virus taxonomy is aiming at this objective and could become a tool by itself to study and evaluate virus evolution.

Virus nomenclature cannot be dissociated from classification. There must be a coherent system for naming viruses accompanied with a system for classifying viruses. Furthermore, using correct orthography and typography of virus taxa is not simply an excercise meant to complicate the task of virologists but is based on rules that help scientists to extract useful information from what is written down. It is therefore important to establish and follow guidelines for orthography, nomenclature, and classification of viruses. For all these reasons, virus classification and nomenclature have always been very controversial and have led to passionate discussions over the past four decades.

Historical Background of Virus Taxonomy

The first evidence for the existence of viruses was shown by Beijerinck in 1898, but it was not until the 1920s that virologists began to classify viruses. The first system referred to pathogenic properties of animal and human viruses and to symptoms for plant viruses. For example, viruses sharing the pathogenic properties causing hepatitis (e.g., hepatitis A virus, hepatitis B virus, yellow fever virus, Rift Valley fever virus) were grouped together as 'the hepatitis viruses'. In 1939, Holmes published a classification of plant viruses dependent on host reactions and differential host species using a binomial–trinomial nomenclature based on the name of the infected plant. It was only in the 1950s, with the utilization of the electron microscope, that

the first real virus classification was established. Naturally the shape and size of virus particles became major criteria for virus classification. Because of that powerful and rapid technology the number of newly discovered viruses increased rapidly and several hundreds of new viruses were listed in a short period of time.

In 1966 in Moscow, at the International Congress for Microbiology, 43 virologists created the International Committee on Nomenclature of Viruses (ICNV) with the aim of developing a worldwide recognized taxonomy and nomenclature system for all viruses. The name of the ICNV was changed in 1974 to the more appropriate ICTV. The ICTV, which is the only committee of the Virology Division of the International Union of Microbiological Societies, is now recognized as the official international body that decides on all matters related to taxonomy and nomenclature of viruses.

Since 1966, virologists have agreed that all viruses isolated from different organisms should be classified together in a unique system, separate from that of microorganisms such as fungi, bacteria, and mycoplasma. However, there has been much controversy on how to achieve this aim. Lwoff, Horne, and Tournier in 1962 proposed the adoption of a system classifying viruses into subphyla, classes, orders, suborders, and families. It was also proposed that the hierarchical classification would be based on the type of nucleic acid (DNA or RNA), the strandedness (single = ss or double = ds), the presence or absence of an envelope, the capsid symmetry, the type of replication cycle (with or without an RNA intermediate for DNA viruses), and the number of genome segments. This hierarchical classification system has never been recognized by the ICTV, but most of the criteria used to demarcate the major classes of viruses formed the basis of the universal taxonomy system now in place, and all published ICTV reports have used this scheme with only minor changes.

It is only in the last 15 years that a hierarchical classification level higher than the family was proposed and accepted. A first order, *Mononegavirales*, was accepted in 1990, and the orders *Caudovirales* and *Nidovirales* were adopted in 1996. In 2005, ICTV considered introducing four new orders namely *Picornavirales, Herpesvirales, Reovirales,* and *Retrovirales*, and these may become accepted in the near future.

It is important to note that the species category for viruses was only adopted in 1991. From then onwards viruses were assigned to species or tentative species. In addition, a list of species demarcation criteria has been established for each family. It is anticipated that by 2010 the ICTV will have introduced species criteria for all viruses and that some level of homogeneity will have been reached, although it is perfectly acceptable to have different sets of criteria for different families of viruses.

Since the establishment of the ICTV, a total of eight virus taxonomic reports have been published. At the first meeting of the Committee in Mexico City in 1970, two families with corresponding two genera and 24 floating genera were adopted to begin grouping the vertebrate, invertebrate, and bacterial viruses together, and in addition, 16 plant virus 'groups' were introduced. Although virologists working with vertebrate viruses had assigned viruses to genera and families for many years, plant virologists until 1993 used the term 'group' to designate viruses with similar properties. It was only in 1995 that the ICTV adopted a uniform system for all viruses, encompassing 2644 assigned viruses. The *Eighth ICTV Report on Virus Taxonomy*, published in 2005 describes a Universal Virus Classification that comprises 3 orders, 73 families, 9 subfamilies, 287 genera, and 5450 viruses belonging to 1950 species (**Table 1**).

Over the past four decades the number of classified viruses, as well as the number of each type of taxa, has increased exponentially and continues to grow (**Figure 1**). Because DNA sequencing has become a routine technique, it seems likely that the number of recognizes viruses and viral taxa will continue to grow exponentially. Furthermore, virus genome sequences provide qualitative and quantitative criteria for defining the molecular variability of viruses that are useful for classification purposes. Sequencing will also permit identification and classification of many viruses that are difficult to isolate and characterize by other methods.

Organization and Structure of ICTV

The ICTV is the only Committee of the Virology Division of the International Union of Microbiological Societies. It is a non-profit organization composed of volunteered virologists from many countries who make decisions on virus names and taxa through a democratic process. The ICTV operates through subcommittees and study groups consisting of more than 500 virologists with expertise in human, animal, insect, protozoa, archaea, bacteria, mycoplasma, fungi, algae, and plant viruses.

Taxonomic proposals are initiated and formulated by study groups or by single individuals. The proposals are examined, offered to public scrutiny, accepted by the relevant subcommittee and presented for approval by the Executive Committee of the ICTV. All decisions are ratified by postal vote, where all members of the ICTV and more than 50 national microbiological societies are represented. Presently, there are 75 study groups working in concert with six subcommittees: one each for the vertebrate, invertebrate, plant, bacterial, and fungal viruses and one for the virus ICTV DataBase (ICTVdB). The ICTV does not impose taxa but ensures that all propositions are compatible with the International Code for Virus Classification and Nomenclature for accuracy, homogeneity, and consistency. The ICTV regularly

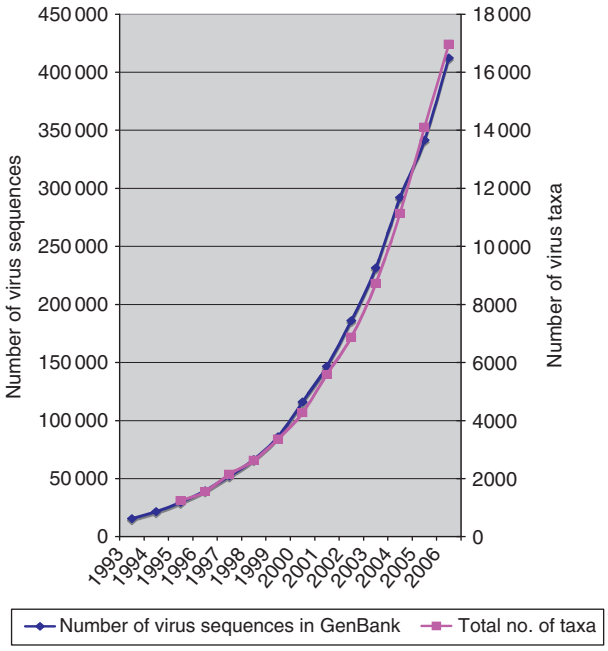

Figure 1 Number of virus taxa (including isolates) and virus sequences stored at GenBank since 1993.

publishes reports describing all existing virus taxa and containing a complete list of classified viruses with their abbreviations. The ICTV published its Eighth Report in 2005. An internet website is also maintained where all new taxonomic proposals are loaded and where the most important information relative to virus taxonomy is made available and updated regularly. The increasing number of virus species and virus strains being identified, along with the explosion of data on many descriptive aspects of viruses and viral diseases, particularly sequence data, has led the ICTV to launch an international virus database project (ICTVdB) and a Taxonomic Proposal Management System specifically to handle taxonomic proposals.

Polythetic Classification and Demarcation Criteria

There are currently two systems in use for classifying organisms: the Linnean and the Adansonian systems. The Linnean system is the monothetic hierarchical classification applied by Linnaeus to plants and animals, while the Adansonian is a polythetic hierarchical system. Although convenient to use, the Linnean system has shortcomings when applied to the classification of viruses because there is no obvious reason to privilege one criterion over another. The Adansonian system considers all available criteria at once and makes several classifications, taking the criteria successively into consideration. Criteria leading to the same classifications are considered correlated and are therefore not discriminatory. Subsequently, a subset of criteria is considered, and the process is repeated until all criteria can be ranked to provide the best discrimination of the species. Furthermore, qualitative and quantitative data can be simultaneously considered when building such a classification. In the case of viruses, the method is not used on a systematic basis, although it has been shown that at least 60 characters are needed for a complete virus description (**Table 2**).

The increasing number of reported viral nucleic acid sequences allows the construction of phylogenetic trees based on a single gene or a group of genes. Sequence comparisons by themselves have not satisfactorily provided a clear classification of all viruses together but are widely used at the order, family, and genus levels. Recently the National Center for Biotechnology Information (NCBI) in Washington developed a system of pairwise sequence comparisons (the so-called PASC system) between viral sequences which allows a new virus to be assigned to known taxa. It seems probable that, in future, virus classification will make increasing use of sequence data.

For more than 40 years, the ICTV has been classifying viruses essentially at the family and genus levels using a nonsystematic polythetic approach. Viruses are first clustered in genera and then in families. A subset of characters including physicochemical, structural, genomic, and biological criteria is then used to compare and group viruses. This subset of characters may change from one family to another according to the availability of the data and depending on the importance of a particular character for a particular family. Obviously, there is no homogeneity in this respect in the current virus classification system, and virologists weigh the criteria in a subjective process. Nevertheless, over time, there has been a great stability of the current classification at the genus and family levels. It is also clear that hierarchical classification above the family level will encounter conflicts between phenotypic and genotypic criteria and that virologists may have to reconsider the entire classification process in order to progress at this level.

Virus Taxa Descriptions

Virus classification continues to evolve with the technologies available for describing viruses. The first wave of descriptions, those before 1940, took into account mostly the visual symptoms of viral diseases along with modes of viral transmission. A second wave, between 1940 and

Table 2 Virus family descriptors used in virus taxonomy

I. Virion properties
  A. Morphology properties of virions
    1. Virion size
    2. Virion shape
    3. Presence or absence of an envelope and peplomers
    4. Capsomeric symmetry and structure
  B. Physical properties of virons
    1. Molecular mass of virions
    2. Buoyant density of virions
    3. Sedimentation coefficient
    4. pH stability
    5. Thermal stability
    6. Cation (Mg^{++}, Mn^{++}) stability
    7. Solvent stability
    8. Detergent stability
    9. Radiation stability
  C. Properties of genome
    1. Type of nucleic acid – DNA or RNA
    2. Strandedness – single stranded or double stranded
    3. Linear or circular
    4. Sense – positive, negative, or ambisense
    5. Number of segments
    6. Size of genome or genome segments
    7. Presence or absence and type of 5′-terminal cap
    8. Presence or absence of 5′-terminal covalently linked polypeptide
    9. Presence or absence of 3′-terminal poly(A) tract (or other specific tract)
    10. Nucleotide sequence comparisons
  D. Properties of proteins
    1. Number of proteins
    2. Size of proteins
    3. Functional activities of proteins (especially virion transcriptase, virion reverse transcriptase, virion hemagglutinin, virion neuraminidase, virion fusion protein)
    4. Amino-acid-sequence comparisons
  E. Lipids
    1. Presence or absence of lipids
    2. Nature of lipids
  F. Carbohydrates
    1. Presence or absence of carbohydrates
    2. Nature of carbohydrates

II. Genome organization and replication
    1. Genome organization
    2. Strategy of replication of nucleic acid
    3. Characteristics of transcription
    4. Characteristics of translation and post-translational processing
    5. Site of accumulation of virion proteins, site of assembly, site of maturation and release
    6. Cytopathology, inclusion body formation

III. Antigenic properties
    1. Serological relationships
    2. Mapping epitopes

IV. Biological properties
    1. Host range, natural and experimental
    2. Pathogenicity, association with disease
    3. Tissue tropisms, pathology, histopathology
    4. Mode of transmission in nature
    5. Vector relationships
    6. Geographic distribution

1970, brought together an enormous amount of information from studies of virion morphology (electron microscopy, structural data), biology (serology and virus properties), and physicochemical properties of viruses (nature and size of the genome, number and size of viral proteins). The impact of descriptions on virus classification has been particularly influenced by electron microscopy and the negative-staining technique for virions in the 1960s and 1970s. With this technique, viruses could be identified from poorly purified preparations of all tissue types and information about size, shape, structure, and symmetry could be quickly provided. As a result, virology progressed simultaneously for all viruses infecting animals, insects, plants, and bacteria. Since 1970, the virus descriptors list has included genome and replication information (sequence of genes, sequence of proteins), as well as molecular relationships with virus hosts.

The most recent wave of information used to classify viruses is virus genome sequences. Genome sequence comparisons are becoming more and more prevalent in virus taxonomy as exemplified by the presence of a significant number of phylogenetic trees in the *Eighth ICTV Report.* Some scientists promote the concept of quantitative taxonomy, aimed at demonstrating that virus genome sequences contain all the coding information required for all the biological properties of the viruses. This is in complete agreement with the polythetic concept of virus species definition if one considers that the unique sequence of a genome contains in fact all the information of the virus to perform all the steps of its replication cycle with structural and nonstructural genes and all of its biological functions. A good example of quantitative taxonomy is the re-classification of flaviviruses from the genus *Flavivirus* in the family *Togaviridae* into the new family *Flaviviridae* based upon sequencing of the yellow fever virus genome and comparisons with the gene sequence arrangement of members of the genus *Alphavirus* in the family *Togaviridae.* Another recent example is the merging of the genera *Rhinovirus* and *Enterovirus* in the family *Picornaviridae,* based on the fact that phylogenetic trees and pairwise comparisons did not support the continued distinction between the two genera.

There is a correlative modification of the list of virus descriptors, and **Table 2** lists the family and genus descriptors which are used in the current ICTV report. **Table 2** lists 45 different types of properties where each property (e.g., morphology) can take on different individual states (e.g., filamentous, icosahedral, etc.). A universal lists of virus descriptors has been established which is used by the ICTVdB. It contains a common set of descriptors for all viruses and subsets for specific viruses in relation to their specific hosts (human, animal, insect, plant, and bacterial).

The Order of Presentation of the Virus Classification

Currently, and for practical reasons only, virus classification is structured according to the 'Order of Presentation of Viruses' indicated in **Table 1**. The presentation of virus orders, families, and genera in this particular order reflects convenience rather than any hierarchical or phylogenetic consideration. The Order of Presentation of Viruses follows four criteria: (1) the nature of the viral nucleic acid, (2) the strandedness of the nucleic acid (single stranded (ss) or double stranded (ds)), (3) the use of a reverse transcription process (DNA or RNA), and (4) the sense of gene coding on the encapsidated genome (positive, negative, or ambisense). These four criteria give rise to six clusters comprising the 86 families and unassigned genera (genera without a designated family). Within each cluster, families and unassigned genera have been listed according to their possible affinities. For example, the families *Picornaviridae, Dicistroviridae, Sequiviridae, Comoviridae,* and *Potyviridae* are listed one after another because they share a number of similarities in their genome organization and sequence relatedness and they may form the basis for a proposed order in the future.

Table 3 List of criteria demarcating different virus taxa

I. Order
Common properties between several families including:
Biochemical composition
Virus replication strategy
Particle structure (to some extent)
General genome organization
II. Family
Common properties between several genera including:
Biochemical composition
Virus replication strategy
Nature of the particle structure
Genome organization
III. Genus
Common properties within a genus including:
Virus replication strategy
Genome size, organization, and/or number of segments
Sequence homologies (hybridization properties)
Vector transmission
IV. Species
Common properties within a species including:
Genome arrangement
Sequence homologies (hybridization properties)
Serological relationships
Vector transmission
Host range
Pathogenicity
Tissue tropism
Geographical distribution

A New Virus Taxon: The Virus Species

For many years, virologists debated the existence of virus species which was a very controversial issue and a series of definitions surfaced at regular intervals but none was adopted. However, in 1991, the ICTV Executive Committee accepted the species concept and the adopted definition is "A virus species is a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecological niche." This simple definition has already and will continue to have a profound effect on virus classification. In the *Eighth Report of the ICTV*, the 'List of Species' and the 'List of Tentative Species' are accompanied by a 'List of Species Demarcating Criteria' provided for each genus. Naturally, this list of criteria should follow the polythetic nature of the species definition, and more than one criterion should be used to determine a new species. It is obvious that most criteria are shared among the different genera, within and across families. These shared criteria include host range, serological relationships, vector transmission type, tissue tropism, genome rearrangement, and sequence homology (**Table 3**). However, while the nature of the criteria is similar, the levels of demarcation clearly differ from one family to another. This may reflect differences in appreciation from one family to another, but most likely reflects the differential ranking of a particular criterion in different families. The huge differences in sequence homologies (up to 30%) among lentivirus nucleoprotein sequences may not have the same biological significance as small differences for potyvirus capsid protein sequences (0–10%), and therefore universal levels of sequence identity for similar genes may not exist for viruses. However, it is important to note that the nature of the demarcating criteria at the genus level will probably not change since they have passed the test of years. Despite the fact that they were mostly established using biochemical and structural criteria, most of them have remained valid when correlated with genome organization and sequence data.

A Uniform Nomenclature for All Virus Taxa

Nomenclature is tightly associated with classification, in the sense that the taxonomic names indicate, to some extent, the nature of the taxa. Similarly for viruses, the ICTV has set rules for virus nomenclature and the orthography of taxonomic names that are regularly revised and improved. The international virus species names end in 'virus', international genus names in

'...virus', international subfamily names in '...virinae', international family names in '...viridae', and international order names in '...virales'. In formal taxonomic usage, the virus order, family, subfamily, genus, and species names are printed in italics (or underlined) and the first letter is capitalized. For all taxa except species, new names are created following ICTV guidelines. Because of the difficulty in creating new official international names for virus species, it has been decided in 1998 by the ICTV to use the existing English vernacular virus names. However, to differentiate virus species names from virus names it has also been decided that their typography would be different, that is, the species names would be italicized, and the first letter of the name capitalized while the virus names would not. In addition ICTV had created an additional category called 'Tentative Species Names' to accommodate viruses that seemed to belong to a new species, but did not have enough data to support this decision; it was also a way to 'reserve' a name already used in literature. In 2005, ICTV decided to replace this category by 'Unassigned Viruses' in the genus.

Latinized binomials for virus names have been supported by animal and human virologists of the ICTV for many years but have never been implemented. Their recommendation was in fact withdrawn from ICTV nomenclature rules in 1990, and consequently, such names as *Herpesvirus varicella* or *Polyomavirus hominis* should not be used. For several years, plant virologists adopted a different nomenclature, using the vernacular name of a virus but replacing the word 'virus' by the genus name: for example, *Cucumber mosaic cucumovirus* and *Tobacco mosaic tobamovirus*. This system is called 'the non-latinized binomial system', although the binomial order is the opposite of the typical latinized binomial system where the genus name ends with the virus name. Though this usage is favored by many scientists, and examples of such a practice can be found for human, animal, and insect viruses (e.g., *Human rhinovirus*, *Canine calicivirus*, and *Acheta densovirus*), it has not yet been adopted as a universal system by the ICTV; however, it has been decided that each study group would decide what is best for the viruses they deal with and the new names would have to be ratified through a formal taxonomic proposal by the ICTV.

In formal usage, the name of the taxon precedes the name of the taxonomic unit: for example, "the family *Picornaviridae*' or "the genus *Rhinovirus*'. In informal vernacular usage, virus order, family, subfamily, genus, and species names are written in lower case roman script; they are not capitalized or italicized (or underlined) – for example 'animal reoviruses'. To avoid ambiguous identifications, it has been recommended to journal editors that published virological papers follow ICTV guidelines for proper virus identification and nomenclature and that viruses should be cited with their full taxonomic terminology when they are first mentioned in an article, for example, order *Mononegavirales*, family *Paramyxoviridae*, subfamily *Pneumovirinae*, genus *Pneumovirus*, species *Human respiratory syncytial virus*.

A Universal Classification System

The present universal system of virus taxonomy is set arbitrarily at the hierarchical levels of order, family, subfamily, genus, and species. Lower hierarchical levels, such as suborder, subgenera, and subspecies, may be considered in the future if need arises. Hierarchical levels under the species level such as strains, serotypes, variants, and pathotypes are established by international specialty groups and/or by culture collections, but not by the ICTV.

Species

The species taxon is always regarded as the most important taxonomic level in classification but has proved difficult to apply to viruses. In 1991, the ICTV accepted the definition of species, stated above, proposed by Marc van Regenmortel. The major advantage of this definition is that it can accommodate the inherent variability of viruses and is not dependent on the existence of a unique set of characteristics. Members of a polythetic class are defined by more than one property and no single property is absolutely indispensable. Thus, in each family, it might be possible to determine the set of properties of the class 'species' and thus to verify if the family members are representatives of the class 'species' or if they belong to a different taxonomic level.

Many practical matters are related to the definition of a virus species. These include (1) homogeneity of the different taxa across the classification, (2) diagnostic-related matters, (3) virus collections, (4) evolution studies, (5) biotechnology, (6) sequence database projects, (7) virus database projects, (8) publication matters, and also (9) intellectual property rights.

Genera

There is no formal ICTV definition for a genus, but it is commonly considered as "a population of virus species that share common characteristics and are different from other populations of species." Although this definition is somewhat elusive, this level of classification seems stable and useful. Some genera have been moved from one

family to another (or from one family to an unassigned genus status such as the genus *Hepevirus*) over the years, but the composition and description of these genera has remained very stable. The characters defining a genus are different from one family to another. The use of subgenera has been abandoned in current virus classification.

Families

Genera are usually clustered in families, and most of the time, when a new genus, obviously not belonging to any existing family, is created, virologists also create a new family. Even after the creation of the ICTV, plant virologists have continued to classify plant viruses in 'groups', refusing to place them in genera and families. This position was mostly caused by a refusal to accept a binomial nomenclature. However, because of obvious similarities, plant reoviruses and rhabdoviruses had been integrated into the families *Reoviridae* and *Rhabdoviridae* (**Table 1**). Plant virologists subsequently accepted in 1995 the placing of plant viruses into species, genera, and families. The number of unassigned genera is regularly decreasing with time; the most recent clustering is the creation of the family *Flexiviridae* with the genera *Potexvirus*, *Carlavirus*, *Mandarivirus*, *Foveavirus*, *Capillovirus*, *Allexivirus*, *Vitivirus,* and *Trichovirus*. However, there are still 22 unassigned genera that do not belong to any family. Their presence originates mostly from the preference of plant virologists for accumulating data on virus species and genera before clustering genera in families. The unassigned genus status is now being used by animal virologists as a convenient temporary classification status. Examples are the unassigned genera *Anellovirus*, that is close to the family *Circoviridae* but different enough to be separated, the previously unassigned genus *Cripavirus* that has been upgraded to full family status (*Dicistrovirida*), and another unassigned genus *Iflavirus* that has been created to accommodate new picorna-like viruses that are not typical picornaviruses.

Orders

As mentioned above, the higher hierarchical levels for virus classification are extremely difficult to establish. To date only three orders have been accepted: *Caudovirales*, *Mononegavirales*, and *Nidovirales*. The first order, *Mononegavirales*, was established in 1990 and comprises the nonsegmented ssRNA negative-sense viruses, namely, the families *Bornaviridae*, *Filoviridae*, *Paramyxoviridae*, and *Rhabdoviridae*. This order was formed because of the great similarity between these families over many criteria, including their replication strategies. A second order, *Caudovirales*, contains all families of dsDNA phages possessing a tail, including the *Myoviridae*, *Podoviridae*, and *Siphoviridae*. The order *Nidovirales* comprises the families *Coronaviridae*, *Arteriviridae,* and *Roniviridae* and was created because it was clear that the viruses belonging to these families share many properties and yet are so different that they cannot be placed together in the same family. Many members of the ICTV advocate the creation of many more orders, and as a matter of fact four new orders encompassing the families *Herpesviridae, Picornaviridae, Reoviridae, and Retroviridae* have been proposed and provisionally named but it has been decided to proceed cautiously in this area so as to avoid creation of short-lived orders. The creation of formal taxa higher than the orders – for example kingdoms, classes, and subclasses – has not been considered by the ICTV.

Glossary

RNA silencing Evolutionarily conserved mechanism in many eukaryotes to target and degrade aberrant RNA molecules. It constitutes an antiviral defense in plants and insects.

Introduction

The tenuiviruses were first described in the Fifth Report of the International Committee on Taxonomy of Viruses in 1982 as nonenveloped plant viruses possibly possessing a negative single-stranded (ss) RNA genome. Their name comes from the Latin 'tenuis', (thin, fine, weak) which refers to the structure of the viral particle as seen by electron microscopy (**Figure 1**). Epidemics of rice stripe virus (RSV) and rice hoja blanca virus (RHBV) cause important yield losses in rice-growing areas of Asia and the former USSR and of tropical America, respectively. Tenuiviruses exhibit unique properties that make them different from other plant viruses. Some properties of tenuiviruses are the following:

1. The peculiar flexuous viral particles have a thread-like morphology and can adopt circular forms (**Figure 1**(**a**)).
2. The viruses are persistently transmitted by a particular species of planthopper in a circulative, propagative manner. For some of the members of the genus, it has been demonstrated that the virus multiplies both in the host plant and in the insect vector. Multiplication of the virus in the vector may have deleterious effects on the insect. The viruses can be transmitted transovarially by viruliferous female planthoppers to their offspring, and through sperm from viruliferous males.
3. The genome of tenuiviruses is multisegmented and composed of ssRNAs that have either negative or ambisense polarity (**Figure 2**).
4. An RNA-dependent RNA polymerase (RdRp) is associated with the viral particle.
5. A nonstructural protein of 16–22 kDa accumulates in large amounts in infected plants, forming large inclusions (**Figure 1**(**b**)).
6. It has been observed for some tenuiviruses that the mRNAs are synthesized via cap-snatching (**Figure 3**).
7. Tenuiviruses infect plants of the family Poaceae.

Type Species and Other Species in the Genus

Rice stripe virus (RSV) is the type species of the genus *Tenuivirus*. Other species in the genus are *Echinochloa hoja blanca virus* (EHBV), *Maize stripe virus* (MSpV), *Rice grassy stunt virus* (RGSV), *Rice hoja blanca virus* (RHBV), and *Urochloa hoja blanca virus* (UHBV). Tentative species are Brazilian wheat spike virus (BWSpV), European wheat striate mosaic virus (EWSMV), Iranian wheat stripe virus (IWSV), rice wilted stunt virus, and winter wheat mosaic virus.

Virion Properties

Morphology

The particles also referred as ribonucleoproteins (RNPs) are thin filaments that may appear circular or spiral shaped (**Figure 1**(**a**)). The RNPs are 3–10 nm in diameter, with lengths proportional to the sizes of the RNAs they contain. No envelope has been observed.

Physical and Physicochemical Properties

RNP preparations can be separated into four or five components by sucrose density gradient centrifugation. The buoyant density of the RNP in CsCl when centrifuged to equilibrium is 1.282–1.288 g cm^{-3}. RNA constitutes 5–12% of the particle weight.

Components

The tenuivirus genome is composed of 4–6 noncapped ssRNA segments; the approximate size of the genome of the type member RSV is 17 kbp (**Figure 2**). The largest segment (RNA1, ~9 kbp) of RSV, MSpV, and RHBV is of negative polarity and encodes the RdRp. Segments 2 (RNA2, 3.3–3.6 kbp), 3 (RNA3, 2.2–2.5 kbp), and 4 (RNA4, 1.9–2.2 kb) of RSV, MSpV, and RHBV are ambisense. Segment 5 (1.3 kbp) detected in virions of MSpV and of EHBV is of negative polarity. A fifth RNA segment has also been reported for some isolates of RSV. RGSV RNA1, 2, 5, and 6 are homologous to RNA1, 2, 3, and 4, respectively, of other tenuiviruses, whereas RNA3 (3.1 kbp) and 4 (2.9 kbp) are ambisense and unique to RGSV. Subgenomic RNAs (sgRNAs) of different sizes and of either polarity are detected; they serve as mRNA for the synthesis of the viral proteins (**Figure 3**).

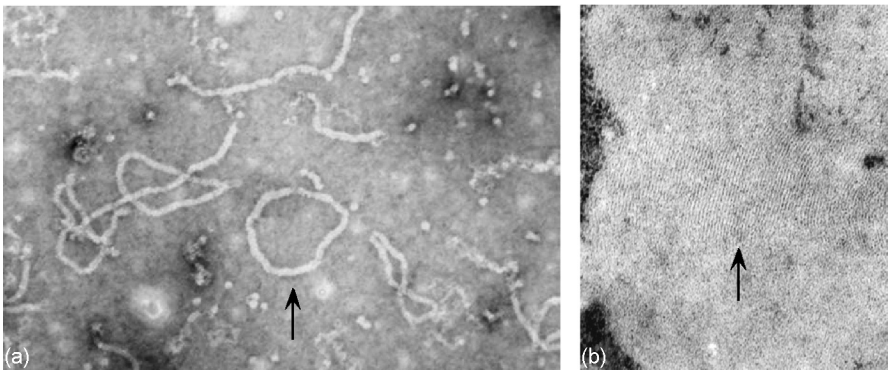

Figure 1 (a) Micrograph of purified ribonucleoproteins (RNPs) of rice hoja blanca virus (RHBV): An RNP is indicated by the arrow. (b) Ultrathin section of a rice leaf cell infected with RHBV. The arrow indicates viral inclusion bodies inside the nucleus with cytopathic effects.

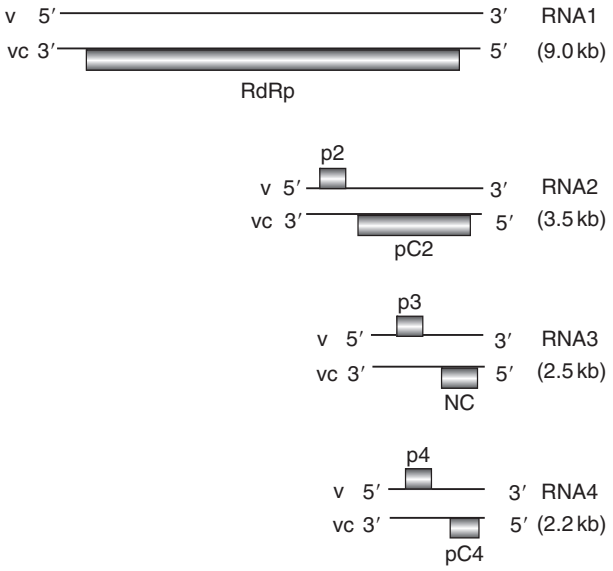

Figure 2 Schematic representation of the genome organization of RSV. RdRp, RNA-dependent RNA polymerase; NC, nucleocapsid protein; p4, nonstructural protein, which accumulates in viral inclusion bodies; v, viral sense RNA; vc, viral complementary RNA.

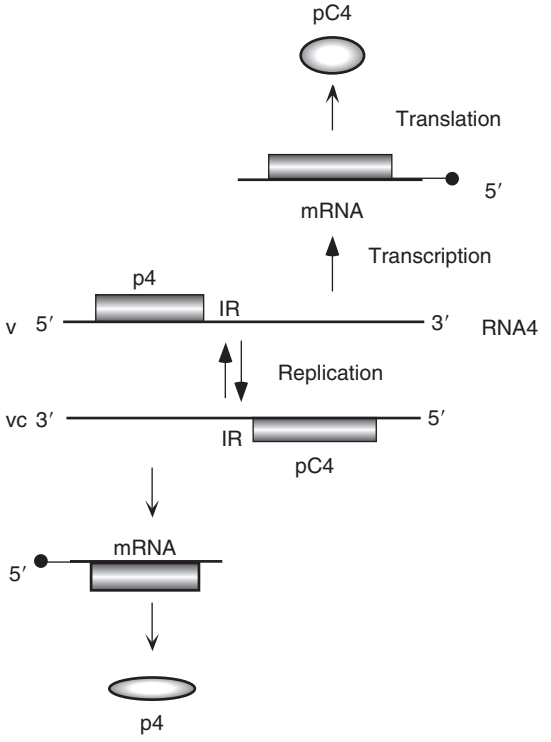

Figure 3 Schematic representation of the replication, transcription, and translation strategies of the ambisense RNA segments of tenuiviruses. Cap and nonviral nucleotides of host origin used as primers by the RdRp as a result of cap-snatching are represented by '—●'. IR, intergenic region.

The RNPs contain a nucleocapsid (NC) protein of 34–35 kDa, and small amounts of a 230 kDa protein which is co-purified with RNPs of RSV, RHBV and RGSV. This protein is the RdRp, associated with filamentous RNPs. The RNA polymerase activity of RHBV is capable of replicating and transcribing the RNA segments *in vitro*.

Genome Organization, Encoded Proteins, Replication and Transcription

The 5′ and 3′ terminal sequences (for about 20 nt) are complementary to each other: they can base-pair and give rise to circular RNPs. The terminal 8 nt (5′ ACACAAAG) and their complement are conserved between tenuiviruses and viruses of the genus *Phlebovirus* of the family *Bunyaviridae*. Several RNA segments encode two proteins in an ambisense arrangement (**Figure 2**). The RdRp and NC protein (32 Kda) are encoded by the viral complementary (vc)RNA1 and vcRNA3, respectively. The p3 (24 Kda) encoded by the viral (v)RNA3 is a suppressor of RNA silencing as demonstrated for RHBV in both plant and insect hosts. A major nonstructural protein (p4; 22 Kda) that accumulates in infected plants

is encoded by vRNA4. The sizes of other RSV proteins shown in **Figure 2** are 23 kDa (p2), 94 kDa (pC2), 24 kDa (p3), and 32 kDa (pC4).

For MSpV, RHBV, and RSV, the mRNAs are synthesized via cap-snatching (**Figure 3**). The 5′ end of the mRNAs contains 10–17 nonviral nucleotides and are capped, these extra sequences are derived from host cell mRNAs that are taken or snatched by the RdRp and used as primers to initiate mRNA synthesis. Intergenic noncoding regions located between the open reading frames (ORFs) can in certain cases adopt hairpin structures. The cap-snatching mechanism has been observed for mRNA synthesis of influenza viruses and viruses of the families *Bunyaviridae* and *Arenaviridae*.

Antigenic Properties

The NC proteins of RSV and MSpV are serologically related, as are the NC and p4 proteins of RSV and RGSV. Likewise, the NC proteins of RHBV, EHBV, and UHBV are serologically related. The NC protein of RSV reacts weakly with antibodies made to virion preparations of RGSV or RHBV.

Biological Properties

Host Range

Plant hosts of tenuiviruses all belong to the family Poaceae.

Cytopathology

In infected plants large inclusion bodies (**Figure 1(b)**) are observed which contain the major nonstructural protein p4.

Symptoms

Infected plants exhibit chlorotic stripes and yellow stippling on the leaf blade. Rice plants infected with RHBV at an early stage of development are stunted and may develop necrosis.

Insect Vector and Kind of Transmission

Each virus species is transmitted by a particular species of planthopper in a circulative, propagative manner and can be transmitted transovarially by viruliferous female planthoppers to their offspring, and through sperm from viruliferous males. The principal vectors of the species are *Laodelphax striatellus* for RSV, *Tagosodes cubanus* for EHBV, *Peregrinus maidis* for MSpV, *Nilaparvata lugens* for RGSV, *Tagosodes orizicolus* for RHBV, and *Caenodelphax teapae* for UHBV. Known vectors of the tentative species are *Sogatella kolophon* for BWSpV, *Javesella pellucida* for EWSMV, and *Ukanoes tanasijevici* for IWSV.

Criteria for Species Demarcation and Phylogenetic Relationships between Species in the Genus

The criteria for species demarcation are given as follows:

1. Vector specificity: transmission by different species of vector.
2. Different sizes and/or numbers of RNA segments.
3. Host range: abilities to infect different key plant species.
4. Amino acid (aa) sequence identity of less than 85% between corresponding gene products.
5. Nucleotide sequence identity of less than 60% between corresponding noncoding intergenic regions.

An example of species discrimination is that between RSV and MSpV. RSV is transmitted by *L. striatellus* and infects 37 graminaceous species including rice and wheat. MSpV is transmitted by *P. maidis* and infects maize, occasionally sorghum, and a few other graminaceous plants but not rice or wheat. RSV isolates have genomes of four RNA segments and the MSpV genome consists of five segments.

An example of difficult species demarcation is the group of the hoja blanca viruses (RHBV, EHBV, and UHBV). They have different vectors, different sizes, and numbers of RNA segments, different hosts, and the nucleotide sequence identity of their intergenic regions is less than 60%. However, the aa sequences of the four proteins on RNAs 3 and 4 are about 90% identical between RHBV, EHBV, and UHBV. Since four of five criteria are met, these viruses could be considered as distinct species that possibly separated recently and are now diverging with little field contact between them.

Phylogenetic analysis of the sequence data from RNA3 and RNA4 of the tenuiviruses shows that RHBV, EHBV, and UHBV are related and form a group distinct from RSV and MSpV (**Figure 4**).

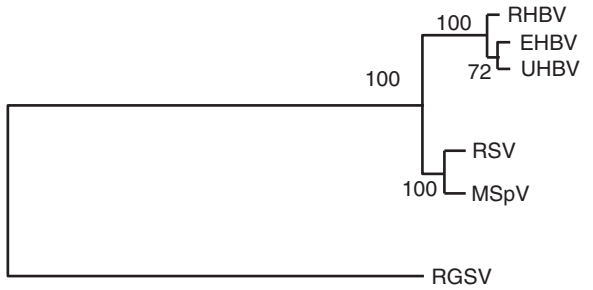

Figure 4 Phylogenetic tree showing the relationships between tenuiviruses on the basis of the nucleotide sequences of the ORFs on RNAs 3 and 4 (RNAs 5 and 6 for RGSV). Shown is the percentage bootstrap support at each node. RHBV, *Rice hoja blanca virus;* EHBV, *Echinochloa hoja blanca virus*; UHBV, *Urochloa hoja blanca virus*; RSV, *Rice stripe virus*; MSpV, *Maize stripe virus*; RGSV, *Rice grassy stunt virus*.

Relation to Other Taxa

Viruses of the genus *Tenuivirus* share several properties with those of the genus *Phlebovirus* of the family *Bunyaviridae*. The multisegmented genomes of tenui- and phleboviruses contain negative-sense and ambisense components. The 5′ and 3′ terminal complementary sequences of viruses of either genus can base-pair and could give rise to circular RNPs. The terminal 8 nt (5′ ACACAAAG) and their complement are conserved between tenui- and phleboviruses. Synthesis of mRNA by the viral RdRp follows a cap-snatching mechanism for viruses of the two genera. Tenuiviruses and most genera in the family *Bunyaviridae* infect their insect vectors as well as their plant hosts. The different number of genome components and the apparent lack of an enveloped viral particle distinguish tenuiviruses from viruses in the family *Bunyaviridae*.

Tetraviruses

J A Speir and J E Johnson, The Scripps Research Institute, La Jolla, CA, USA

© 2008 Elsevier Ltd. All rights reserved.

Introduction

The *Tetraviridae* are a family of viruses with nonenveloped $T=4$ particles that package single-stranded, positive-sense RNA genomes and infect only a single order of insects, the Lepidoptera (moths and butterflies). This family stands out from the rest of the known viruses based on these properties alone. It is the only RNA virus family with a host range restricted to insects and the only family with nonenveloped icosahedral $T=4$ particles. The unusual symmetry of their capsids has become the basis for their family name (from the Greek *tettares*, four).

The first report of a larvae disease later to be attributed to a tetravirus was from South Africa in 1941. Researchers Tooke and Hubbard described a devastating annual mortality of the emperor pine moth, *Nudaurelia cytherea capensis*, such that the dead larvae formed a carpet beneath the pine trees (*Pinus radiata*). The outbreaks have now

reduced the larvae population on the pine plantations to a great extent. Five different viruses were found in the infected larvae that were named nudaurelia α, β, γ, δ, and ε, with β being the most abundant. The nudaurelia β virus (NβV) was extensively studied and became the type member of a new virus group called the nudaurelia β-like viruses (betatetraviruses) that was officially recognized in 1982. These studies showed NβV had a monopartite genome and the first known $T=4$ icosahedral capsid. The most recently characterized betatetravirus is from the USA, named Providence virus, which was discovered by Pringle, Ball, and colleagues in 2003. Importantly, this is the first tetravirus that replicates in cell culture, greatly aiding the study of tetravirus molecular biology (see below).

While the betatetraviruses were the first tetraviruses discovered and form the majority of the family, Hendry and colleagues isolated another virus from *Nudaurelia* larvae in 1985, the nudaurelia ω virus (NωV), which was physically similar to NβV but encapsidated a second genomic RNA. NωV became the type member for a second genus within the *Tetraviridae*, the ω-like genus (omegatetraviruses). A second omegatetravirus was isolated by Hanzlik and colleagues in 1993 from Australia, the helicoverpa armigera stunt virus (HaSV), and a third was discovered in 2005 by Yi and colleagues from the Yunnan Province of China, the dendrolimus punctatus tetravirus (DpTV). Both HaSV and DpTV are closely similar to NωV (see below). Currently, the family consists of three omegatetraviruses, and nine betatetraviruses, as well as eight other possible members (**Table 1**). The tetravirus family has grown little in recent years, with only a few new members identified in the last decade. This is due to their limited host range, the difficult field collections of the insect hosts due to the locations where they thrive, and the difficulty or impossibility of rearing the host insects in the laboratory. Also, several aspects of their life cycle remain poorly characterized due to their inability to grow in cell culture despite extensive efforts covering a wide variety of cell types. In spite of these drawbacks, studies of the tetraviruses have expanded to a great extent. It is possible to raise HaSV from laboratory-grown insects, Providence virus is the first tetravirus found to replicate in cell culture, and virus-like particles (VLPs) can be produced in a baculovirus expression system for NωV, HaSV, and TaV. These systems have allowed for advances in detailed biophysical descriptions of these capsids, including a crystal structure of NωV, and new data on replication, pathology, and the biotechnological potential of this unique virus family.

Table 1 Members of the *Tetraviridae*

Virus	*Acronym*	*Family of Lepidoptera host*	*Geographic location*
Betatetraviruses			
Nudaurelia capensis β virus[a]	NβV	Saturniidae	South Africa
Antheraea eucalypti virus[b]	AeV	Saturniidae	Australia
Dama trima virus	DtV	Limacodidae	Malaysia
Dasychira pudibunda virus[c]	DpV	Lymantriidae	UK
Philosamia cynthia X ricini virus	PxV	Saturniidae	UK
Providence virus	PrV	Noctuidae	USA
Pseudoplusia includens virus	PiV	Noctuidae	USA
Thosea asigna virus[d]	TaV	Limacodidae	Malaysia
Trichoplusia ni virus	TnV	Noctuidae	USA
Omegatetraviruses			
Nudaurelia capensis ω virus[a]	NwV	Saturniidae	South Africa
Dendrolimus punctatus tetravirus	DpTV	Lasiocampidae	China
Helicoverpa armigera stunt virus	HaSV	Noctuidae	Australia
Unassigned possible members[e]			
Acherontia atropas virus	AaV	Sphingidae	Canary Islands
Agraulis vanillae virus	AvV	Nymphalidae	Argentina
Callimorpha quadripuntata virus	CqV	Arctiidae	UK
Eucocytis meeki virus	EmV	Cocytiidae	Papua New Ginea
Euploea corea virus	EcV	Danadidae	Australia/Germany
Hypocritae jacobeae virus	HjV	Arctiidae	UK
Lymantria ninayi virus	LnV	Lymantriidae	Papua New Ginea
Nudaurelia ε virus[f]	NεV	Saturniidae	South Africa

Genome Organization, Replication, and Capsid Assembly

General Characteristics of Tetravirus Genomic RNAs

The main characteristic separating the betatetraviruses and omegatetraviruses is the RNA encapsidated by the particles in each genus. All tetraviruses analyzed for RNA content share the presence of a large genomic RNA strand of about 5.3–6.5 kbp in length and a smaller genomic or subgenomic RNA strand of about 2.5 kbp. In the monopartite β-like viruses, both the replicase and capsid protein genes are on the large genomic RNA strand (~6.5 kbp). In the bipartite ω-like viruses, the replicase and capsid protein genes are split between the large (~5.3 kbp) and small (~2.5 kbp) genomic RNA strands, respectively.

Although the betatetraviruses are monopartite, the capsids often package two RNA species. A subgenomic mRNA of 2.5 kbp coding for the capsid protein is also encapsidated with the genomic RNA strand in NβV, PrV, TaV, and TnV. Thus, virus particles from both genera package two RNA molecules totaling ~7.8–9.0 kbp. Experimental evidence also suggests that the ω-like viruses package both genomic RNAs in a single particle, as is the case for the nodaviruses, the only other small spherical RNA animal viruses with a bipartite genome. This contrasts with plant viruses having multipartite genomes, which package single genomic RNA strands in different particles.

Analysis of the HaSV genomic RNAs revealed 5′ cap structures and distinctive tRNA-like structures at the 3′ termini, which are not polyadenylated. A tRNA-like structure also exists at the 3′ terminal of the NβV RNA, and no β-like virus genome has been found to be polyadenylated. However, both the HaSV and NβV RNAs could be polyadenylated, indicating no terminal blockage. Therefore, all tetravirus genomic RNAs are likely to have unblocked, tRNA-like 3′ termini and 5′ caps, although the existence of the cap has not been experimentally tested with any β-like virus.

β-Like Genome Organization and Replication Model

The complete nucleotide sequence of the NβV genome (6625 nt) was elucidated in 1998, and partial cDNA clones of the TaV and PrV genomes have been analyzed more recently (2001 and 2003, respectively). All three show nearly identical organization. The single genomic RNAs are dicistronic and have overlapping open reading frames (ORFs) (**Figure 1**). The 5′ ends encode the replicase and the 3′ ends encode the capsid protein genes, which have extensive overlap with the replicase. The NβV replicase ORF contains 5778 nt encoding 1925 amino acids with a calculated molecular weight of 215 kDa. It contains the three domains characteristic of viruses in the α-like RNA virus superfamily (the N-terminal methyltransferase domain, the nucleotide-binding or helicase domain, and the RNA-dependent RNA polymerase (RdRp) domain), but lacks the motifs for the papainlike protease and proline-rich hinge domains that are implicated in autoprocessing of the replicase proteins of some +RNA viruses of vertebrates. Finally, the genomic RNA appears to be the mRNA for the replicase, since its initiation codon is the first located at the 5′ end of the genomic RNA. Translation studies of other β-like virus genomic RNAs have also produced large polypeptides, supporting this scenario.

The sequence of the putative TaV replicase shows a novel permutation among RNA viruses, and together with birnaviruses and an unassigned possible tetravirus (Euprosterna elaeasa virus) defines a unique, ancient lineage of RdRp's. None of the other sequenced tetravirus replicases have a permutation. The TaV replicase lacks both the methyltransferase and helicase domains and the RdRp has little homology with other RNA virus replicases, which as a group have a universal sequence conservation. In 2002, Gorbalenya and colleagues discovered that the catalytic palm subdomain of the TaV RdRp had permuted the conserved 'A–B–C' motif to 'C–A–B' by moving the C motif, which has two Asp residues critical for activity, 110 residues upstream in the sequence. Strikingly, structural modeling demonstrated that this permutation can be accommodated in the conserved RdRp structures by simply rearranging the connectivity of three loops, all of which are positioned away from the active site. Thus, the TaV RdRp is likely to have a conserved fold but with unique connectivity, which might be a major event in the evolution of polymerases.

The 3′ proximal ORF of NβV has 1836 nt and encodes the 66 kDa capsid protein precursor (named α). The capsid protein ORF overlaps the replicase ORF by more than 99% and is in the +1 reading frame relative to the replicase. The capsid protein gene is apparently translated through the production of the previously mentioned 2.5 kbp subgenomic RNA (**Figure 1**), yet replication experiments designed to detect double-stranded RNA (dsRNA) intermediates do not show evidence for a separate complex for the β-like subgenomic RNA indicating that both genomic and subgenomic RNAs are produced from a single full length (−)RNA template. One copy of the genomic (+)RNA, one copy of the subgenomic (+)RNA, and 240 copies of the expressed capsid protein precursor assemble to form an ~400 Å diameter icosahedral $T = 4$ virion (**Figure 2**). The capsid protein is labeled a precursor at this stage because each copy executes an autocatalytic cleavage to produce a large protein (β, ~60 kDa) and a small protein (γ, ~6 kDa), but only after the capsid is assembled (**Table 2**). Both the β and γ polypeptides remain part of the virion after cleavage.

The capsid protein precursors in TaV and PrV may be significantly larger than that of NβV. An additional codon

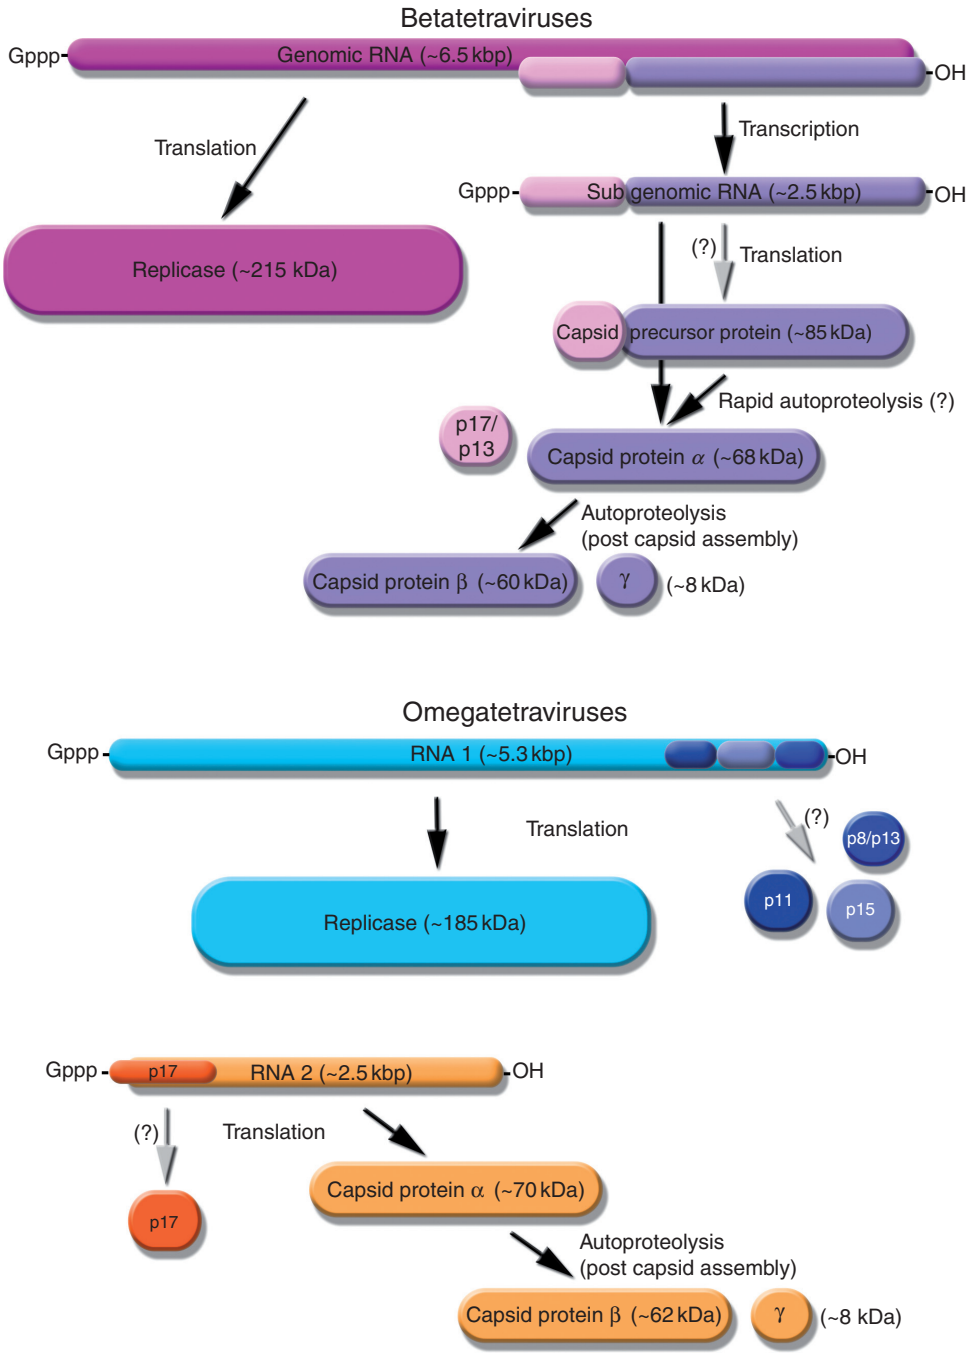

Figure 1 Genome organization and replication strategy of the tetraviruses. Each diagram represents the consensus of available data, but some group members may have slightly different organizations and steps from those shown. The individual events and gene products are discussed in the text. The gray arrows with question marks represent little, if any, translation of those gene products or an unverified event. While autocatalytic processing of the 68–70 kDa capsid protein is nearly identical, significant differences exist between the two groups in their pathways and their potential products. The β-like group utilizes a subgenomic RNA for translation of the capsid precursor protein, which may have two autoproteolytic processing events. The ω-like group has additional ORFs that overlap the end of the replicase gene with unknown functions. Both groups encode 13–17 kDa proteins on the small RNAs in addition to the capsid protein, but it is an additional ORF that would be translated as part of a polyprotein in the β-like group and an overlapping ORF that would be translated separately in the ω-like group.

exists upstream from the known N-terminus of the capsid proteins found in the TaV and PrV virions, yet the extra codon is transcribed to their subgenomic RNAs (**Figure 1**). The additional codons would add approximately 17 and 13 kDa to the TaV and PrV capsid protein precursors, respectively. Since the assembled capsids do not have a protein of this size, these precursors possibly undergo two post-assembly, autocatalytic cleavages, with the

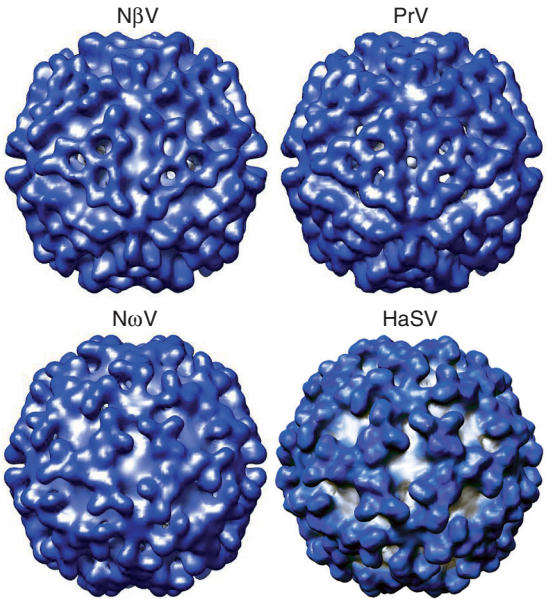

Figure 2 Cryoelectron microscopy reconstructions of the icosahedral tetravirus virions. All four structures are at ~25–30 Å resolution and are viewed down their icosahedral twofold axes. The capsids are ~400 Å in diameter and have $T = 4$ quasi-icosahedral symmetry. The capsid morphologies within each group are closely similar (β-like at top, ω-like at bottom), but differ between the groups. Most notably, within the triangular facets, the β-like viruses have a pitted surface where the ω-like surface is filled in. TaV also displays the same pitted surface in negative-stain EM photographs. The recent crystal structure determination of PrV showed this is mainly due to different rotations of the Ig-like domains relative to the β-barrels when compared to the subunits in the NωV crystal structure (see **Figure 3**). This supports the suggested role of the Ig-like domain in determining the restrictive host cell specificity of these viruses by displaying distinctly different surfaces to cellular receptors.

additional N-terminal cleavage producing polypeptides corresponding to the extra codons (p17, p13). Evidence for this came from expressing the entire capsid protein precursor of TaV in a recombinant baculovirus system as a single polypeptide (p17 + α). TaV VLPs were produced and contained only polypeptides of 58 and 7 kDa, suggesting that the additional 17 kDa had been previously removed by auto-proteolysis. However, it has not yet been shown that the extra codons are translated *in vivo* as part of the capsid protein precursor, and neither p17 nor p13 has been found in assembled particles (authentic or VLPs) of either virus.

ω-Like Genome Organization and Replication Model

The complete sequences of both RNA1 and RNA2 from HaSV and DpTV were determined in 1995 and 2005, respectively, and the complete RNA2 sequence from NωV was initially determined in 1992 and amended in 2005. Partial data for the RNA1 sequence of NωV are also available (**Table 2**). Like the β-like group, the RNAs of the ω-like group have near-identical organization. The length of RNA1 is 5312 nt in HaSV and 5492 in DpTV. Both RNAs contain a single large ORF covering over 90% of their total length, and three smaller ORFs located within the 3′ portion of the large ORF (**Figure 1**). While the three smaller ORFs are in the same reading frame, they are out of frame with the large ORF.

The large ORFs encode the viral replicases with calculated molecular weights of 187 and 180 kDa for HaSV and DpTV, respectively. Like the replicases of the β-like viruses, they also contain the N-terminal methyltransferase domain, the nucleotide-binding or helicase domain, and the RdRp domain, but lack the motifs for the papain-like protease and proline-rich hinge domains. The domains share from 63% to 76% identity between the HaSV and DpTV replicases, and about 36% identity with the same domains from the β-like replicases. The HaSV and NωV replicases are more closely related, sharing close to 90% identity. RNA1 self-replication has been detected before RNA2 replication has been observed, and protein expressed from HaSV RNA1 in a baculovirus system is able to replicate RNA2 transcripts at very low levels.

The three small ORFs encode proteins of 11, 15, and 8 kDa in HaSV and 11, 15, and 13 kDa in DpTV. In both genomes, the stop codon for p11 is located immediately to the 5′ side of the p15 ORF, allowing these two ORFs to form a single 26 kDa protein if the stop codon was suppressed. Expression of these proteins would almost certainly require a subgenomic RNA due to the long 5′ leading sequence; however, the existence of this RNA has not been confirmed. The amino acid sequences of all three ORFs show no discernible relationship to other proteins; therefore, no putative functions can be assigned.

The RNA2 lengths in NωV, HaSV, and DpTV are 2445, 2478, and 2490 nt, respectively. Each has a long (~280 nt) 5′ lead sequence followed by two overlapping genes starting at the first two AUG codons. The first ORF encodes a 17 kDa protein (p17) and overlaps the larger second ORF that encodes the 70–71 kDa capsid protein precursor (**Figure 1**). The initiation codon for p17 is in a poor context, suggesting that it will be translated inefficiently by scanning ribosomes. However, *in vitro* translation studies of both NωV and HaSV RNA2's revealed both gene products were produced. The function of p17, if any, remains unclear, but preliminary experimental observations have supported a regulatory role in genomic RNA replication, and/or a function analogous to that of the movement proteins of plant viruses.

The close relationship between the ω-like viruses is seen in their capsid protein precursors (α). The amino acid lengths of the precursors are 644, 647, and 643 for NωV, HaSV, and DpTV, respectively, and they share

between 66% and 86% sequence identity (**Table 3**). One copy of the genomic (+)RNA1, one copy of the genomic (+)RNA2, and 240 copies of the expressed capsid protein precursor assemble to form an ~400 Å diameter icosahedral $T = 4$ virion (**Figure 2**). As in the β-like viruses, each copy of α undergoes an autocatalytic cleavage to produce a large protein (β, ~62–63 kDa) and a small protein (γ, ~7–8 kDa) after the capsid is assembled (**Table 2**), and both the β and γ polypeptides remain part of the virion after cleavage. Both genomic RNAs are likely to be replicated from separate (−)RNA templates based on larvae infected with NωV having separate dsRNAs corresponding to each of the genomic RNAs. RNAs 1 and 2 represent the complete genomic information required for virus growth based on studies of HaSV assembly and replication in plant and insect cells.

Providence Virus Replication in a Fat Body Cell Line

PrV is currently the only tetravirus shown to replicate in cell culture. The virus was discovered in 2003 as a persistent infection of a midgut cell line (MG8) derived from the corn earworm (*Helicoverpa zea*). In addition to the *H. zea* midgut, PrV was also shown to infect the *H. zea* fat body cell line (FB33) at low doses. A time course study of the PrV infection cycle was conducted using the FB33 cells. Input virus genomic and subgenomic (+)RNA is detected inside the cells at 6 h post infection (h.p.i.). Viral RNA synthesis is first detected at 18 h.p.i. and significantly increases between 18 and 24 h.p.i. At 36 h.p.i., total viral RNA accumulation reaches its maximum level, and (−)RNA also reaches its peak level, which is about 10-fold lower than that of corresponding (+)RNA.

The PrV β capsid protein (~60 kDa) appears at 6 h.p.i. along with the genomic and subgenomic RNAs. The β protein begins increasing in copy number after about 24 h.p.i., and after 36 h the uncleaved capsid protein precursor (α) also accumulates, slightly lagging behind the appearance of the subgenomic RNA that is thought to drive its translation. Although the α protein accumulated in infected cells, it is not detected in purified virions. In contrast, p13 translation was not detected during the time course experiment and it is not found in purified virions. However, proteolytic processing and degradation of this precursor could be extremely rapid as observed with the baculovirus-expressed TaV precursor.

To determine if assembled virions could be seen in infected cells, both MG8 and FB33 cells infected with PrV for 3 days were sectioned and examined by TEM. Both cell lines contained virus particles that were ~400 Å in diameter. The particles were seen only in the cytoplasm and often associated with one or more unidentified cytoplasmic vesicles that appear to be induced by the infection. In a few percent of the FB33 cells with very high virus accumulation, large crystalline particle arrays appeared within the cytoplamic structures.

Capsid Assembly

PrV particles are seen only in the cytoplasm of sectioned fat body cells at all time points measured; thus, it is highly probable they assemble in the cytoplasm and the cytoplasmic structures produced by the infection may aid in the process. In lieu of cell culture systems, assembly of VLPs has been achieved using the capsid proteins from NωV, HaSV, and TaV (the only β-like virus for which successful VLP production has been reported). The VLPs will assemble upon expression of only the capsid protein precursor in heterologous expression systems, namely yeast, plant protoplasts, and baculoviruses. Considerable yields of VLPs can be purified from the baculovirus expression systems and this has enabled a number of biophysical and biochemical studies of tetravirus capsids, particularly those of NωV and HaSV (see below). Like native virions, the VLP capsid protein subunits undergo autocatalytic cleavage from α to β and γ peptides, can specifically package viral RNA, and can bind specifically to a larval midgut cell receptor.

Capsid Structure and Dynamics

High-Resolution Capsid Structure

Both X-ray crystallography and cryoelectron microscopy image reconstruction (cryoEM) have been used to examine the different structural states of tetravirus capsids. The crystal structure of authentic NωV was determined in 1996 to 2.8 Å resolution, and is currently the only tetravirus crystal structure that has been published. Recently, the authors' laboratory has also determined the crystal structure of purified HaSV VLPs, and found it closely similar to that of NωV. The NωV crystal structure showed that the capsid is icosahedral, 420 Å in diameter, and composed of 240 capsid proteins arranged with $T = 4$ quasi-symmetry. Thus, the 60 icosahedral asymmetric units each have four subunits, named A–D, in unique chemical environments (**Figure 3**(**a**)). The 644 amino acid capsid subunit has three domains: an exterior immunoglobulin (Ig)-like fold, a central β-barrel in tangential orientation, and an interior helix bundle (**Figure 3**(**b**)). The helix bundle is created by the N- and C-termini of the polypeptide before and after the β-barrel fold, and the Ig-like domain is an insert between the E and F β-strands of the barrel. The exterior Ig domain is unique in nonenveloped viruses and is expected to be involved in cell binding and virus tropism, and has the least conserved sequence among tetravirus subunits. The interior helix domain is anticipated to interact with the RNA genome and may have a role in capsid polymorphism (see below). All 240 of the NωV capsid subunits have undergone autoproteolysis between residues N570 and F571 after assembly, leaving the cleaved portion of the C-terminus, called the γ peptide, associated with the capsid. The quasi-symmetry is controlled by a molecular switch (**Figures 3**(**a**) and **3**(**b**)). In NωV, a segment of the γ peptide (residues 608–641) is only ordered in the C and D subunits, and functions as a wedge between the ABC and DDD morphological units to prevent curvature and create a flat contact. The interface between two ABC units is bent partly due to the lack of ordered γ peptide. Importantly, the subunit structure and auto-proteolysis revealed a strong relationship between tetraviruses and the $T = 3$ insect nodaviruses. Indeed, the β-barrel folds and autocatalytic sites superimpose with little variation, and the γ peptide in the nodaviruses is also involved in quasi-equivalent switches.

The crystal structure of PrV, the first high-resolution structure of a β-like virus, was recently determined in the authors' laboratory (data not shown). The PrV subunit retains the three domains and a superimposable autoproteolysis site (all four subunits show a clear break at the cleavage site), but the Ig domain and the first and last ordered residues of the termini in the helical domain have different positions and structure compared to NωV. The different Ig domain position was first observed in the cryoelectron microscopy reconstruction of NβV as a distinctly different surface structure compared to the ω-like particle surfaces (**Figure 2**). The use of subunit termini in PrV is more like that seen in the nodaviruses. The quasi-symmetry switch in PrV has swapped elements compared to the omegatetraviruses, and represents a new and unique mixture of structural features among the insect viruses.

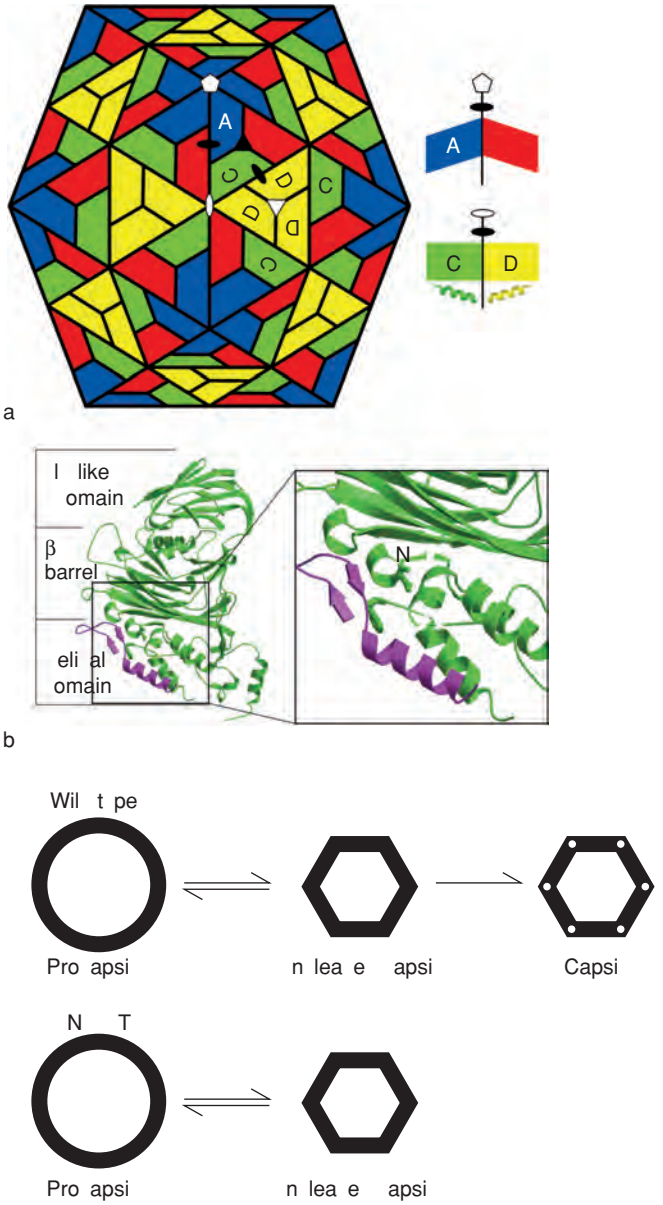

Figure 3 Structure and dynamics of the NωV capsid. (a) The subunit organization in the NωV $T = 4$ capsid crystal structure. There are four subunits in the asymmetric unit (A in blue, B in red, C in green, and D in yellow). Icosahedral symmetry axes are marked with white symbols, quasi-symmetry axes are marked with black symbols. Quasi-twofold dimer interfaces occur with the bent A–B or flat C–D conformations (right). The well-ordered C-terminal helices in the C–D subunits comprise a molecular switch that stabilizes the flat interface. (b) Ribbon diagram of the C subunit illustrates the three domain tertiary structure present in all 240 subunits (exterior of capsid on top, interior on bottom). Maturation cleavage occurs within the helical domain between residues Asn570 and Phe571. The molecular switch, present only in the C or D subunits, is highlighted in magenta. (c) In the wild-type virus, the procapsid converts to uncleaved capsid with the drop of pH, followed by a maturation cleavage, which locks the particle in capsid conformation after ~10% of the subunits are cleaved. In the cleavage-defective mutant (N570T), particle conformational change becomes reversible.

Capsid Maturation, Auto-Proteolysis, and Large-Scale Transitions

NωV and HaSV coat proteins expressed in the baculovirus system assemble into round and porous intermediate VLPs that are 480–490 Å in diameter, called procapsids, when purified at neutral pH (pH 7.6). The procapsid coat proteins remain in the uncleaved α precursor form until a reduction in pH. When exposed to acidic conditions (pH 5.0), procapsids underwent a large-scale structural rearrangement (maturation) to the

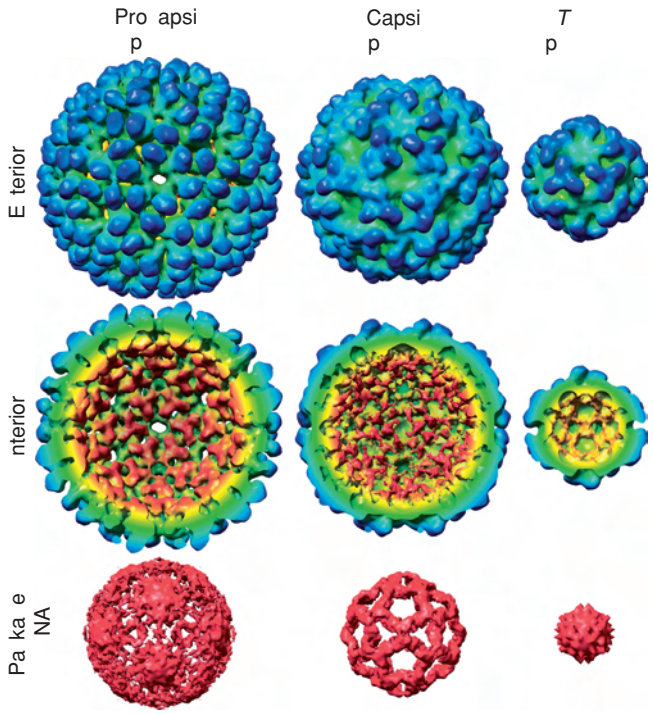

Figure 4 CryoEM reconstructions between 23 and 27 Å resolution of three HaSV polymorphic capsid forms. The polymorphic form and its associated pH are given at the top. Three views of each form are shown with radial coloring from red on the interior to blue on the exterior. The procapsid and capsid diameters are similar to those of NωV (490 and 430 Å, respectively). Note the well-ordered dodecahedral RNA structure in the mature capsid, which has been observed in several insect viruses. The $T = 1$ form has so far been found only in HaSV purifications as an extra peak in the sucrose gradients, and only appears after the acid maturation step (i.e., not found at pH 7.6). The diameter of the $T = 1$ particles is 260Å and the protein shell is composed only of a truncated version of the β subunits (55 kDa).

smaller, angular mature capsid, where α begins to cleave into the β and γ polypeptides (**Figures 3(c)** and **4**). Small-angle X-ray scattering (SAXS) demonstrated that the pH-induced conformational change occurs in less than 100 ms in NωV, while the autocatalytic cleavage event had a half-life of hours. The relationship of the conformational change and cleavage was also examined using SAXS, which suggested that the conformational change was initially reversible until approximately 10% of the subunits had cleaved, and then the particles were 'locked' in the capsid conformation (**Figure 3(c)**). Finer pH titrations of NωV revealed intermediate capsid states at pH 5.8 and 5.5 (data not shown). Presumably similar intermediates also exist for HaSV.

Both ANS (1-anilino-8-naphthalene sulfonate) and the thiol-reactive fluorophore, maleimide-ANS (MIANS), have been bound to procapsids to further characterize the conformational transition to capsid. Absorption of the covalently attached MIANS (forms covalent thiol-ether linkage with cysteines) situated at subunit interfaces can report on environment changes as it is buried during maturation. Unexpectedly, acidification of the labeled particles trapped them at an intermediate stage of maturation and the autocatalytic cleavage was inhibited. The labeled VLPs showed no cleavage after 4 h of incubation at pH 5.0 buffer while wild-type particles were fully cleaved. A cryoEM image reconstruction of the MIANS-labeled VLPs at pH 5.0 revealed the particles are 440 Å in diameter, having only progressed about halfway along the trajectory between procapsid and capsid. This demonstrates that cleavage depends on the conformational change and is not triggered by just lowering the pH, and provides support for the strategy of targeting subunit interfaces with antiviral compounds as a means of disrupting the viral life cycle.

Cleave Site Mutation Allows Reversible Transition and Procapsid Structure Analysis

Mutagenesis studies have shown the asparagine at the scissile bond (N570) in NωV is required for cleavage. Substituting threonine for asparagine (N570T) results in assembly of less stable particles, but they do not cleave and continue to undergo the conformational change reversibly as a function of pH (**Figure 3(c)**). CryoEM structures at 8 Å resolution of cleaved and N570T VLPs showed the role of cleavage in stabilizing the capsid form. There are more extensive inter-subunit contacts between the C-termini and the neighboring N-termini in cleaved

particles that results in more ordered C-terminal helices, which accounts for the added stability.

The N570T mutant was also used to study the structure of the uncleaved procapsid state. An 11 Å resolution cryoEM structure of N570T procapsids displays a morphology indistinguishable from procapsids formed by wild-type subunits. The higher resolution showed, at pH 7.6, that portions of the C-terminal regions of the γ polypeptides of the A and B subunits, which are not ordered in the capsid form, are ordered and contribute to a second molecular 'wedge' that prevents hinging between the A and B subunits. It makes the quasi-twofold interactions at the A–B and C–D interfaces closely similar in the procapsid, producing its round morphology and consistent with its role as an assembly intermediate during NωV particle maturation.

Pathobiology

Host Range

Lepidopteran insects are the only known hosts for tetraviruses. No replication in other animals has been detected. The hosts are confined largely to the Noctuidae, Saturniidae, and Limacodidae families within the Lepidoptera order. The range of species that they are able to infect differs between the viruses. HaSV appears unable to infect species outside the Heliothinae subfamily, while TnV and DpV are able to infect insects outside the family of their nominal host.

Transmission and Symptoms

Horizontal transmission via ingestion by larvae has been demonstrated for several tetraviruses with a widely varying range of symptoms. Only slight growth retardation is observed using high doses of TnV, but NβV infection of larvae is lethal, causing cessation of feeding, and moribund, discolored, and flaccid appearance at 7–9 days post infection. A dependence upon the larval life stage has also been seen. HaSV is highly active against neonate larvae in the first three instars of development, needing as little as 5000 particles to cause them to stunt and cease feeding within 24 h and to die within 4 days. In contrast, no detectable symptoms occur in later larval development, signifying a high degree of developmental resistance. It has not been demonstrated whether adults or pupae are capable of being infected by tetraviruses. Vertical transmission of tetraviruses is also believed to occur, but the evidence remains undefinitive.

Histopathology and Tropism

Natural infection by tetraviruses appears to be exclusively in the larval midgut, although PrV has been cultured in fat body cells. In a definitive experiment, Northern blots of RNA extracted from HaSV-infected larvae showed viral RNA only in the midgut tissue, even after virus was injected into the hemocoel.

In a quantitative study of HaSV infection of its host, the African or cotton bollworm, supplying the virus to larvae *per os* during the first three instars of development resulted in an infection restricted to three of the four midgut cell types. The virus initiated infection in closely situated foci that expanded and converged with others over time. In response, the midgut cells increased their rate of sloughing and apoptosis to an extent that incapacitated the midgut due to loss of all but a few cells. Infection of older larvae results in only sparsely situated foci, which fail to expand and eventually disappear presumably due to cell sloughing. These data indicate that cell sloughing is an immune response existing throughout development, but older larvae have an additional mechanism for increased resistance to infection.

Biotechnology

Application as Biopesticides

Small RNA viruses offer attractive properties as biological control agents for pests: high specificity, high efficacy, and potentially self-replicating. A notable drawback is the difficulty in producing large quantities of infectious virions, but the simplicity of the tetraviral genomes makes production of virions in nonhost cells feasible. Agrobacterium-mediated transgenesis has been used to place the genes required for HaSV assembly into tobacco plants, which resulted in stunted, HaSV-infected larvae when they fed on the modified plants. Expanding on this result, Hanzlik and colleagues conducted the first field trial of HaSV as a control agent in 2005 on a sorghum crop in Queensland, Australia. The semipurified HaSV preparation reduced the larval population by 50% at both 3 and 6 days post application (dpa), which was equivalent to a commercial baculovirus preparation. Notably, the amount of HaSV on the sorghum heads increased at 5.5 dpa, probably reflecting dispersal of newly produced virus from cadavers and frass. These results indicate that HaSV could be used effectively as a biopesticide.

Application as Chemical Platforms

A study in 2006 demonstrated that the Ig domains of NωV particles could be modified to possibly alter its tropism and/or to carry specific chemical tags. A $(His)_6$ tag was inserted into the GH loop (between A378 and G379) of a capsid precursor construct that was then expressed in a baculovirus system. The His-tagged p70 self-assembled into VLPs that had similar morphological and RNA encapsidation properties as wild-type VLPs. Two assays

using paramagnetic nickel beads confirmed that multiple affinity tags were present on the surface of the modified VLPs and could bind the beads. Thus, the GH loop of NωV appears to be a suitable modification site for further biotechnology applications.

Glossary

Cardiovirus Genus in the family *Picornaviridae*.
Demyelination Pathological process of damage to the proteolipid coat around nerve fibers (axons).
L* Virus-encoded protein that is translated in alternative reading frame to that of the polyprotein.
Theilovirus Species within the genus *Cardiovirus*.
Theiler's murine encephalomyelitis viruses (TMEVs) Abbreviation for mouse Theiler's viruses.

History, Geographic Distribution, and Host Range

The mouse encephalomyelitis viruses are enteric pathogens of mice. Discovered by Max Theiler in the early 1930s and originally called murine polioviruses, these agents are commonly referred to as Theiler's murine encephalomyelitis viruses (TMEVs). Theiler initially recovered isolates from mice with spontaneous paralysis housed at the time in the animal colony at the Rockefeller Institute; subsequently, TMEVs were found in virtually all nonbarrier mouse colonies, where they caused asymptomatic intestinal infections. While TMEVs are widely distributed in the world, their host range is narrow, including mice and rats. Serological evidence indicates that *Mus musculus*, the feral house mouse, is the natural host, but several other species of voles and possibly rats may also serve as hosts. As is the case for other picornaviruses, following peripheral routes of infection, TMEV spreads to the central nervous system (CNS) producing encephalitis or poliomyelitis (spontaneous paralysis). In the older literature, the incidence of spontaneous paralysis was reported to be approximately one paralyzed animal per 1000–5000 colony-bred mice. Since TMEVs may go undetected unless appropriate serological tests are performed, these agents are a potential hazard for investigators using mice in biomedical research.

In recent years, this group of viruses has assumed additional importance, because TMEV infection in mice provides one of the few available experimental animal models for multiple sclerosis. TMEV-induced demyelinating

disease in mice is a relevant model for multiple sclerosis because: (1) chronic pathological involvement is virtually limited to the CNS white matter; (2) myelin breakdown is accompanied by mononuclear cell inflammation; (3) demyelination results in clinical disease, for example, spasticity, from involvement of upper motor neuron pathways; (4) myelin breakdown is in part immune-mediated; and (5) the disease is under multigenic control with a strong linkage to the major histocompatibility complex (MHC) gene H2D.

Classification and Serologic Relationships

Based on the complete nucleotide sequence and genome organization, TMEVs have been classified in the genus *Cardiovirus* of the family *Picornaviridae* along with encephalomyocarditis virus (EMCV). EMCV and TMEV (or Theilovirus) constitute separate species within the genus *Cardiovirus*. Polyclonal antisera show no cross-neutralization between TMEV and EMCV; however, since the coat proteins of the two *Cardiovirus* species share ~50% identity of their amino acid sequences, cross-reactions are observed with antibody binding assays such as enzyme-linked immunosorbent assay (ELISA) and complement fixation. Phylogenetic analysis of the complete P1 capsid-coding region has revealed three major clades: TMEV, Vilyuisk human encephalomyelitis virus (VHEV), and the Theiler's-like virus (TLV) of rats (**Figure 1**). These three clades presumably represent three distinct serotypes of the species *Theilovirus*; however, comprehensive serological studies remain to be performed.

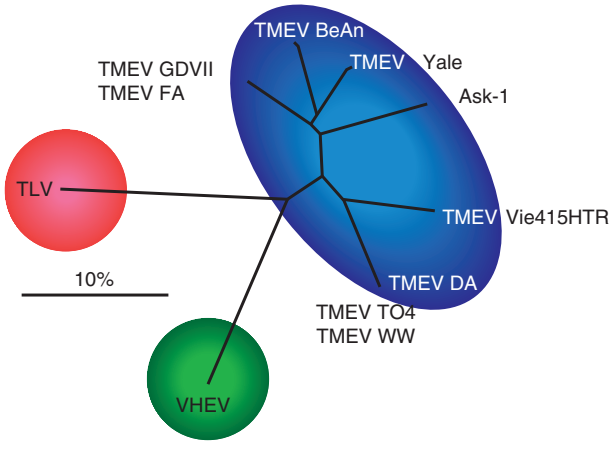

Figure 1 Phylogenetic analysis of the P1 capsid-coding region of the Theiloviruses showing three clades, presumably representing three distinct serogroups: TMEV, Vilyuisk human encephalomyelitis virus (VHEV), and Theiler's-like virus of rats (TLV).

Physical Properties

Because the TMEVs do not have an envelope they are insensitive to chloroform, ether, nonionic detergents, such as deoxycholate, NP40 and Tween-80, and the ionic detergent sodium dodecyl sulfate, but are inactivated by 0.3% formaldehyde and HCl 0.1 mol l^{-1}. TMEVs are rapidly destroyed at temperatures over 50 °C and lose some infectivity upon lyophilization. Purified virions can be stored for long periods of time at −70 °C without loss of infectivity, but slowly lose infectivity on storage at −20 °C. Enteroviruses require stability at low pH to pass through the acidic conditions of the stomach. TMEVs are stable over the entire pH range from 3 to 9.5, but in contrast to the other cardioviruses, such as EMCV, they are not highly thermolabile in the presence of 0.1 mol l^{-1} chloride or bromide in the pH range 5–7.

Virion Structure

Picornavirions have a relative molecular mass of ~8.5 × 10^6 Da, of which 30% is RNA and 70% protein. Theiler's virions are 30 nm in diameter and their structure reveals only a spherical virion by negative staining (**Figure 2(a)**). Virions have a sedimentation coefficient of 150 S by velocity centrifugation in sucrose and a buoyant density of 1.34 g ml^{-1} by isopycnic centrifugation in cesium salts.

The three-dimensional structures of the GDVII, BeAn, and DA strains have been determined at ~3 Å resolution by X-ray crystallography (**Figures 2(b)** and **2(c)**). The overall architecture is quite similar to that of other picornaviruses and closely resembles that of Mengo virus, another member of the EMCV species. Each virion is composed of 12 pentamers, with each pentamer made up of five protomers, each containing a single copy of the four capsid proteins. Each of the three major capsid proteins VP1, VP2, and VP3 consist of a wedge-shaped eight-stranded antiparallel β-barrel. The N-termini of the capsid proteins form an extensive, intertwined network on the inner surface of the protein shell. The loops connecting the β-strands form the outer surface features of the protein shell and provide surface differences with Mengo virus. A 25 Å depression on the virion surface at the junction between VP1 and VP2 along the twofold axis, termed the pit, is believed to be the viral receptor and is a broad depression. The TMEV surface structures are differentiated from that of Mengo virus in having: (1) a larger VP1 CD double loop, with loop I containing an extra five residues, that is shifted more toward the VP2 EF puff at the twofold axis, while loop II is directed more toward the fivefold axis; (2) an 11-residue insertion in the VP2 EF puff forming a double loop in which the inserted loop interacts with

Figure 2 Theiler's virions. the VP1 FMDV GH loop; and (3) the tip of the VP3 knob (a loop inserted in βE) points directly outward on the rim of the pit.

Properties of the Genome

The genetic component of the TMEV virion is a single-stranded, positive-polarity RNA molecule 8100 nt in size that has a sedimentation coefficient of 35 S. The virion RNA has a virally encoded 20 amino acid protein, VPg, covalently linked to the 5′ uridine, and a poly(A) tract on the 3′ end. The complete genomes of the GDVII, DA, BeAn strains, as well as TLV have been sequenced. With the notable absence of a poly(C) tract in the 5′ untranslated region, the organization and sequence of the TMEV genome is remarkably similar to that of EMCV. The polyprotein of the prototypic BeAn strain initiates at the AUG codon at nucleotide 1065 and extends for 6909 nt (or 2303 codons), ending at the single UGA termination triplet at base 7972 (**Figure 3**). The polyprotein-coding region is flanked by 5′ and 3′ untranslated sequences of 1064 and 125 nt, respectively. In BeAn the 5′ untranslated region contains a stretch of 11 pyrimidines interrupted by a single purine before the AUG at nucleotide 1065. In picornaviruses, the 5′ untranslated region mediates cap-independent translation and serves as an internal ribosome entry site (IRES). The TMEV 5′ untranslated sequences have been predicted to form stable secondary structures, which in the 500 nt upstream of the authentic AUG (at 1065) are nearly identical to those predicted for EMCV and foot-and-mouth disease virus. In BeAn, eight AUGs precede the initiator AUG, but none of them has an optimum Kozak context sequence. Hence, it could be argued that selection of the authentic initiator AUG after binding of ribosomes to TMEV RNA does not involve internal ribosome binding. However, BeAn nucleotides ~500–1065 determine a structure that serves as an IRES in bicistronic mRNAs both *in vitro* (BHK-21 cells). A poly(A) tail of indeterminate length is present on the 3′ end of the viral genome.

Translation: Polyprotein Processing and Final Gene Products

The 12 TMEV gene products are the result of post-translational processing of a 2303 amino acid polyprotein (mol. weight of 256 kDa) (**Figure 3**). The polyprotein of GDVII virus contains no insertions or deletions; however, two VP1 amino acids are deleted in DA, TO4, and WW viruses. The processing scheme follows a standard L-4-3-4 picornavirus polypeptide arrangement, that is, the leader protein (L), four capsid proteins in part one (P1) of the genome, three proteins in P2, and four proteins in P3 (**Figure 3**). The coding limits of individual viral proteins have been predicted by analogy with those of EMCV since the only confirmation to date of a deduced sequence is that of the N terminus of 1D. The eight amino acids flanking the putative cleavage sites are highly conserved for the two viruses. All of the cleavage sites in the polyprotein except for two, 1A/1B and 2A/2B, are processed by the viral protease 3C. The TMEV 3C protease therefore processes Q-C, as well as Q-S and Q-A, dipeptides and, in addition, the E-N dipeptide at the 1D/2A cleavage. However, only 6 of 8 Q-G, 2 of 13 Q-S, and 1 of 7 Q-A dipeptides in the polyprotein are cleaved by 3C, indicating that involvement of secondary, tertiary, or both types of structure is also important for recognition of these particular dipeptides. The tetrapeptide NP/GP at 2A/2B which is the primary cleavage site in the cardiovirus polyprotein is cleaved autocatalytically, as it is in EMCV.

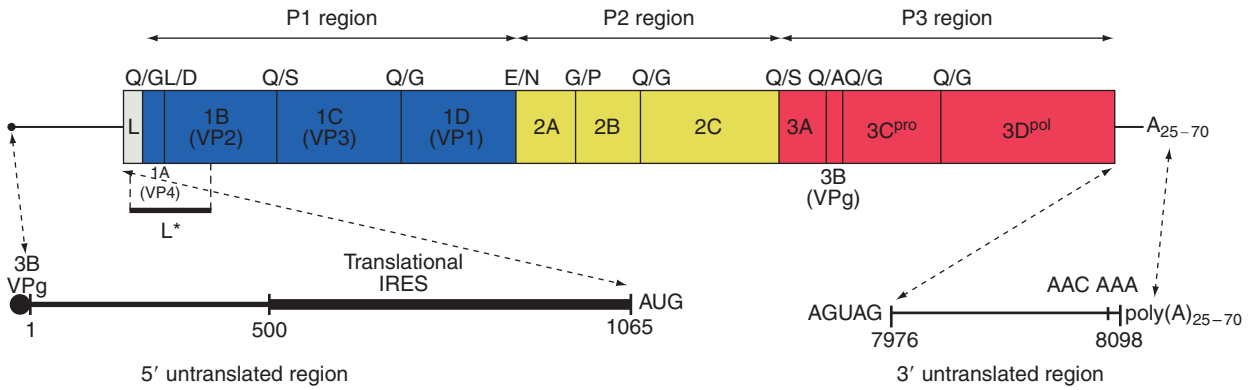

Figure 3 TMEV 8 kbp genome showing 5′ and 3′ untranslated regions (enlarged) and the polyprotein which is superimposed over the 7 kbp nucleotide open reading frame (ORF) and contains the final 12 viral gene products. The 5′ end of the viral RNA is not capped but has protein 3B (VPg) covalently attached to the first nucleotide. A ~500 base internal ribosome entry site (IRES) is present in the 5′ untranslated region immediately upstream of the authentic AUG initiation codon for the polyprotein. The 3′ untranslated region ends in a poly (A) tail. The ORF is divided into L, P1 (blue) encoding the four capsid proteins, P2 (yellow) three nonstructural proteins, and P3 (red) four nonstructural proteins, including the 3C cysteine protease which makes all but two of the cleavages in the polyprotein, and the 3D, the RNA-dependent RNA polymerase. Cleavage dipeptides are shown above viral protein boundaries. Finally, the location of the L* protein that is translated out-of-frame is shown near the N-terminus of the polyprotein.

Table 1 Functional activities of the TMEV nonstructural proteins

Nonstructural protein	*Activities*
Leader (L)	Binds to Ran, inhibiting import and export of proteins to and from the nucleus, including those involved in the innate interferon response
L*	Out-of-frame 19-kDa protein initiated by AUG or ACG codons immediately downstream of the authentic AUG for polyprotein translation; has a putative role in TMEV persistence
2A	A C-terminal tetrapeptide NP/GP responsible for autocatalytic cleavage of 2A/2B, the primary cleavage in the cardiovirus polyprotein
2B	Possible role in cell membrane permeability
2C	A multifunctional protein involved in viral RNA replication, including ATPase, GTPase, membrane binding, and RNA binding activities
3A	Inhibition of ER-to-Golgi transport that results in reduction of host cell cytokine secretion
3B	Covalently linked to the 5′-terminal uridine of the single-stranded RNA and primer for the viral RNA-dependent RNA polymerase
3C	Cysteine-reactive protease responsible for all of the monomolecular and bimolecular cleavages in the polyprotein except for the assembly-dependent maturation cleavage of VP0 (1A/1B) and autocatalytic cleavage at 2A/2B
3D	RNA-dependent RNA polymerase responsible for viral RNA replication

Cleavage of the polyprotein gives rise to three primary products, the first of which (116 kDa) contains the leader protein (8 kDa), the P1 capsid proteins, and the first P2 protein 2A (15 kDa). Thus, the initial precursor released from the polyprotein is like that of the other cardioviruses but differs from that of other groups of picornaviruses. The capsid proteins are arranged in the following order: 1A (VP4; 7 kDa), 1B (VP2; 29 kDa), 1C (VP3; 25 kDa), and 1D (VP1; 30 kDa). The second processing precursor (2BC) is 51 kDa and gives rise to 2B (14 kDa) and 2C (37 kDa). The third or C-terminal precursor protein is 88 kDa and is processed into the four mature proteins 3A (10 kDa), 3B (2 kDa), 3C (24 kDa), and 3D (52 kDa). The functions of the nonstructural proteins are shown in **Table 1**. Another protein, termed L*, translated out-of-frame, is initiated 22 nt downstream of the authentic AUG in the polyprotein, giving rise to an 18 kDa protein that was originally shown to be involved in the TMEV persistent infection.

Viral RNA Replication

Cardiovirus replication is similar to that of other picornaviruses. Following entry, VPg is removed from the 5′ end of the RNA, and the RNA is directly translated using

cellular factors. The viral genomic RNA (plus-sense), is then transcribed into negative-strand copies, and each one is used as template for reiterative synthesis of ~25–50 plus-sense RNAs identical to the genome of the virus. An RNA structure located within the VP2 sequence of TMEV is necessary for RNA replication, and is referred to as the *cis*-acting replicative element (CRE). The CRE functions as a template for uridylylation of viral protein 3B (VPg) forming $VPgpUpU_{OH}$ which primes positive-strand RNA synthesis. Viral protein 3D is the RNA-dependent RNA polymerase which catalyzes both of these processes.

Viral Genomic Determinants in Pathogenesis

The existence of two naturally occurring TMEV neurovirulence groups provides a useful system for investigating molecular pathogenesis. Moreover, the difference in neurovirulence in terms of mean 50% lethal dose between high and low neurovirulence strains is of the order of 10^5 plaque forming units. With the advent of reverse genetics the generation of full-length cDNA clones of high neurovirulence GDVII and low virulence DA and BeAn viruses was feasible. Viral RNAs transcribed from cDNAs are infectious upon transfection of mammalian cells. To identify pathogenetic determinants, for example, those of neurovirulence and persistence, recombinant viruses between parental cDNAs have been assembled and point mutations introduced into wild-type strains for analysis in cell culture and mice.

Neurovirulence and persistence have been mapped to the L-P1 regions encoding the L and L* proteins and the capsid proteins. The results suggest that the mechanism for the pathogenetic properties of neurovirulence and persistence involve several determinants, including an exclusive role for the capsid in neurovirulence and the out-of-frame L* protein and capsid (exterior surface of the virion) in persistence. The latter observation suggested that receptor-mediated events may be involved in persistence; it was demonstrated that persistence required the ability of low neurovirulence strains to bind to its sialic acid co-receptor. The L* protein was initially recognized because only the low neurovirulence strains have an out-of-frame AUG start codon. However, the ACG codon in high neurovirulence strains was then shown to initiate L* translation, and chimeric TMEVs that contain a high neurovirulence L protein in a low neurovirulence background were shown to persist in the mouse CNS as well as the low neurovirulence parental virus. The role of the L* protein in persistence will require further study.

Transmission and Tissue Tropism

TMEVs are transmitted by the fecal–oral route and are separable into two biological groups based on neurovirulence (**Table 2**). The first group, consisting of three isolates, GDVII, FA, and ASK-I, possesses high neurovirulence, causing a rapidly fatal encephalitis in mice. Some 10–15 isolates, including viruses recovered from the CNS of spontaneously paralyzed mice and feces of asymptomatic mice, form a second, low neurovirulence group. Experimentally, the low neurovirulence strains produce poliomyelitis (early disease) followed by demyelinating disease (late disease). When mice are inoculated intracerebrally with cell culture-adapted low neurovirulence strains, the poliomyelitis phase is attenuated (subclinical); whereas, brain-derived stocks of these viruses produce both disease phases.

Pathogenesis

Very little information is available about the pathogenesis of TMEV infection following peripheral routes of infection, including the oral route. In general, isolates from either of the neurovirulence groups do not readily produce CNS disease following peripheral routes of inoculation, with the exception of TO(B15), a mutant selected for its invasiveness from the intestinal tract. When mice are inoculated intracerebrally with the high neurovirulence strains, virus replicates widely in the brain and spinal cord, causing encephalitis or encephalomyelitis. Thus,

Table 2 Two TMEV neurovirulence groups

Characteristic	*High neurovirulence*	*Low neurovirulence*
Isolates (strains)	GDVII, FA, ASK-1	DA, BeAn 8386, Yale, WW, TO4, TO(B15), Vie415HTR
Disease	Encephalomyelitis	Poliomyelitis/demyelination
Incubation period	1–10 days	7–20 days/>30 days
CNS target cell	Cortical and motor neurons	Motor neurons/macrophages and oligodendrocytes
LD_{50}	1–10 PFU	$>10^5$ PFU
Persistent infection	No	Yes
Temperature sensitive	No	Yes
Carbohydrate co-receptor	Heparan sulfate	α2,3-linked sialic acid
Differences in virion structure	Only in the Cα chain of the VP2 puff B	

neurons as well as glial cells (astrocytes and oligodendrocytes) become infected in the cerebral cortex, hippocampus, basal ganglia, thalamus, brainstem, and spinal cord. Affected mice develop hunched posture and hind-limb paralysis. A rapid demise is the result of widespread cytolytic infection. The following sections focus on the pathogenesis of the biphasic disease produced by the low neurovirulence strains, which provides an experimental model system for human demyelinating disease, multiple sclerosis.

Clinical Features of Infection

The intracerebral route of inoculation maximizes the incidence of neurological disease. Following intracerebral inoculation, the low neurovirulence strains produce a distinct biphasic CNS process in susceptible strains of mice, which is characterized by poliomyelitis during the first 2 weeks post infection, followed by chronic, inflammatory demyelination that begins during the second or third week post infection and becomes clinically manifest between 1 and 3 months post infection. Some investigators who inoculated lower amounts of virus observed an even later onset of demyelinating disease. Mice with poliomyelitis develop flaccid paralysis, usually of the hind limbs; only one limb may be affected or paralysis may involve both hind limbs and spread to involve the forelimbs, occasionally leading to death. In contrast to the fatal outcome of paralysis produced by the Lansing strain of human poliovirus type 2, complete recovery from TMEV-induced poliomyelitis is usually seen. Residual limb deformities may be seen as the result of extensive anterior horn cell infection and severe paralysis (early disease).

Gait spasticity is the clinical hallmark of the demyelinating (late) disease. Late disease is first manifest by slightly unkempt fur and decreased activity, followed by an unstable, waddling gait. Subsequently, generalized tremulousness and ataxia develop, and the waddling gait evolves into overt paralysis. Incontinence of urine and priapism are seen. As the disease advances, prolonged extensor spasms of the limbs occur spontaneously followed by difficulty in righting. Extensor spasms can be induced by turning an animal over on its back by quickly rotating the tail. Weight loss occurs during late disease. The clinical manifestations of late disease are progressive and lead to an animal's demise in several to many months post infection. A functional motor assay using a rotorod apparatus has been used to quantitate motor function in this disease.

Pathogenesis and Histopathology

Motor neurons in the brainstem and spinal cord are the main targets of infection during poliomyelitis, but sensory neurons and astrocytes are also infected. TMEVs do not replicate in endothelial and ependymal cells. A brisk microglial reaction is elicited, with the appearance of numerous microglial nodules, particularly in the anterior gray matter of the spinal cord. Examples of neuronophagia are quite frequent at this time, but little lymphocytic response is seen. The poliomyelitis phase lasts 1–4 weeks, after which time little residual gray matter involvement is inapparent other than for astrocytosis.

As early as 2 weeks post infection, inflammation of the spinal leptomeninges begins to appear, followed by involvement of the white matter. Initially, the inflammatory infiltrates are almost exclusively composed of lymphocytes, but at later times plasma cells and macrophages become numerous (**Figure 4**(**a**)). The influx of macrophages is in close temporal and anatomic relationship with myelin breakdown. Both light microscopic and ultrastructural studies show that myelin breakdown is related to the presence of macrophages (**Figure 4**), which either actively strip myelin lamellae from otherwise normal-appearing axons or are found in contact with myelin sheaths undergoing vesicular disruption. Foci of inflammation and myelin destruction extend from the perivascular spaces into the surrounding white matter, leading to sharply demarcated plaques of demyelination (**Figure 4**(**b**)). The ultrastructure studies during the initial phase of myelin breakdown have not shown alterations in oligodendroglia, which are in close apposition with naked but otherwise normal axons; however, oligodendrocytopathology has been observed later although it appears to be a minor contributor to demyelination.

Sites of TMEV Persistence

TMEV persistence clearly involves active virus replication, since infectious virus can be readily isolated from the CNS of infected mice and high viral genome copy numbers are present. *In situ* hybridization has revealed two populations of CNS cells differing in the number of viral genomes. Virus replication in the majority of these cells ($>90\%$) appears to be restricted, as they contain <500 viral genomes. A small percentage of CNS cells contain >1500 genomes, possibly as many as 10^4–10^5, and are probably productively infected. The absolute number of viral genomes as determined by *in situ* hybridization is probably only an approximation. Restricted virus production has been demonstrated in macrophages isolated from the CNS of diseased mice; therefore, macrophages appear to be the primary target for persisting virus. It is also possible that some of the cells with restricted infection are astrocytes. The kinetics of virus replication in the CNS cells with restricted infection remains to be elucidated – the length of the replicative cycle and whether the cells are lysed or continue to produce infectious virus for longer times is not known. TMEV infection *in vitro*

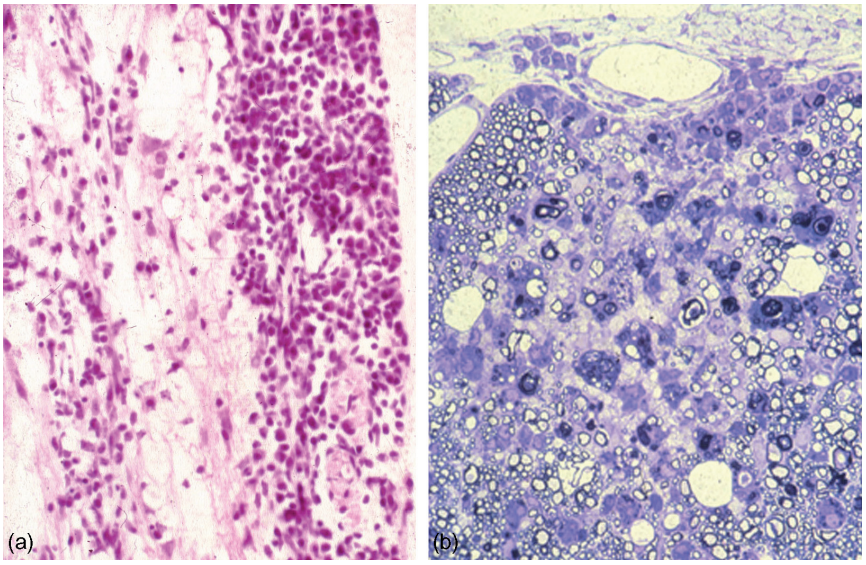

Figure 4 Histopathology of TMEV-induced demyelinating disease (late disease) in an SJL mouse. (a) H&E-stained longitudinal section (6 μm) of the spinal cord showing intense mononuclear inflammatory cell infiltrates in the leptomeninges (right) and parenchyma where many vacuolated macrophages are observed. (b) Toluidine blue-stained, Epon-embedded coronal section (1 μm) of a spinal cord showing a discrete plaque-like area of demyelination (many naked axons present) and lipid-laden macrophages at the cord margin and surrounded by normal myelinated axons. Magnification ×400 (a); ×300 (b).

only occurs in monocytes once they have differentiated into macrophages. Virus production in infected macrophage cell lines is restricted but viral translation, polyprotein processing, and assembly of virion intermediates (protomers and pentamers) as well as virions appear to be normal. Ultimately infected macrophages undergo apoptosis, which is caspase-9 and -3 dependent, consistent with activation of the mitochondrial pathway. In contrast, oligodendrocytes appear to be productively infected, since ultrastructural analysis has shown crystalline arrays of virions in oligodendrocytes in demyelinating lesions in mice. Oligodendrocytes may correspond to the CNS cells containing large numbers of viral genomes by *in situ* hybridization. These data suggest that a cytolytic infection of oligodendrocytes contributes to demyelination along with immune-mediated mechanisms of myelin damage.

Immune Response

During the first week, TMEV-infected mice mount a virus-specific humoral immune response that reaches a peak by 1–2 months post infection and is sustained for the life of the host. Neutralizing and other virus-specific antibodies have been measured. The majority of the antiviral IgG response in persistently infected, susceptible mice is IgG2a subclass, with little antiviral IgM detected by day 14 post infection, whereas IgG1 antiviral antibodies appear to predominate in resistant as well as in immunized mice. Murine CD4+ T cells of the Th1 subset mediate delayed-type hypersensitivity (DTH) and regulate IgG2a production via interferon-γ production, whereas CD4+ Th2 cells regulate IgG1 and IgE production via interleukin 4. Thus, the predominant IgG2a antiviral response in susceptible mice may be an *in vivo* measure of preferential stimulation of a Th1-like pattern of cytokine synthesis. Virus-specific CD8+ cytolytic T-cell responses have also been shown to help in virus clearance during the acute phase of the infection, and may be responsible for the resistance of C57BL/6 mice to the demyelinating disease.

Infected, susceptible strains of mice also produce substantial levels of virus-specific CD4+ T-cell responses. T-cell proliferation and DTH appear by 2 weeks post infection and remain elevated for at least 6 months. Both DTH and T-cell proliferation have been shown to be specific for TMEV and mediated by CD4+ class II restricted T cells. A temporal correlation has also been found between the onset of demyelination and the appearance of virus-specific CD4+ T-cell responses, as well as for high levels of virus-specific DTH. High levels of the Th1 cytokines interferon-γ and TNF-α also correlate temporally with the evolution of demeylination. DTH and CD4+ T-cell proliferative responses in infected and immunized susceptible SJL mice are directed toward immunodominant regions (peptides) in each of the three major coat proteins. T-cell responses to these epitopes in VP1 and VP2 are believed to participate in the immunopathology.

Although mice mount virus-specific humoral and cellular immune responses early in the infection and peak CNS virus titers fall by 100 000-fold, TMEVs

somehow evade immune clearance to persist at low infectious levels indefinitely. Extraneural persistence has not been observed. Current dogma holds that humoral immunity is more important than cellular immunity in clearing infections by nonenveloped viruses, such as picornaviruses. Evidence has been presented for a role for both neutralizing antibodies and cytolytic CD8+ T cells in TMEV clearance. The precise mechanism by which TMEVs evade immune surveillance is not known but does not appear to involve antigenic variation. Although complement and virus-antibody deposition in the CNS parenchyma has detected extracellular transport of virus as infectious virus antibody complexes, viral aggregates, or as virus contained within cellular membranes, are a possible means whereby virus could be protected from TMEV-specific immune responses and continue to infect other cells. This is an area for further study to enable a better understanding of how TMEV evade immune surveillance.

Immune-Mediated Mechanism of Demyelination

Appropriately timed immunosuppression can prevent the clinical signs and pathological changes of TMEV-induced demyelinating disease, indicating that the immune response participates in myelin breakdown. A number of different immunosuppressive modalities have proved to be effective, including cyclophosphamide, antilymphocyte serum, antitumor necrosis factor antibodies, and monoclonal anti-IA, CD4+, and CD8+ antibodies. If given too early in the course of early disease, the infection in neurons is potentiated and results in encephalitis and a high mortality rate. Thus, immunosuppression may be most effective when administered after the first week of infection. The incidence of demyelinating disease is increased in SJL mice infected with a dose of virus that normally produces a low incidence of disease and adoptively immunized with TMEV VP2-specific T-cell line. This observation supports a role for CD4+ T cells in mediating TMEV-induced demyelinating disease.

The effector mechanism by which a nonbudding virus, such as TMEV, might lead to immune-mediated tissue injury is unknown. Because TMEV antigens have been primarily found in macrophages, it has been proposed that myelin breakdown results from an interaction between virus-specific T cells trafficking into infected areas of the CNS and the virus. Thus, myelinated axons may be nonspecifically damaged as a consequence of a virus-specific immune response, that is, an 'innocent bystander' response. In this circumstance, cytokines produced by MHC class II-restricted, TMEV-specific T_{DTH} cells primed by interaction with infected macrophages lead to the recruitment and activation of additional macrophages in the CNS, resulting in nonspecific macrophage-mediated demyelination. This hypothesis is consistent with the CNS pathology observed in mice exhibiting TMEV-induced demyelinating disease and the fact that antigen-specific T cells and T-cell lines have been shown to cause bystander CNS damage via macrophage activation in other model systems. Alternatively, in the case of extensive infection of oligodendrocytes, demyelination might result from immune injury to these myelin-maintaining cells expressing TMEV antigens in conjunction with H-2 class I determinants. CD8+ T cells would then be the likely T cells to kill infected oligodendrocytes; however, widespread degeneration of oligodendrocytes has not been observed.

Tick-Borne Encephalitis Viruses

T S Gritsun and E A Gould, University of Reading, Reading, UK

Taxonomy, Nomenclature, and Phylogenetic Relationships

'Tick-borne encephalitis antigenic complex' was the original term for viruses now classified as the mammalian tick-borne flaviviruses. Together with the seabird-associated tick-borne flaviviruses they comprise one ecological group in the genus *Flavivirus,* family *Flaviviridae*. The genus contains two other groups, namely, the mosquito-borne flaviviruses and the flaviviruses with no known arthropod vectors. Other flaviviruses are referred to as nonclassified flaviviruses. The prototype TBEV is a human and animal pathogen. The earliest TBEV isolate, known as Russian Spring and Summer Encephalitis virus, was isolated in 1937 in far-East Asia. Currently, the TBEV (currently classified as virus species in the group of mammalian tick-borne flaviviruses) is subdivided into three subtypes, far-Eastern, Siberian, and West European reflecting their antigenic, phylogenetic, and geographic relationships. Other antigenically related but distinct tick-borne flaviviruses include Omsk hemorrhagic fever virus, Powassan virus (POWV), Langat virus, Kyasanur Forest disease virus, Alkhurma virus, Louping ill virus, Spanish sheep encephalomyelitis virus, Turkish sheep encephalomyelitis virus, and Greek goat encephalomyelitis virus. Each of them may cause encephalitis and/or hemorrhagic disease in humans, farmed, domestic, and wild animals. Other related mammalian tick-borne flaviviruses, not known to cause human or animal disease, include Royal Farm virus, Karshi virus, Gadgets Gully virus, and Kadam virus. The viruses associated primarily with seabirds and their ticks are Saumarez Reef virus, Meaban virus, and Tyuleniy (Three Arch) virus. They are not recognized pathogens but they show interesting geographic dispersion that reflects the flight patterns of the birds with which they are associated. The phylogenetic relationships between the TBEVs are illustrated in **Figure 1**.

Virions

Infectious (mature) virions are spherical particles (50 nm) with a relatively smooth surface and no distinct projections. They have an electron-dense core (30 nm) surrounded by a lipid membrane. The core consists of positive-polarity genomic RNA (~11 kbp) and capsid protein C (12K). The lipid membrane incorporates an envelope glycoprotein (E, 53K) and a membrane glycoprotein (M, 8K). The immature (intracellular) virions contain a precursor membrane protein (prM, 18K), the cleavage of which occurs in the secretory pathway during egress of virions from infected cells.

Virions sediment at about 200S and their buoyant density is 1.19 g ml^{-1}, although there is significant heterogeneity among them. Electron micrographs frequently revealed virions in association with cellular membranes, probably explaining this heterogeneity. They are most stable at pH 8.0, although TBEV virions remain infectious in normal human gastric juice at pH 1.49–1.80. As with all enveloped viruses, infectivity of TBEVs decays rapidly at temperatures above 40 °C. Most flaviviruses agglutinate erythrocytes but a few nonagglutinating strains of TBEVs have been described. Most of the physical characteristics of the TBEVs were established using virus isolated from mammalian cells. However, after adaptation to ticks, they become less cytopathic for cultured cells and laboratory animals. These virions do not move toward the cathode in rocket immunoelectrophoresis and they have reduced hemagglutinating activity. These phenotypic characteristics may be reversed following re-adaptation to mammalian cells and host-selection of virions with a shifted net surface charge due to a single amino acid substitution in the E glycoprotein.

The E glycoprotein mediates virus binding to cellular receptors and thereby directly affects virus host range, virulence, and immunological properties by inducing

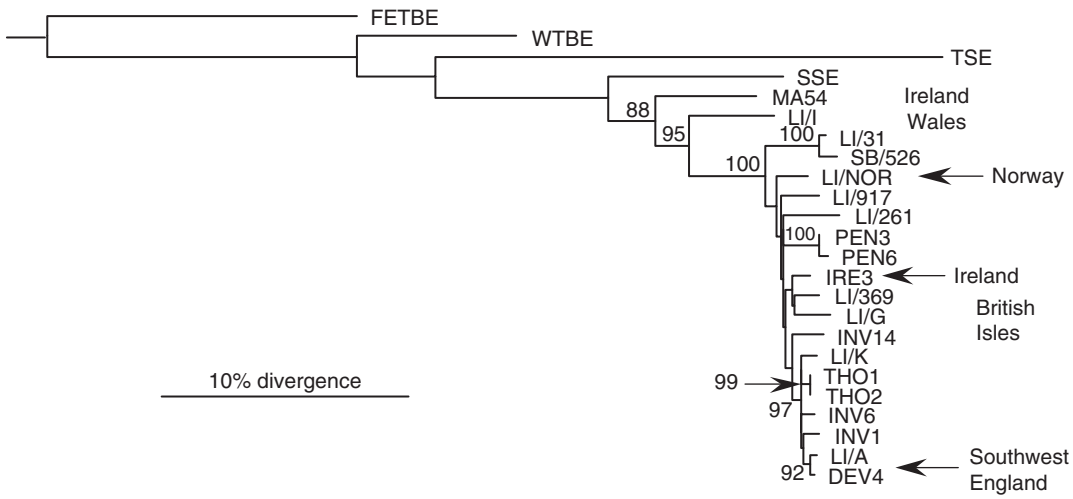

Figure 1 Maximum likelihood phylogenetic tree of the E gene from 24 tick-borne flaviviruses. Branch lengths are drawn to scale and all nodes supported by more than 75% bootstrap support are indicated. The tree is rooted with the sequence from FETBE virus, Sofjin (RSSE) strain. The three main populations of virus in the British Isles are indicated, along with those viruses secondarily introduced into Ireland and Norway, and the viruses found in the south-west of England. Reproduced from McGuire K, Holmes EC, Gao GF, Reid HW, and Gould EA (1998) Tracing the origins of Louping ill virus by molecular phylogenetic analysis. *Journal of General Virology* 79: 981–988.

protective antibodies. X-ray crystallography has revealed the E-protein ectodomain (N-terminal 395 amino acids) as homodimers folded in a 'head-to-tail' manner (**Figure 2**(**a**)) and orientated parallel to the membrane surface. It contains three structural domains, each based on β-sheets: the central domain I, the dimerization (fusion) domain II, and receptor domain III (dI, dII, and dIII in **Figure 2**). The C-terminal 101 residues of the E protein form a stem-anchor region consisting of two stem α-helices and two transmembrane α-helices that anchor the E protein into the lipid bilayer (**Figure 3**). Domain II contains a hydrophobic fusion peptide consisting of 13 residues that is highly conserved between all flaviviruses. It is located on the tip of domain II and plays a central role in fusion of the virion membrane to cellular endosomal membranes resulting in release of virion RNA into the cytoplasm (**Figure 2**).

A three-dimensional image reconstruction of the virion surface reveals a protein shell composed of 90 E-dimers organized into a 'herringbone' configuration; three quasi-parallel E-dimer molecules make up the main structural asymmetric unit of the shell (**Figures 4**(**b**) and **4**(**c**)). The fivefold symmetry axes that appear as holes are generated by appropriate positioning of five domain IIIs and their lateral surface is accessible to cellular receptors and neutralizing antibodies. The M protein protrudes through holes formed between dimerization domains of E molecules. The transmembrane regions of the M and E proteins traverse the external but not the internal layer of the lipid membrane and there is no direct contact with the nucleocapsid (**Figure 3**).

In contrast with those of many other enveloped viruses, the flavivirus capsid is poorly organized and appears to be positioned randomly in the core. In solution, the capsid protein appears as dimer molecules with four helices (**Figure 5**). Two C-terminal helices fold into the positively charged interface interacting with viral RNA; the residues on the opposite side of these helices are hydrophobic and support dimerization. Two of the internal α-helices form capsid-dimers, are hydrophobic, and are required for contact with the virion membrane.

TBEV Life Cycle

Virus Entry into the Cells

Cellular receptors for tick-borne flaviviruses

The virus life cycle commences with the attachment of virions to specific receptors on clathrin-coated pits on the cell surface. Flaviviruses infect a wide variety of primary and continuous cells, derived from mammalian, avian, and arthropod tissues. It is not yet clear if the different flaviviruses use similar or different cell surface receptors. Cellular heparan sulfate molecules are involved in TBEV attachment to cells. Nevertheless, cells that lack heparan sulfate are still sensitive to virus infection. For TBEV, a number of different proteins have been associated with cell receptor activity, including the high-affinity laminin receptor and α1β3-integrin that also recognizes laminin as a natural ligand.

The E protein mediates attachment and entry of virions into cells

The immunoglobulin-like folding of the E-protein domain III implies that it is involved in cell attachment,

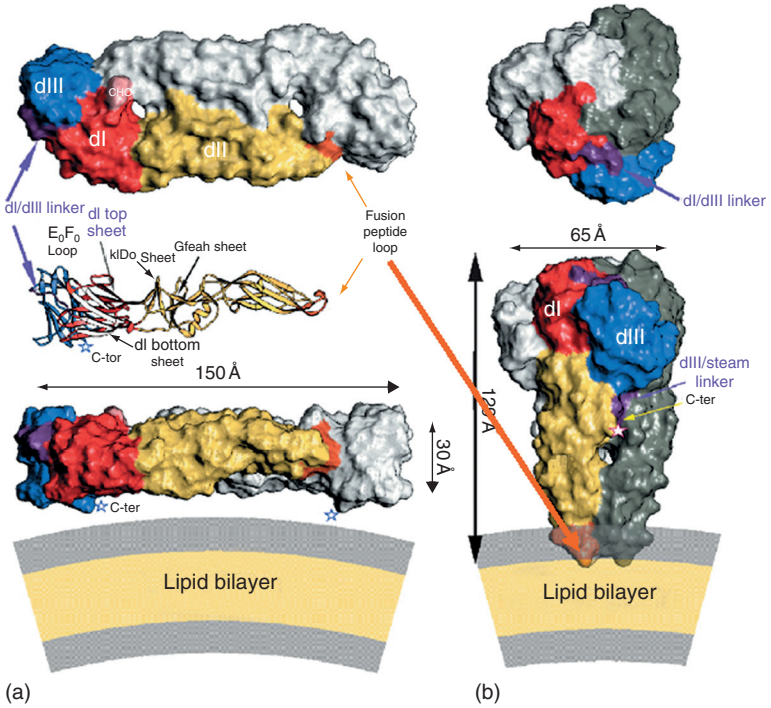

Figure 2 Three-dimensional analysis of TBEV envelope (E) glycoprotein (a) at neutral pH (in mature virion) and (b) acidic pH (postfusion conformation). mediated by high-affinity cellular receptors. The receptors on the surface of vertebrate and invertebrate cells are different and probably recognized by different residues on domain III. However, domains I and II on the surface of the E protein also appear to play a role in virus–cell interactions. Domain I carries N-linked carbohydrates, which are recognized by cell surface lectins. Domain II is enriched with patches of basic positively charged surface residues that have been shown to mediate virion attachment to the cellular, negatively charged, heparan sulfate; domains I and III might also contribute to this type of interaction.

Virus attachment to the cell receptors initiates receptor-mediated endocytosis, followed by fusion of virion and endosomal membranes (**Figures 4(c)–4(e)**). Exposure of the attached virus to the endosomal acid pH converts the herringbone configuration into a fusogenic structure resulting in particle expansion and eventually in the re-assembly of the E dimers into vertical trimers (**Figures 2** and **4**). It is believed that during this process domains I and II flex relative to each other, allowing domain II and the stem region to move toward the endosomal membrane facilitating trimerization of domain II; the fusion tripeptide is embedded into the target membrane followed by formation of a pre-fusion intermediate (**Figure 6**). Trimerization spreads from fusion peptides to domain I; meanwhile domain III rotates relative to domain II pushing the stem region back toward the fusion peptide. This refolding

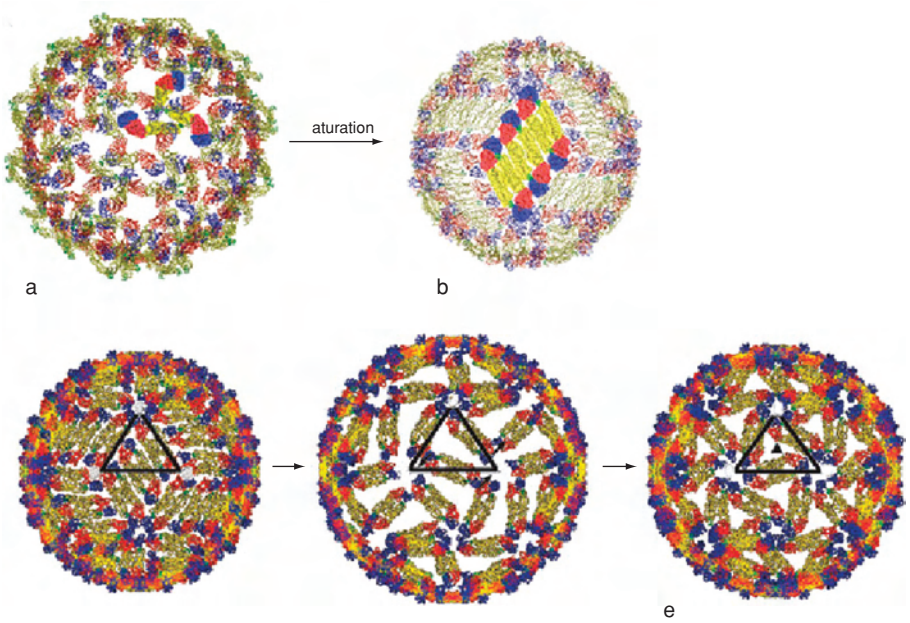

Figure 4 Different conformations of E protein during the transition from immature (a) into the mature (b) particles and during pH-dependent fusion of mature particles (c), through the putative intermediates T = 3 (d and e). Domains I, II, and III are depicted with the same colors as those on the **Figure 2**. Reproduced from Ma L, Jones CT, Groesch TD, Kuhn RJ, and Post CB (2004) Solution structure of Dengue virus capsid protein reveals another fold. *Proceedings of the National Academy of Sciences, USA* 101: 3414–3419, with permission from National Academy of Sciences USA.

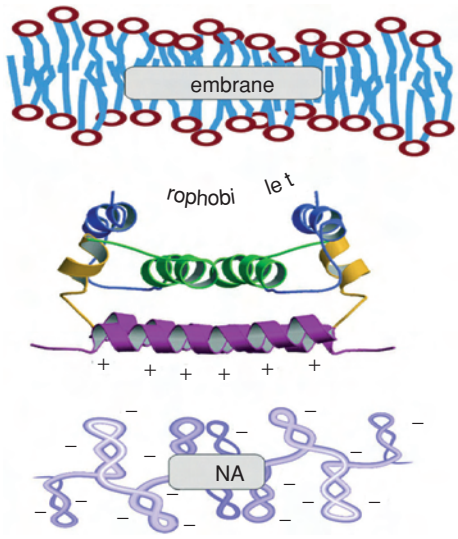

Figure 5 Model for the molecular interactions of flavivirus capsid dimers with genome RNA and virion membrane. Reproduced from Ma L, Jones CT, Groesch TD, Kuhn RJ, and Post CB (2004) Solution structure of Dengue virus capsid protein reveals another fold. *Proceedings of the National Academy of Sciences, USA* 101: 3414–3419, with permission from National Academy of Sciences USA.

brings two membranes together, resulting in the formation of the 'hemifusion stalk' with only the proximal lipid leaflets fused. The 'zipping' up of stems followed by the migration of transmembrane domains eventually leads to fusion of the distal lipid outlets and formation of a fusion pore. In the final low-pH conformation, domains I and III appear to move to the tip of the vertical trimer whereas the fusion peptide becomes embedded in the membrane eventually being juxtaposed to the transmembrane domains (**Figures 2(b)** and **6**). Five trimers form the fusion pore; the stem region appears to play an essential role in promoting and stabilizing trimer assembly. Although the E-protein domains shift and rotate during exposure to acidic pH, each retains the neutral-pH conformation, the essential feature of class II fusion molecules that do not require major molecular rearrangements at acidic pH.

Strategy of the TBEV Genome

Translation and processing of virus proteins

After uncoating, the RNA is translated into a polyprotein of ~3400 residues from one open reading frame (ORF) that is co-translationally translocated and anchored in the endoplasmic reticulum (**Figure 7**). It is then processed by cellular signalases and viral serine protease producing three structural (capsid, prM, and E) and seven nonstructural (NS1 through NS5) proteins. The gene order, protein molecular masses, and their membrane localization are shown in **Figure 7**. Viral protease activity is provided by the N-terminal domain (~180 residues) of the NS3 protein in association with cofactor activity of the NS2B protein that probably anchors the NS3 into

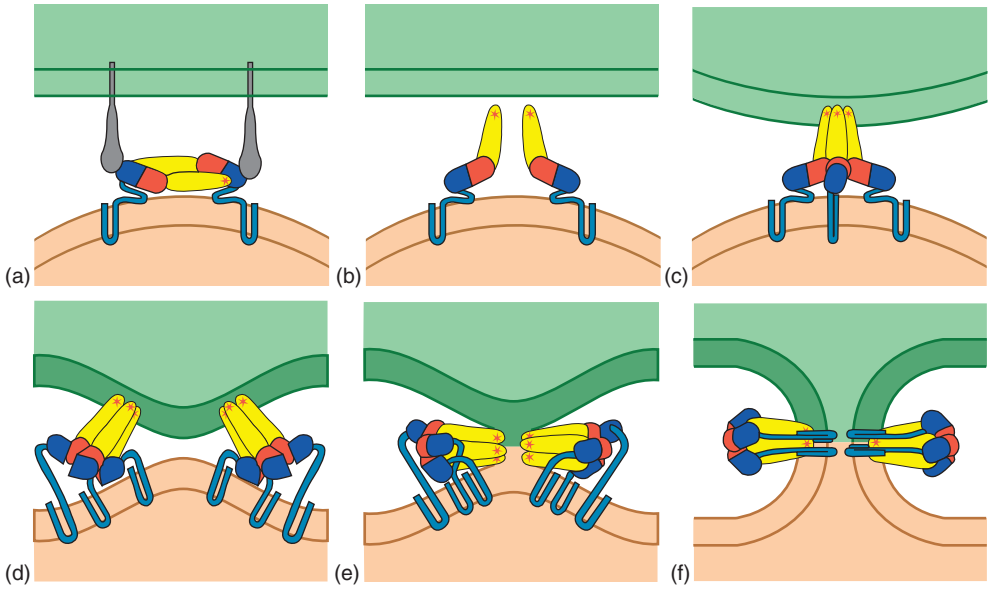

Figure 6 Tentative mechanism for the fusion of viral (brown) and endosomal (green) membranes mediated by the flavivirus E protein following interaction with cellular receptor (gray) (a). Acidic pH triggers the movement of domain II (with fusion peptide on the top) toward the endosomal membrane (b) with its subsequent trimerization and insertion into the endosomal membrane (c). Trimerization spread toward domains I and III (d) causing the C-terminal part of E protein to fold backwards toward the fusion peptide. The trimerization between stem-anchor and domain II (e) results in partial fusion (e) and eventually in the formation of a fusion pore (f). Reproduced with permission from Modis Y, Ogata S, Clements D, and Harrison SC (2005) Variable surface epitopes in the crystal structure of Dengue virus type 3 envelope glycoprotein. *Journal of Virology* 79: 1223–1231.

the membrane. The ORF is flanked by 5′- and 3′-untranslated regions (UTRs; ~ 130 and 700 bp, respectively) that contain signals essential to initiate translation and replication. The 5′-UTR preceding the ORF is capped by $m^7GpppAmpN_2$ and initiates virus translation *in vitro* although an interactive effect from the 3′-UTR has also been demonstrated. Computer-assisted prediction has demonstrated folding of the 5′-UTR into a Y-shaped structure, conserved between all flaviviruses; mutations in this structure appear to impact on virus translation and replication. The translation of flavivirus proteins is probably carried out in specialized smooth membrane structures, called convoluted membranes, derived from proliferation of the rough endoplasmic reticulum in response to flavivirus infections.

Replication of viral RNA

The initiation of viral replication (synthesis of negative strand on positive strand from the 3′-UTR) requires direct interaction between the 5′- and 3′-UTRs resulting in the formation of a double-stranded RNA (dsRNA) stem and circularization of the virus genome. A terminal 3′ long stable hairpin (3′ LSH) structure has been revealed in the 3′-UTR that, together with the 5′-Y-shaped-structure and dsRNA circularization stem, forms a complex promoter required to initiate virus RNA replication. Additional predicted conserved secondary RNA structures in the 3′-UTR might function as replication enhancers, essential for efficient RNA synthesis and virus transmission. The synthesis of genome-size dsRNA (replicative form, RF) accomplishes the first stage of viral replication.

Flavivirus RNA replication is semiconservative and asymmetric, with an average of one nascent positive-sense single-stranded RNA (ssRNA) molecule (genomic) per negative-sense template, with no free minus-strands and with 10–100 times excess of positive-strand relative to negative-strand RNA synthesis. The replicative intermediate presents a partially double-stranded RNA with nascent, and displaced, plus-sense ssRNA molecules undergoing elongation. Viral RNA capping of the 5′-UTR occurs on the displaced plus-strand RNA; the trifunctional NS3 and NS5 proteins provide nucleoside triphosphatase and guanylyl/methyltransferase activities, respectively.

Formation of the replication complex involves nonstructural proteins (**Figure 8**) most of which are bi- and even trifunctional. The C-terminal domain of NS5 protein acts as a viral RNA polymerase and the C-terminal domain of NS3 as a helicase; both NS5 and NS3 proteins interact with 3′-LSH to initiate virus replication. The functions of other nonstructural proteins are less precisely identified. The NS1 glycoprotein forms membrane-associated hexamers that dissociate into dimers. This protein is translocated in the endoplasmic reticulum and secreted together with virions in mammalian but not in mosquito cells; its anchoring into the membranes is mediated by

Figure 7 Genome strategy of TBEV. Transmembrane domains are shown as cylinders. Glycosylation is indicated as (*). The polyprotein is processed by ER signalases (s) and viral-specific protease NS2B-NS3 (V). The cleavage of M from prM is carried out by the Golgi protease, furin (f) and cleavage between NS1 and NS2A is by an unknown (?) ER protease.

glycosyl-phosphatidylinositol. The NS1 protein induces the production of protective antibodies that also participate in complement-mediated lysis of infected cells, implying a role in immunopathology. The NS2A protein is found in association with the NS3 helicase domain, the NS5 protein, and the 3′-LSH. It may be involved in trafficking of viral RNA between the translation, replication, and virion assembly sites. The NS2B protein is a membrane-anchored cofactor of the serine proteinase, NS3. It also has membrane-permeability modulating activity possibly related to replication. The hydrophobic NS4A protein in conjunction with the NS1 protein probably anchors the polymerase complex to cell membranes and is involved in virus-induced membrane rearrangements that compartmentalize virus translation, replication, and assembly processes (**Figure 8**).

Replication of flavivirus RNA is associated with host membrane 75–100 nm vesicular packets enclosed in the second outer membrane and connected to convoluted membranes, the sites of virus translation. The vesicular packets proliferate in the perinuclear region in response to virus infection and are probably derived from the *trans*-Golgi network. The architecture of the replication complex in relation to vesicular packets and convoluted membranes is illustrated in **Figure 9**. The replicative forms and replication complexes are enclosed within vesicular packets, whereas nascent ssRNA is externally located. In addition, a variety of cellular proteins associates with the 5′-UTR, 3′-UTR, and the RNA polymerase; they probably facilitate assembly of the replication complex and trafficking of the viral RNA/polymerase into the appropriate cellular compartment for replication.

Assembly, Maturation, and Release of Virions

The sequence of molecular events during virion morphogenesis is not completely understood. On completion of post-translational processing, the prM and E proteins rapidly form heterodimeric complexes; the

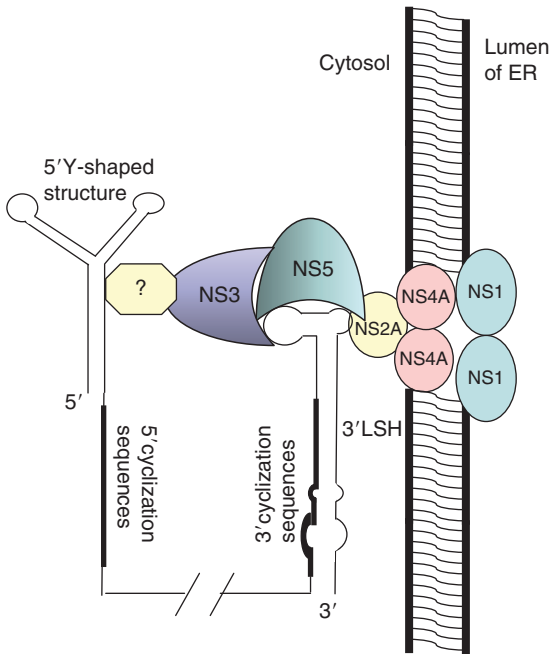

Figure 8 Representation of the assembly of the membrane-anchored polymerase complex. The conformations of 3′LSH and 5′ Y-shaped structure are shown. This stage probably precedes the cyclization of the virus genome mediated by direct interaction between the inverted complementary 5′- and 3′-cyclization sequences (thick lines); this is followed by the initiation of minus-strand RNA synthesis. Adapted from Westaway EG, Mackenzie JM, and Khromykh AA (2002) Replication and gene function in Kunjin virus. *Current Topics in Microbiology and Immunology* 267: 323–351.

chaperone-like function of the prM protein is essential for correct folding of E protein. Heterodimers are rapidly assembled into immature particles or, in the absence of capsid, into virus-like particles that also accumulate during infection. Virion packaging is coupled with RNA replication; only actively replicating RNA is encapsidated. The orientation of structural proteins in the lipid membrane suggests that assembly is mediated by capsid budding through the endoplasmic reticulum. However, assembled virus capsids have never been visualized, neither have budding particles nor specific release mechanisms been identified.

Assembly of structural proteins in the viral lipid membrane initially results in the formation of immature (intracellular) virions that are noninfectious, resistant to acidic pH, and unable to be structurally rearranged prior to fusion. Image reconstruction has defined the different organization of E/prM proteins compared with E/M proteins on the surface of immature and mature virions, respectively (**Figure 4**). Sixty projections were identified on the surface of immature virions making them look larger (60 nm) in comparison with smooth 50 nm mature virus particles. Each spike is formed by three heterodimeric E/M molecules. In immature particles the E protein points away from the membrane with the fusion peptide at its extremity. Virion maturation is accompanied by cleavage of prM to M, mediated by the cellular protease furin in the *trans*-Golgi network at acidic pH, during the transportation of virions to the cell surface. PrM-to-M cleavage results in the dissociation of E/M trimeric spikes with the formation of E/E homodimers, probably following shift of the stem-transmembrane domain relative to the ectodomain. In mature particles, the E ectodomain lies on the virus membrane, with the fusion peptide embedded in the cavity between domains I and III of the neighboring dimer. Formation of the herringbone building unit and release of the glycosylated pre-peptide then follows. Eventually, *trans*-Golgi-derived vesicles packed with mature virions follow the host secretory pathway, fuse with the plasma membrane, and release mature virions.

Pathogenesis of TBEV

Incidence of Tick-Borne Encephalitis

Classical tick-borne encephalitis (TBE) is contracted by humans when they are fed upon by infected *Ixodes* spp. ticks. Forested areas across the Northern Hemisphere, with thick moist undergrowth and abundance of small wild animals, provide ideal habitats for ticks and for TBEV. Long-term survival of the virus occurs mainly in ticks, which remain infected throughout their 2–5-year life cycle. Efficient virus transmission between infected nymphs and noninfected larvae occurs on the forest animals when these ticks co-feed. There is no requirement for viremia, since the virus can be transmitted to the larvae in animals that are not susceptible to the virus. Moreover, nonviremic transmission between the ticks can occur even on immune animals. Cells that migrate between the skin surface and local lymph nodes (e.g., dendritic cells) become infected and are then imbibed by the feeding noninfected larvae. Nonviremic transmission provides an efficient mechanism for long-term virus survival in the absence of overt disease. At the same time, susceptible animals such as sheep, goats, horses, pigs, dogs, grouse, and even humans may inadvertently become infected by ticks either in the forests or by ticks carried away from the forests. Under these circumstances the vertebrate host may become viremic and the virus may then be transmitted to a noninfected tick that subsequently transmits the virus to another vertebrate host when the infected tick feeds for a second time. Such situations arise on the sheep-rearing moorlands in the British Isles, Norway, Spain, Turkey, Greece, and other parts of Europe. In some situations sheep/goat and grouse populations may be severely affected.

The incidence of human TBE varies from year to year in different areas. The Urals and Siberia annually

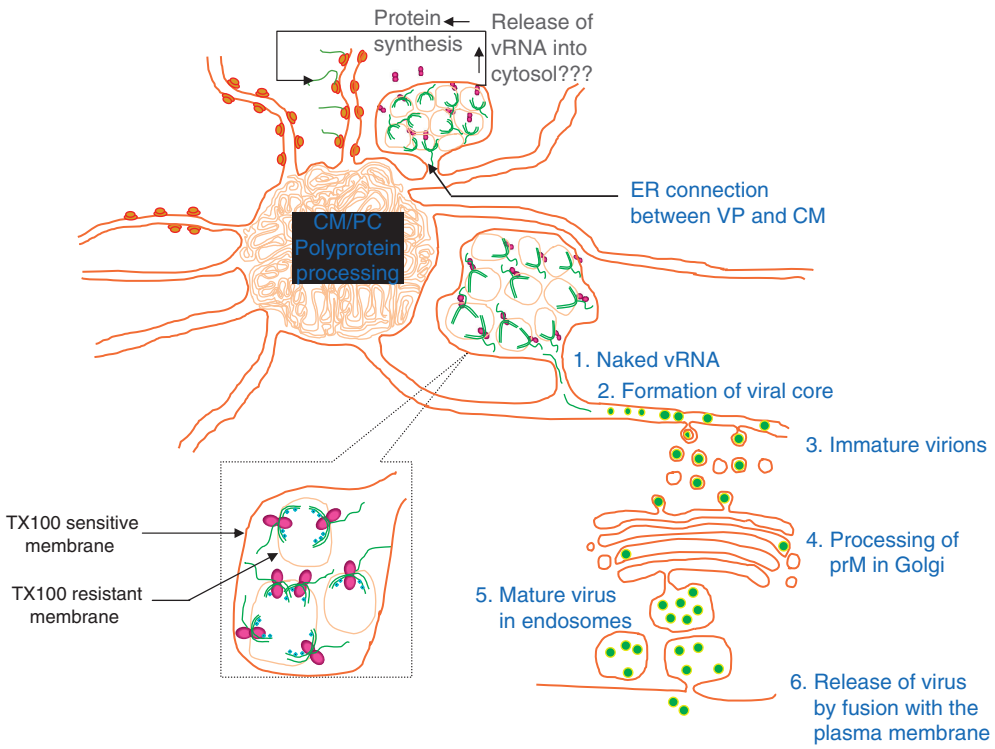

Figure 9 Proposed model of flavivirus replication in connection with cellular membranous structures. Translation of viral proteins is associated with CMs whereas replication is carried out within VPs. The dsRNA of RF in association with proteins of the polymerase complex (RC) is anchored to the internal leaflet of VP membrane whereas newly synthesized plus ssRNA is released from the RC. Protease, nuclease, and detergents reveal encasement within double-layered membrane compartments. *Journal of Biological Chemistry* 278: 24388–24398.

record the highest number of hospitalized cases. These numbers have risen from 700 to 1200 cases per year in the 1950s and 1960s to greater than 11 000 per year in the 1990s, following *Perestroika* and initial breakdown of the infrastructure. The incidence in Europe is lower but nonetheless significant, with about 3000 cases per year. Although it can affect people of all ages, the highest incidence occurs among the most active groups, that is, 17–40 year olds.

The incidence of clinical disease in endemic regions is dependent on the frequency of forest visits, the density of ticks in different years, the concentration of virus in ticks, and the virulence of circulating strains. Taking all these factors into account, it was estimated that one clinical case must occur for every 100 people bitten by ticks, and this correlates with the observation that in regions where more than 60% of ticks carry virus, about 1.4% of people develop TBE after being bitten.

Variety of Clinical Manifestations

TBEV is recognized as a dangerous human pathogen, causing a variety of clinical manifestations, although asymptomatic infections constitute about 70–95% of all TBEV infections. Symptoms include (1) mild or moderate fever with complete recovery of patients (about 90% of all clinical manifestations), (2) subacute encephalitis with nearly complete recovery or residual symptoms that may or may not disappear with time, (3) severe encephalitis associated with irreversible damage to the central nervous system (CNS), resulting in disability or death (about 4–8%), and (4) slow (months to decades) progressive or chronic encephalitis (1–2%).

Initially in the 1940–50s it was believed that the same virus produced encephalitis over the whole of Europe and Asia. However, with the improvement of serological diagnosis and the advent of phylogenetic analysis, three subtypes of TBEV were identified.

Human infections with far-Eastern TBEV subtype viruses produce the most severe form of CNS disorder, with a tendency for the patient to develop focal meningoencephalitis or polyencephalitis, and case–fatality rates between 20% and 40%. Siberian strains are often associated with high prevalence of the nonparalytic febrile form, with case–fatality rates rarely exceeding 6–8%. There is a tendency for some patients to develop chronic TBE, predominantly in association with Siberian TBEV strains. The disease produced by West European TBEV strains is biphasic, with fever during the first phase and neurological disorders of differing severity during the

second phase, which occurs in 20–30% of patients, with a case–fatality rate of 1–2%. While Louping ill virus and the related Spanish, and Turkish/Greek viruses produce fatal encephalitis in animals, they are only rarely associated with disease in humans, probably primarily because of the lower (in comparison with TBEV) rates of human exposure to infected ticks.

Biphasic milk fever is an unusual form of TBE originally observed in western Russia mainly associated with the consumption of goat's milk. West European strains of TBEV were isolated from unpasteurized goat's milk and from patients. Later, similar outbreaks of biphasic milk fever were reported in central Europe and Siberia. The apparent difference in clinical manifestations of TBE contracted by tick-bite or by the alimentary route may be explained by differences in the type of immunological response.

Human Disease Produced by Other Tick-Borne Flaviviruses

POWV also produces encephalitic infections in humans although not on an epidemic scale. POWV circulates in Russia, the USA, and Canada, where it may cause human encephalitis with a high incidence of neurological sequelae and up to a 60% case–fatality rate. In North America POWV has diverged to produce a closely related deer tick virus (DTV) that has a predilection for different rodent species. Langat virus has been isolated in Malaysia and Thailand; there are no registered cases of human disease associated with this virus. However, when Langat virus was used as a live, attenuated vaccine in human trials in Russia, one in 10 000 patients developed encephalitis.

Three tick-borne flaviviruses cause hemorrhagic disease rather than encephalitis in humans, namely Omsk hemorrhagic fever virus, Kyasanur Forest disease virus, and Alkhurma virus. As yet there is no explanation for these differences in virulence characteristics. Epidemic foci of Omsk hemorrhagic fever virus in the Omsk and Novosibirsk regions of western Siberia usually follow epizootics in muskrats (*Ondatra zibethica*) from which local hunters become infected by the virus when they handle infected animals. The most marked pathological signs of the disease are focal visceral hemorrhages in the mucus of the nose, gums, uterus, and lungs. Convalescence is usually uneventful without residual effects; fatal cases have been recorded, but rarely (0.5–3%).

Kyasanur Forest disease virus was first recognized in 1957 in India where it caused hemorrhagic disease among monkeys and humans, frequently with fatal outcome. It is believed that perturbation of regions of the forest for land development led to increased exposure of monkeys and humans to ticks carrying the virus. Subsequently, it has become evident that this virus circulates throughout western India and this may explain the close antigenic and genetic link with Alkhurma virus, which was isolated from fatal human cases of hemorrhagic fever in Saudi Arabia. Recent evidence has demonstrated the presence of Alkhurma virus in ticks associated with camels. Whether or not this or a closely related virus circulates in Africa remains to be determined.

Prevention and Control of TBE

Vaccination is the most efficient method available for preventing TBE in enzootic regions. Currently two inactivated vaccines are commercially available. The European vaccine has significantly reduced the annual incidence of TBE in Austria and Germany. A similar vaccine, based on a far-Eastern strain of TBEV, has been used successfully in Russia to immunize at-risk laboratory personnel. Other preventive measures routinely employed in TBE endemic areas are (1) education of residents in methods of avoiding tick-bites (when visiting tick-infested areas, wearing appropriate clothing, regularly inspect for feeding ticks, report tick-bite to medical authorities); (2) treat cats and dogs with acaricides; (3) clear thick, moist vegetation areas from around houses; and (4) spray acaricides in forested areas, close to habitation.

Human trials of a live, attenuated vaccine for Langat virus produced an unacceptably high incidence of TBE (1/10 000). However, these trials demonstrated the higher protection efficiency of live, attenuated vaccines in comparison with inactivated vaccines. Currently safer strategies to produce live, attenuated vaccine are being developed such as (1) RNA- or DNA-based vaccines; (2) engineering TBEV mutants with multiple attenuating mutations or large deletions within their genomes, resulting in the loss of neuroinvasiveness; and (3) engineering chimeric yellow fever virus vaccine containing substituted TBEV E and M proteins.

Currently there are no safe, effective antivirals for TBEV infections, but there is promising progress in tests with small-interfering RNAs (siRNAs). These short molecules, ~21 nt long, bind to homologous regions of viral mRNA, thus interfering with the replication cycle. Another antiviral strategy with which rapid progress is being made is based on the design of molecules that can target specific regions within viral replicative enzymes. If the twentieth century was significant for its development of effective vaccines, the twenty-first century might be recognized for its development of effective antivirals.

Tobacco Mosaic Virus

The Beginnings of Virology

Tobacco mosaic virus occupies a unique place in the history of virology and was in the forefront of virus research since the end of the nineteenth century. It was the German Adolf Mayer, working in the Netherlands, who in 1882 first described an important disease of tobacco which he called tobacco mosaic disease. He showed that the disease was infectious and could be transmitted to healthy tobacco plants by inoculation with capillary glass tubes containing sap from diseased plants. Although Mayer could not isolate a germ as the cause of the disease, he did not question the then prevailing view that all infectious diseases were caused by microbes and he remained convinced that he was dealing with a bacterial disease.

About the same time, in St. Petersburg, Dmitri Ivanovsky was studying the same disease and he reported in 1892 that when sap from a diseased tobacco plant was passed through a bacteria-retaining Chamberland filter, the filtrate remained infectious and could be used to infect healthy tobacco plants. Ivanovsky was the first person to show that the agent causing the tobacco mosaic disease passed through a sterilizing filter and this gave rise to the subsequent characterization of viruses as filterable agents. A virology conference was held in 1992 in St. Petersburg to celebrate the centenary of this discovery. Although Ivanovsky is often considered one of the fathers of virology, the significance of his work for the development of virology remains somewhat controversial because all his publications show that he did not really grasp the significance of his filtration experiments. He remained convinced that he was dealing with either a small bacterium or with bacterial spores and never appreciated that he had discovered a new type of infectious agent.

Following in the footsteps of Mayer, Beijerinck in Delft, Holland, again showed in 1898 that sap from tobacco plants infected with the mosaic disease was still infectious after filtration through porcelain filters. He also demonstrated that the causative agent was able to diffuse through several millimeters of an agar gel and he concluded that the infection was not caused by a microbe.

Beijerinck called the agent causing the tobacco mosaic disease a *contagium vivum fluidum* (a contagious living liquid), in opposition to a *contagium vivum fixum.* In those days the term *contagium* was used to refer to any contagious, disease-causing agent, while the term *fixum* meant that the agent was a solid particle or a cellular microbe. On the basis of his filtration and agar diffusion experiments, Beyerinck was convinced that the agent causing tobacco mosaic was neither a microbe nor a small particle or corpuscle (meaning a small body or particle from the Latin *corpus* for body). He proposed instead that the disease-causing agent,which he called a virus, was a living liquid containing a dissolved, nonparticular and noncorpuscular entity.

Lute Bos has claimed that Beijerinck's introduction in 1898 of the unorthodox and rather odd concept of a *contagium vivum fluidum* marked the historic moment when virology was conceived conceptually. However, it is clear that his definition of a virus as a soluble, living agent not consisting of particles certainly does not correspond to our modern view of what a virus is. It is Beijerinck's insistence that a virus is not a microbe and his willingness to challenge the then widely held view that all infectious diseases are caused by germs that make many people regard his contribution to the development of virology as more important than that of Ivanovsky. In 1998, a meeting held in the Netherlands commemorated the centenary of the work of Beijerinck on TMV. About the same time a meeting was held in Germany to honor the contribution of Loeffler and Frosch who, also in 1898, had shown that the agent causing the foot-and-mouth disease of cattle was able to pass through a Chamberland-type filter, in the same way as TMV. In addition the German workers also established that their disease-causing agent was not able to go through a finer grain Kitasato filter, from which they concluded that the agent, which was multiplying within the host, was corpuscular and not soluble as claimed by Beijerinck. Loeffler, however, continued to believe that his pathogen was a very small germ or spore, invisible in the light microscope, that was unable to cross the small pores of a Kitasato filter.

There is no doubt that none of these 'fathers' of virology realized the nature of the filterable pathogenic agents they were investigating and that the term virus which they used did not have the meaning it has today. It took another 30 years before chemical analysis eventually revealed what viruses are actually made of.

Physical and Chemical Properties of TMV

A major change in our perception of what viruses are occurred in 1935 when Stanley, working at the Rockefeller Institute in Princeton, obtained needle-like crystals of TMV that were infectious and consisted of protein. He used methods that were being developed at the time for purifying enzymes and was greatly helped by a bioassay developed by Holmes in 1929 that made it possible to quantify the amount of TMV present in plant sap. In this assay, extracts containing the virus are rubbed on the leaves of *Nicotiana glutinosa* tobacco plants which leads to a number of necrotic lesions proportional to the amount of virus present.

Stanley's demonstration that TMV was a crystallizable chemical substance rather than a microorganism, a discovery that earned him the Nobel Prize in 1946, had a profound impact on the thinking of biologists because it suggested that viruses were actually living molecules able to reproduce themselves. For a while, it seemed that viruses closed the gap between chemistry and biology and might even hold the key to the origin of life.

Stanley had originally described TMV as a pure protein, but in 1936 Bawden and Pirie showed that the virus contained phosphorus and carbohydrate and actually consisted of 95% protein and 5% RNA. TMV thus became the first virus to be purified and shown to be a complex of protein and nucleic acid. Following the development of ultracentrifuges in the 1940s, ultracentrifugation became the standard method for purifying TMV and many other viruses.

In 1939, TMV became the first virus to be visualized in the electron microscope and in 1941, TMV particles were shown to be rods about 280 nm long and 15 nm wide. Subsequently, X-ray analysis established that the rods were hollow tubes consisting of a helical array of 2130 identical protein subunits with 16(1/3) subunits per turn and containing one molecule of RNA deeply embedded in the protein subunits at a radius of 4 nm (**Figure 1**). The length of the TMV particle is controlled by the length of the RNA molecule which becomes fully coated with protein and is thereby protected from nuclease attack.

The viral protein subunits can also aggregate on their own, without incorporating RNA, to form rods very similar to TMV particles but in this case the rods are of variable length (**Figure 2**). It is possible to degrade the virus particles with acetic acid or weak alkali and to obtain in this way dissociated protein subunits and viral RNA, the latter being rapidly degraded by nucleases. In 1956 Gierer and Schramm in Tübingen, Germany, and Fraenkel-Conrat in Berkeley, California, showed that if the viral RNA was obtained by degrading the particles with phenol or detergent, intact RNA molecules were obtained that were infectious and could produce the same disease as intact virus. This was the first demonstration that the nucleic acid component of a virus was the carrier of viral infectivity and that it possessed the genetic information that coded for the viral coat protein.

In 1960 the TMV coat protein was the first viral protein to have its primary structure elucidated when its sequence was determined simultaneously in Tübingen and in Berkeley and found to consist of 158 amino acids. Subsequently, the coat protein sequence of numerous TMV mutants obtained by treating the virus with the mutagenic agent nitrous acid was also determined and these sequence data helped to establish the validity of the genetic code that was being elucidated in the early 1960s in Nirenberg's and Ochoa's laboratories. One of the changes induced by the action of nitrous acid on viral RNA is the nucleotide conversion of cytosine (C) to uracil (U). This changes the codon CCC for the amino acid proline to the codons UCC or CUC for serine and leucine, respectively. In addition, these two codons can be further converted to UUU which codes for phenylalanine. When the coat protein sequences of various TMV mutants were determined, it was found that

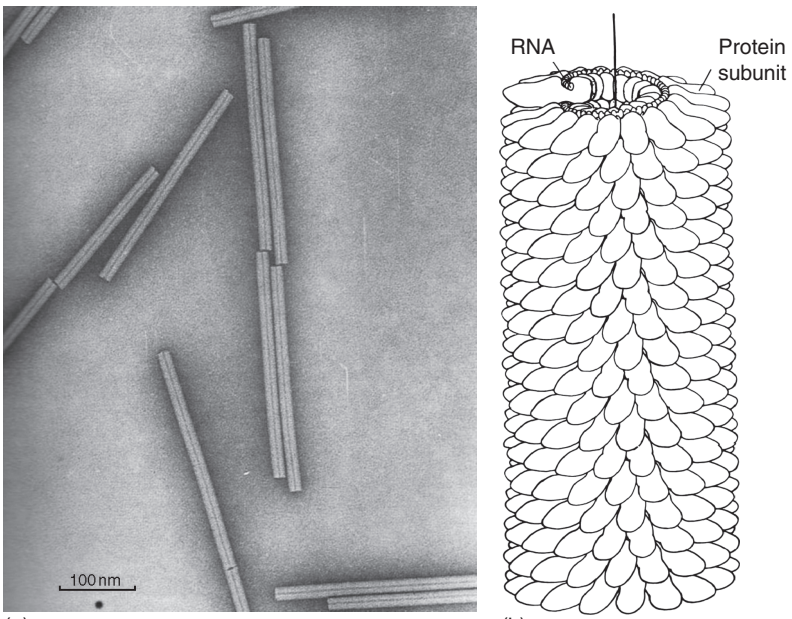

Figure 1 (a) Electron micrograph of negatively stained TMV particles. (b) Diagram of a TMV particle showing about one-sixth of the length of a complete particle. The protein subunits form a helical array with 16(1/3) units per turn and the RNA is packed at a radius of about 4 nm from the helix axis. From Klug A (1999) The tobacco mosaic virus particle: Structure and assembly. *Philosophical Transactions of the Royal Society*: *Biological Sciences* 354: 531–535.

most of the exchanged amino acids could be attributed to C→U nucleotide conversions, which confirmed the validity and universality of the proposed genetic code.

A particularly interesting mutation present in mutant Ni 1927 was the exchange proline to leucine at position 156 in the sequence which was found to greatly decrease the chemical stability of the virus. It had been known for many years that the virus was resistant to degradation by the enzyme carboxypeptidase and that this enzyme released only about 2000 threonine residues from each virus particle. The C-terminal residue in the coat protein is in fact threonine and the enzyme degradation data were interpreted at the time to mean that the virus particle contained 2000 subunits. However, when the proline at position 156 was replaced by leucine in the mutated protein, the enzyme was able to degrade the protein far beyond the C-terminal residue. The location of a proline near the C-terminus together with the presence of an acetyl group on the N-terminus are actually responsible for the remarkable resistance of the virus to exopeptidase degradation. The same exchange at position 156 in mutant Ni 1927 also led to an interesting discovery in immunology (see below).

Self-Assembly of TMV Particles

Dissociated coat protein molecules of TMV are able to assemble into different types of aggregates depending on the pH and ionic strength (**Figure 2**). The disk aggregate is a two-layer cylindrical structure with a sedimentation coefficient of 20 S, where each layer consists of a ring of 17 subunits compared with the 16(1/3) molecules present in each turn of the assembled helix. The disks are able to form stacks which can be either polar or nonpolar, depending on the relative orientation of adjacent disks (**Figure 2**). Short stacks of disks were shown to be nonpolar by immunoelectron microscopy, using monoclonal antibodies that reacted with only one end of the viral helix but were able to bind to both ends of the stacked disks. Whereas short polar stacks of disks can be transformed via lock-washer intermediates into helices (**Figure 2**), this is not possible for nonpolar stacks which cannot be incorporated as such during the elongation process that leads to the formation of RNA-containing virus particles.

It is generally accepted that initiation of TMV assembly from its RNA and protein components requires a 20 S protein aggregate, which could be either a disk or a short, lock-washer type proto-helix. The surface of this aggregate constitutes a template which is recognized by a specific viral RNA sequence. The nucleation of the assembly reaction was found to occur by a rather complex process involving a hairpin structure on the viral RNA, known as the origin of assembly and located about 1000 nucleotides from the 3′ end, which is inserted through the central hole of the 20 S aggregate. The nucleotide sequence of the stem–loop hairpin is responsible for the preferential incorporation of viral RNA rather than foreign RNA. Elongation occurs by addition of more protein subunits which pull up more RNA through the central hole. This

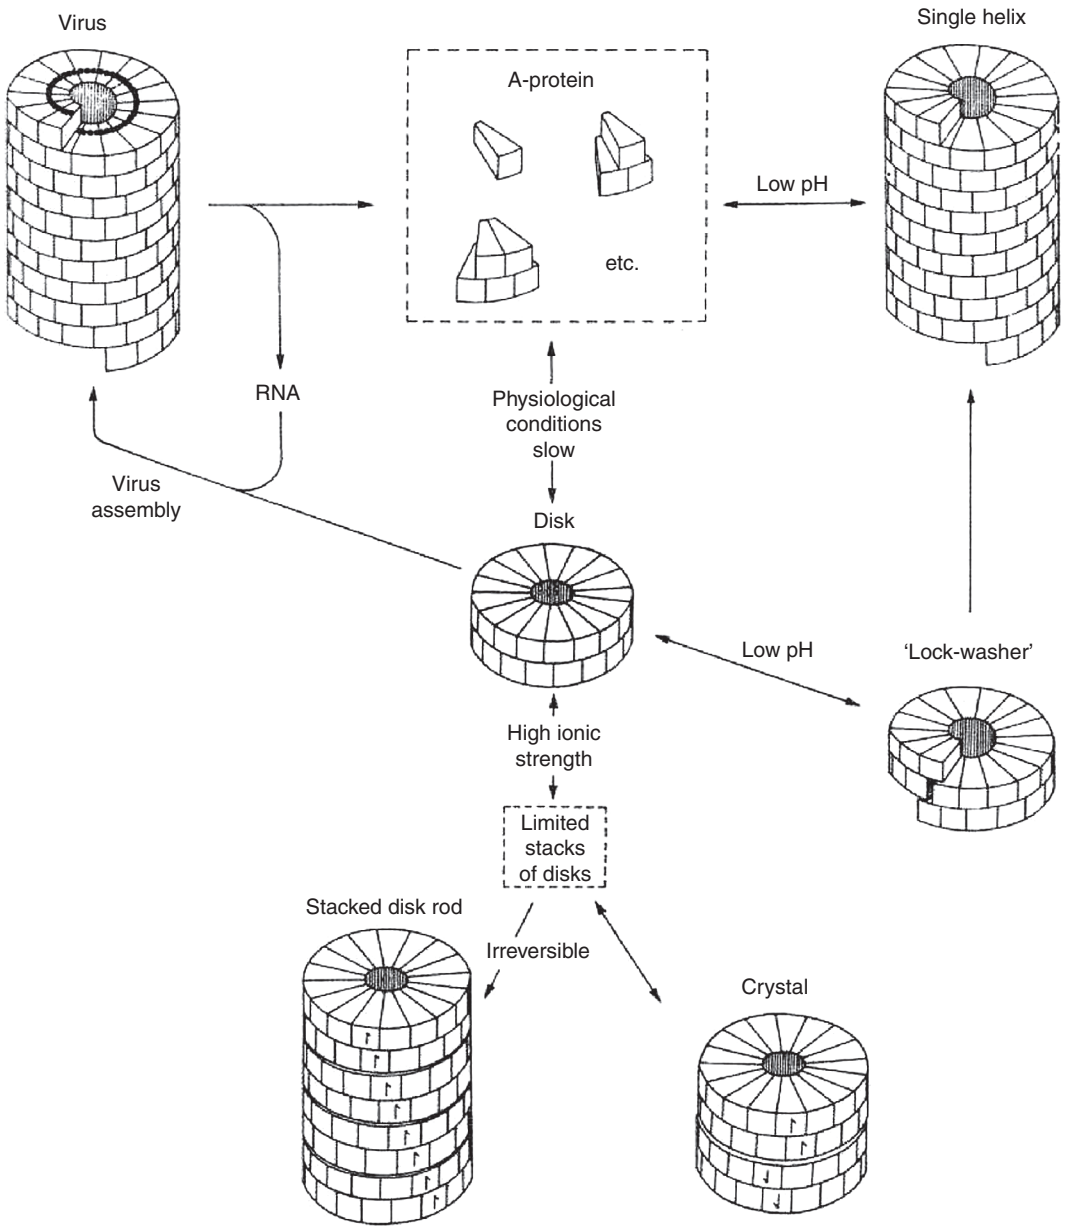

Figure 2 Diagram showing the different polymorphic aggregates of TMV coat protein obtained at different pH values and ionic strengths. Note that both polar and nonpolar stacked disks can be obtained. The 'lock-washer' is not well defined and represents a metastable transitory state. Adapted from Durham ACH and Klug A (1972) Structures and roles of the polymorphic forms of tobacco mosaic virus protein. *Journal of Molecular Biology* 67: 315–332, with permission from Elsevier.

process requires that the 5′ tail of the RNA loops back down the central hole and is slowly 'swallowed up' while the 3′ tail continues to protrude freely from the other end. This unexpected mechanism was visualized by electron micrographs taken in Hirth's laboratory in Strasbourg which revealed how particles were growing with both 3′ and 5′ RNA tails protruding initially from the same end of the particle. The elongation is thus bidirectional and occurs faster along the longer 5′ tail by incorporation of 20 S aggregates and more slowly toward the 3′ end through incorporation of 4 S protein. The elucidation of the assembly process was greatly facilitated by the sequencing of the viral RNA which was completed in 1982. TMV RNA consists of 6395 nucleotides and was the first genome of a plant virus to be sequenced completely.

Virus Disassembly

Since TMV particles are extremely stable *in vitro*, it was not at all obvious how the RNA managed to be released from the particles in order to start the virus

replication cycle. Using a cell-free translation system, Wilson discovered that the disassembly of TMV particles is initiated when the end of the particles containing the 5′ terminus of the RNA becomes associated with ribosomes. This leads to viral subunits becoming dislodged from the particles while the 5′ terminal open reading frame in the RNA is being translated by the ribosomes, a process known as co-translational disassembly. This mechanism allows the coat protein subunits to protect the RNA from enzymatic degradation until the particle has reached a site in the infected cell where translation can be initiated.

Antigenicity of TMV

The antigenic properties of TMV have been studied extensively for more than 60 years and these studies have given us much information on how antibodies recognize proteins and viruses. TMV is an excellent immunogen and antibodies to the virus are readily obtained by immunization of experimental animals. When the sequence of TMV coat protein became available, it was possible for the first time to locate the antigenic sites or epitopes of a viral protein at the molecular level. Initial studies focused on two antigenic regions of the coat protein, the C-terminal region (residues 153–158) situated at the surface of virus particles and the disordered loop region (residues 103–112) located in the central hole of the particles and accessible to antibodies only in dissociated protein subunits (**Figure 3**). The C-terminal hexapeptide coupled to bovine serum albumin was used by Anderer in Tübingen to raise antibodies and the resulting antiserum was found to precipitate the virus and neutralize its infectivity. Since both natural peptide fragments and synthetic peptides were used in this work, Anderer and his colleagues should be credited with the discovery that synthetic peptides can elicit antibodies that neutralize the infectivity of a virus. Only when similar results were obtained with animal viruses 15 years later, did the potential of peptides for developing synthetic vaccines become clear.

It has been known since the 1950s that intact TMV particles and dissociated coat protein subunits harbor different types of epitopes recognized by specific antibodies. Certain epitopes present only on virions are constituted by residues from neighboring subunits that are recognized as a single entity by certain antibodies; other epitopes arise from conformational changes in the protein that result from intersubunit bonds. Both these types of epitopes which depend on the protein quaternary structure and are absent in dissociated protein subunits have been called neotopes. Another type of epitope known as cryptotope occurs on the portion of the protein surface that is buried in the polymerized rod and becomes accessible to antibodies only in the dissociated subunits.

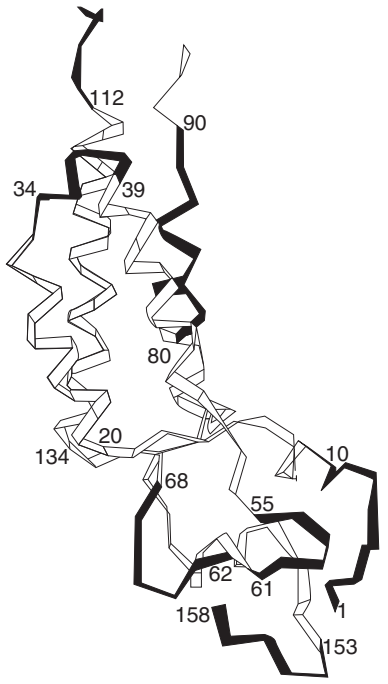

Figure 3 Backbone of the TMV coat protein subunit based on crystallographic data. Residues 94–106 have been omitted because this region, located on the inside of the particle, is disordered. The N and C termini of the protein are located on the outer surface of TMV particles. The position of seven continuous epitopes (residues 1–10, 34–39, 55–61, 62–68, 80–90, 108–112, and 153–158) is indicated by solid lines. Reproduced from Al Moudallal Z, Briand JP, and Van Regenmortel MHV (1985) A major part of the polypeptide chain of tobacco mosaic virus is antigenic. *EMBO Journal* 4: 1231–1235, with permission from Nature Publishing Group.

The mapping of neotopes and cryptotopes on the surface of TMV coat protein was greatly simplified once monoclonal antibodies (Mabs) became available. Many continuous epitopes were identified at the surface of dissociated coat protein subunits by measuring the ability of peptides to react with Mabs or with antisera (**Figure 3**). These epitopes were found to correspond to regions of the protein shown by X-ray crystallography to possess a high segmental mobility. This correlation between antigenicity and mobility along the peptide chain was also found to exist in other proteins and was used to develop algorithms for predicting the location of epitopes in proteins from their primary structure.

The surface of the protein subunits accessible at either end of the virus particle is different and the one located near the 5′ terminus end of the RNA harbors the two helices corresponding to residues 73–89 and 115–135 (**Figure 3**). Many Mabs specific for this surface have been obtained and in addition to reacting with both ends of nonpolar stacked disks, they were found to block TMV disassembly by sterically preventing the interaction between RNA and

ribosomes. It has been suggested that if such antibodies could be expressed in plants, they might be able to control viral infection.

Another interesting immunological phenomenon was discovered when TMV antibodies were analyzed for their ability to react with certain TMV mutants. It was found that all rabbits immunized with TMV induced the formation of heterospecific antibodies, that is, antibodies that were unable to react with the TMV immunogen but recognized the mutant Ni 1927 quite well. When all the antibodies in a TMV antiserum capable of reacting with TMV were removed by cross-absorption with the virus, it was found that the depleted antiserum still reacted strongly with this mutant which had a single proline→leucine exchange. Apparently the removal of the proline at position 156 exposes binding sites for both peptidases and antibodies that are normally out of reach in the wild-type protein structure. The induction of heterospecific antibodies by immunization with TMV is another illustration of the difference between the antigenicity and immunogenicity of proteins. TMV particles possess the immunogenic capacity of eliciting heterospecific antibodies that react with the Ni 1927 mutant but do not have the antigenic capacity of reacting with these antibodies. The reverse situation where an antigenic peptide or protein is able to react with a particular antibody but is unable to induce the same type of antibody when used as immunogen is a more commonly observed phenomenon which greatly hampers the development of synthetic peptide vaccines.

Many of the viruses that are currently classified in the genus *Tobamovirus* were initially considered to be strains of TMV on the basis of similar particle morphology and ability to cross-react with TMV antibodies. Antigenic relationships between different tobamoviruses were quantified using a parameter known as the serological differentiation index (SDI) which is the average number of twofold dilution steps separating homologous from heterologous antiserum titers. A close correlation exists between the antigenic distance of two viruses expressed as SDI values and the degree of sequence difference in their coat proteins. In general, when two viruses differ antigenically by an SDI value larger than 4, they are considered to belong to separate species. This is valid only if relatedness is measured with polyclonal antisera containing antibodies to a range of different epitopes since comparisons made with Mabs specific for a single epitope will emphasize antigenic similarities or differences depending on which particular Mab is used.

Relationships between individual tobamoviruses are nowadays usually assessed by comparisons between viral genomes. Phylogenetic studies have shown that tobamoviruses are very ancient and co-evolved with their angiosperm hosts, which means that they are at least 120 million years old.

Replication and Cell-to-Cell Movement of TMV

TMV-infected tissues contain four viral proteins: the 126 kDa and 183 kDa proteins of the replicase complex, the 30 kDa movement protein, and the 17.6 kDa coat protein. TMV replication is initiated by the translation of the viral RNA to produce the replicase proteins and this leads to the synthesis of minus-sense and plus-sense copies of the RNA. Translation of the viral coat protein gene then occurs leading to the assembly of progeny virus particles from full-length genomic RNA and coat protein. The translation of the coat protein and movement protein is controlled by the production of two separate subgenomic mRNAs, a mechanism later found to occur in many other viruses but first demonstrated with TMV.

The mechanism that allows plant viruses to move from cell to cell in their hosts has remained a mystery for many years. The rigid cellulose-rich walls of plant cells impede intercellular communication which occurs only through tubular connections known as plasmodesmata. However, plasmodesmata are too narrow to allow the passage of virus particles. Studies with the 30 kDa TMV movement protein showed that this protein changed the size exclusion limit of the plasmodesmata, allowing the virus to move through them in the form of a thin, less than 2 nm wide, ribonucleoprotein complex composed of the genomic RNA and the movement protein. Movement proteins have subsequently been found in many other plant viruses and shown to possess RNA-binding properties.

Studies with TMV also revealed how plant viruses encode a suppressor to combat the post-transcriptional gene silencing reaction that plants use to fight virus infection.

Biotechnology Applications of TMV

TMV-resistant plants have been obtained by transforming them with a DNA copy of the TMV coat protein gene. This coat protein-mediated resistance is due to the ability of transgenically expressed coat protein to interfere in transgenic cells with the disassembly of TMV particles. Coat protein-mediated resistance has subsequently been obtained with many positive-sense RNA plant viruses.

A portion of the TMV RNA leader sequence, called omega, was shown to enhance the translation of foreign genes introduced into transgenic plants. This translational enhancer has been incorporated successfully in many gene vectors for a variety of applications.

In another type of application, TMV particles have been used as surface carriers of foreign peptide epitopes for constructing recombinant vaccines and producing them in plants. It was found that the N- and C-termini of the TMV coat protein as well as the surface loop area corresponding to residues 59–65 were able to accept foreign peptide

fusions without impairing the ability of the resulting chimeric virus to infect plants systemically. Several experimental vaccines against viral and parasitic infections that are based on genetically engineered TMV particles produced in tobacco are currently under development.

In conclusion, it is clear that a series of historical accidents together with the fact that large amounts of remarkably stable TMV particles could be obtained from infected plants, allowed this virus to play a major role in the development of virology. In addition, studies of TMV also contributed significantly to the advancement of molecular biology and to our understanding of the physicochemical and antigenic properties of macromolecules.

Glossary

Transient virus vector The use of a virus, such as tobacco mosaic virus, for the expression of a foreign gene following insertion of the sequence at a site in the viral genome.

Virus vector A biological organism, such as an aphid, leafhopper, thrips, whitefly, or fungus, that is capable of specific horizontal transmission of a virus from one plant to another.

Introduction

Tobacco has played a role in agricultural history and in the history of virology. Twenty plant virus names begin with tobacco, indicating that tobacco was a host of great agricultural and economic importance, was susceptible to a large number of viruses, and was the object of early virus research. Early in the last century, when viruses were first discovered and named, research programs emphasized controlling diseases of tobacco, many of which were caused by viruses. This article discusses the role of the tobacco in virology, viruses as causes of tobacco diseases, and some of the major milestones in virology achieved with tobacco viruses.

Tobacco is in the genus *Nicotiana* (family Solanaceae), created in 1565 and named after a French promoter of tobacco, Jean Nicot von Villemain. Although the genus is quite diverse and contains about 100 species, only two species have been extensively cultivated as commercial crops. *Nicotiana rustica* was originally grown by Native Americans in the eastern United States, and was the first tobacco species introduced to England and Portugal. *Nicotiana tabacum* was grown in Mexico and South America, and was introduced to the early Spanish explorers. With the cultivation of the species by the Virginia colony in Jamestown, *N. tabacum* became the preferred tobacco type, and is the predominant species today.

Tobacco is the most widely grown nonfood crop in the world, and is thought to have been used by people in the Americas for smoking and chewing since 1000 BC. It played a major role in the colonization of the Americas by Europeans, and was an economic driver for nearly four centuries. Although always a controversial and exotic commodity, tobacco became established in Europe before coffee, tea, sugar, and chocolate. In spite of the human health risks of tobacco products, tobacco continues to be grown throughout the world.

Three major types of the *N. tabacum* predominate, each with different characteristics depending on the final use of the tobacco product. The most common type is Virginia or flue-cured tobacco, which is used for cigarette, pipe, and chewing tobacco. It is grown worldwide, with the USA and China as major producers. Burley tobacco, the second-most popular type, is air-cured and used in chewing tobacco, and is flavored and blended for American-type cigarettes and pipe tobacco. Burley tobacco is also widely grown, but in not as many countries as is Virginia tobacco. A third type, Oriental or Turkish tobacco, is a small-leafed tobacco and is sun-cured and used in English blends. The name is derived from the eastern Mediterranean area where it is grown. Oriental cultivars Samson from Turkey and Xanthium from Greece have been widely used in virus research.

Viruses as Causal Agents of Tobacco Diseases

There are 20 viruses that were either first isolated from tobacco or contain tobacco as the host in their name (TEV, TWV) (**Table 1**). Chronologically these reports span over a century. Seven viruses naturally infect tobacco, but were first isolated from other crops and named from them (**Table 2**). The viruses are discussed individually, but some are synergistic in mixed infections and cause symptoms more severe than either virus alone. Satellites viruses and RNAs associated with tobacco viruses were the first to be recognized as subviral entities (**Table 3**). The greatest recent new activity with tobacco viral diseases has been in understanding the complexity of the viruses with similarities to tobacco leaf curl virus (family *Geminiviridae*) and their worldwide distribution.

Tobacco in Virology History

Tobacco was used as a host plant for virology research leading to many fundamental discoveries, only a few of which are highlighted here. *Nicotiana* species widely used for virus propagation and host range tests are *N. clevelandii*, *N. tabacum*, *N. glutinosa*, *N. megalosiphon*, *N. sylvestris*, and, more recently, *N. benthamiana*. These species are reported as being experimentally susceptible to 267, 231, 201, 93, 57, and 141 viruses, and insusceptible to 80, >200, 175, 35, 35, and 40 viruses, respectively. Responses of tobacco species and cultivars to mechanical inoculation are used for virus and strain identification. Cytopathic effects and inclusion bodies induced by plant viruses were first observed by light microscopy with X-bodies of TMV and nuclear and cytoplasmic inclusions of TEV and PVY. Details of plant virus replication processes were advanced by studies using tobacco leaf protoplasts. Tobacco was also the first plant to be genetically transformed by recombinant DNA techniques, and the first in which pathogen-derived resistance was demonstrated by the insertion of the coat protein gene from TMV. Tobacco transformed with noncoding viral sequences of TEV led to the discovery of RNAi and viral-induced gene silencing (VIGS).

Viruses Causing Economically Important Diseases of Tobacco

Tobamoviruses

The causal agent of a mosaic disease of tobacco, tobacco mosaic virus (TMV, genus *Tobamovirus*) became the first virus to be purified, crystallized, and characterized. Milestones in virology history that have been accomplished with TMV have been well documented, and will not be repeated here. The virus has a rigid, rod-shaped particle constructed of a single capsid protein arranged helically around a single strand of RNA encoding four proteins, functions of which are well characterized in viral replication and movement. Transient vectors can be constructed from TMV, permitting insertion and expression of foreign genes for new products, or for labeling virus for pathogenicity and cellular biology experiments.

The mosaic disease occurs worldwide wherever tobacco is grown. The stability of the virus in tobacco products, its highly infectious nature, and efficient inoculation by mechanical abrasion contributes to the difficulty tobacco farmers have had in controlling this virus. In certain cultivars of burley and ornamental tobaccos, the *N* gene for resistance has provided durable resistance for nearly 75 years, considered remarkable for an RNA virus, as resistance-breaking strains have not developed. Use of the *N* gene in Virginia or flue-cured tobacco, however, has not been successful because of poor-quality traits associated with linked genes. Efforts to resolve this using hybrids have only been moderately successful because systemic necrosis can develop in field-infected plants and cause more serious loss than that caused by mosaic.

Other tobamoviruses infecting tobacco are tomato mosaic virus (ToMV) and tobacco mild green mosaic virus (TMGMV). ToMV and TMV are seed-borne on tomato seed, but reportedly not on tobacco seed. However, production of tobacco seedlings in float trays in

greenhouses suggests anecdotally that TMV-infested seed may provide inoculum source for seedling infections. Instances of spread of ToMV from tomato seedlings to tobacco seedlings have been observed. ToMV causes more severe symptoms than does TMV. TMGMV naturally infects *N. glauca*, and is often associated with an icosahedral satellite virus, satTMV (**Table 3**).

Bromoviruses

Certain viruses of tobacco are the type members of three genera of the family *Bromoviridae*, namely cucumber mosaic virus (CMV, genus *Cucumovirus*), alfalfa mosaic virus (AMV, genus *Alfamovirus*), and tobacco streak virus (TSV, genus *Ilarvirus*). These viruses continue to occur in tobacco worldwide. Disease outbreaks are sporadic, but are of economic significance in fields infected at a high incidence. All three viruses have very wide host ranges, are known to infect a number of weeds and native plants naturally, and are seed transmitted in many of their host plants. CMV and AMV are transmitted in a stylet-borne, nonpersistent manner by many species of aphids. TSV, however, is spread by contact and through pollen carried by thrips.

Common properties include a tripartite, single-stranded RNA (ssRNA) genome, and encapsidation of a fourth subgenomic RNA encoding the capsid protein. Particles have icosahedral symmetry, but AMV forms multiple bacilliform particles and TSV forms quasi-icosahedrons. CMV capsids are of $T=3$ symmetry.

Cucumber mosaic and alfalfa mosaic viruses

Symptoms caused by CMV are similar to those of TMV. CMV is an important tobacco pathogen in Asia and in certain European countries. In recent surveys in Greece, burley, Virginia, and oriental types all had a high incidence of CMV, even up to 100% infected plants in some fields. Symptoms of AMV on tobacco are a bright yellowing of leaf areas, broad rings, and mosaic on young leaves. AMV incidence was lower, but was highest in tobacco growing near alfalfa fields, a source of the virus.

Many fundamental discoveries of genome structure, organization, and encapsidation occurred with AMV and CMV in the 1960s and 1970s using tobacco as the main test

species. Sucrose density-gradient centrifugation enabled separation of the multiple particles of AMV, leading to experiments to demonstrate the requirement of RNA1, RNA2, and RNA3 plus either RNA4 or free coat protein for infectivity. Genetic experiments were conducted by mixed inoculations with RNA species from biologically distinct strains. Similar experiments were conducted with CMV, which required separation on cesium chloride gradients based on density to demonstrate separate encapsidation of RNA1, RNA2, and RNA3 + RNA4 in a third capsid. Infectivity required RNAs 1, 2, and 3, but not RNA4 or coat protein. A fifth, small RNA species, initially termed RNA5 or CARNA5 (CMV-associated RNA), was later shown to be the first satellite RNA species. These satellite RNAs can either ameliorate or exacerbate symptoms in crops. Severe lethal necrosis symptoms are associated with CMV satellite RNA in tomato in Italy and tobacco in India.

Tobacco streak virus

TSV is rarely reported on tobacco, but is an important pathogen of many annual and vegetatively propagated crops and wild species worldwide. In tobacco, TSV causes necrotic lines along veins of leaves as virus moves systemically from the point of inoculation. Symptoms develop on a few leaves, and then plants recover. Incidence of infected tobacco plants is usually low. Thrips are recognized as a vector of TSV. TSV belongs to subgroup 1 of the genus *Ilarvirus*, which is divided into six subgroups based on serological relatedness.

Potyviruses

Three viruses of the genus *Potyvirus* (family *Potyviridae*), tobacco etch virus (TEV), potato virus Y (PVY), and tobacco vein mottling virus (TVMV), are among the most important viral pathogens of tobacco. All are aphid transmitted, with flexuous filamentous particles *c.* 13 × 750 nm containing an ssRNA genome of about 10 kb. Successful aphid transmission depends upon a DAG sequence in the N-terminus of the coat protein and a viral sequence encoding a helper component (HC). The genome is expressed as a polyprotein, which is cleaved by viral-encoded proteases (Pro) into a single structural and several nonstructural proteins. Both TEV and PVY occur nearly worldwide and have wide host ranges. Diseases caused by potyviruses are managed in part through resistant cultivars such as TN86, a burley tobacco resistant to TVMV, TEV, and PVY. Several burley varieties have partial or high resistance to one or more viruses, as well as resistance to fungi and nematodes.

Tobacco etch virus

TEV has a rather narrow host range, but is found in solanaceous weeds including *Datura* sp., from which it was first isolated in the 1920s. The virus is common only in North and South America. Isolates vary in symptom severity and ability to cause necrosis or severe versus mild etch in tobacco. TEV is also known to cause severe symptoms in pepper and tomato crops in the USA, Central America, and the Caribbean. The few isolates that have been sequenced show very little diversity, and are indistinguishable serologically.

TEV has also been a model virus in the elucidation of many host–virus interactions and viral genome expression. The 5′ leader of TEV genomic RNA is used in many constructs for genetic engineering, as it contains an internal ribosome entry site and directs efficient translation of uncapped mRNA. TEV was the first virus demonstrated to encode proteases, including the autocatalytic small nuclear inclusion proteinase and a protease linked to helper component (HC-Pro).

Transgenic resistance to TEV was the first to be due to RNA interference and gene silencing, as nontranslatable sequences of the capsid protein-encoding region of the viral genome were more effective than the capsid protein translatable sequences. This observation led to the discovery RNA interference as well as the silencing suppression function by the HC-Pro region of the genome.

Potato virus Y

PVY, first isolated from potato in the 1930s as one of a complex of viruses associated with the century-old potato degeneration, is one of the most studied plant viruses and is the type member of the genus *Potyvirus*. PVY remains an important pathogen of potato and also of tobacco. Severe epidemics of PVY in tobacco have been reported recently in China. In Greece, PVY is one of the most prevalent viruses isolated from seedbeds and fields. Symptoms associated with PVY are vein clearing and/or top necrosis in oriental tobacco, and yellowing with veinal necrosis in Virginia and burley tobacco. PVY has a wide host range among the Solanaceae, including 70 species of *Nicotiana* and is also found in annual and perennial weeds in 15 or more plant families. A number of strains have been described both on potato and on tobacco, distinguishable by inoculation to differential hosts and by sequence analysis.

Other potyviruses

TVMV was not described until the 1970s, when it emerged as a new virus in the burley tobacco-growing regions of the USA, namely Kentucky, North Carolina, Tennessee, and Virginia. Severe losses were recorded until resistance to this virus, and partial resistance to PVY and TEV, was incorporated into burley tobacco cultivars. A virus isolated from tobacco in Nigeria was identified as being closely related to the potyvirus pepper veinal mottle virus, and both reacted with TVMV antibody in electron microscope serology, but not enzyme-linked

immunosorbent assay (ELISA). However, this reaction alone is not sufficient to prove virus identity. Only one additional potyvirus, tobacco wilt virus (TWV), has been reported from tobacco, and it is only known in India.

Tospoviruses

Tomato spotted wilt virus (TSWV), a member of the genus *Tospovirus* (family *Bunyaviridae*), is a serious pathogen on tobacco in many regions of the world. This thrips-transmitted virus has a very wide host range infecting over 800 species in 90 or more plant families, both monocots and dicots, and causes significant yield losses in a number of economically important crops. The virus has spherical, membrane-bound particles, 80–120 nm, with a three-segment, ambisense genome encapsided in the same particle. Symptoms in tobacco infected early are severe leaf necrosis and stunting. Several management approaches have involved weed reservoir and vector management. In Georgia in the southeastern US, successful management has been accomplished with compounds to induce resistance combined with imidochloprid insecticide applications in seedling trays and at transplanting. Yield losses were reduced significantly.

Geminiviruses (Family *Geminiviridae*)

Mastreviruses

Tobacco yellow dwarf virus (TYDV) was described in Australia in 1937, and later determined to be one of only three dicot-infecting members of the genus *Mastrevirus* (family *Geminiviridae*). It is yet to be recorded outside of Australia where it causes severe dwarfing and downward leaf curl in tobacco, and a lethal, necrotic disease in bean (syn. bean summer death virus). The virus is transmitted persistently by the brown leafhopper *Orosius argentatus*, but not by other leafhoppers nor mechanically. TYDV also infects several summer annual and autumn–spring growing plants, providing a continuous succession of host plants for the virus, and a source of virus for tobacco. Like other mastreviruses, TYDV has a single-stranded DNA genome, single component, and has coding regions in both virion sense and complementary sense sequences.

Begomoviruses

The tobacco leaf curl disease was first described in Tanzania in the early 1930s, in which infected tobacco plants were severely crinkled, curled, and dwarfed. The disease was successfully transmitted by the whitefly *Bemisia tabaci*, but not mechanically, suggesting that a virus was the causal agent. Similar disease symptoms in tobacco were noted as early as 1902 in South Africa, in 1912 in the Netherlands East Indies, in the 1930s in India, and in Brazil and Venezuela prior to 1950. Positive association of the tobacco leaf curl disease with a begomovirus was not demonstrated until DNA analyses and polymerase chain reaction (PCR) became available. The name tobacco leaf curl virus (TLCV, genus *Begomovirus*, family *Geminiviridae*) is now accepted for this virus.

However, new viruses are being described worldwide in association with severely diseased tobacco. There are numerous recent reports of TLCV-like viruses from Asia, including Japan, China, and India, as well as from Dominican Republic and Cuba. Those viruses are now accepted as members of the genus *Begomovirus*: tobacco leaf curl Japan virus (TbLCJV), tobacco leaf curl Kochi virus (TbLCKoV), tobacco leaf curl Yunnan virus (TbLCYNV), tobacco leaf curl Zimbabwe virus (TbLCZV), and tobacco curly shoot virus (=tobacco leaf curl – China, TbCSV). Sequences have also been reported for tobacco leaf curl virus – Karnataka 1 and 2 from India. Tentative begomovirus members include tobacco apical stunt virus, tobacco leaf curl India virus, and tobacco leaf rugose virus – Cuba.

All TLCV-like viruses have a single-stranded, monopartite DNA genome, and have only the DNA-A component. TbLCYNV was the first virus to be shown to have a DNAβ component, a type of satellite DNA widely associated with the virus in the Yunnan Province of China and with TbCSV (**Table 3**). Like other satellites, DNA β molecules have no sequences in common with their helper virus, DNA-A, which replicates independently of DNA β. With TbCSV, DNA β affects pathogenicity, with increasing symptom severity in the presence of specific molecules.

Viruses Causing Diseases of Tobacco of Lesser or Minor Importance

Nepoviruses

Tobacco ringspot virus (TRSV) caused a severe disease of tobacco in Virginia in the 1920s. Symptoms initially were severe necrotic rings with green centers, and a pattern of necrotic lines described as an 'oak-leaf' pattern. Tobacco plants expressed symptoms on three to four leaves developing following inoculation, but not on later-developing leaves. This apparent recovery was the first phenomenon to be described as acquired immunity. In recent research, recovery from symptoms induced by TRSV was the first to be attributed to plant defenses and to involve RNAi. The ssRNA genome is bipartite and encapsidated in separate icosahedral particles, typical of members of the family *Comoviridae*. Additional small RNAs found in the 1970s to also be encapsidated in TRSV particles were the first satellite RNAs to be discovered (**Table 3**) and later shown to have hammerhead, ribozyme-like structures capable of self-cleavage. These structures are also found in certain viroids.

TRSV is the type species of the genus *Nepovirus*. It is classified in subgroup A of this genus based on RNA2 size and sequence, and on serological relationships. The genus is named from the property of being nematode transmitted (by *Xiphenema* spp.) and having polyhedral particles. The virus is spread naturally in North America by these nematodes as well as by possible arthropod vectors. It has a very wide host range and is found naturally in many weeds and woody species. Additionally, TRSV has been disseminated worldwide in vegetative propagules of perennial crops and ornamentals, but does not appear to spread in the absence of the nematode vector.

Artichoke yellow ringspot virus (AYRSV) is known to infect tobacco naturally, causing chlorotic blotches, rings, and lines, and to spread naturally in Greece, Italy, and Eurasia. It is reported to spread via pollen to seeds or seed parent plants of *N. clevelandii*, *N. glutinosa*, and *N. tabacum*. Serological evidence indicates that AYRSV is a distinct species, and RNA2 properties place it in the subgroup C of nepoviruses, which includes tomato ringspot and cherry leaf roll viruses.

Tobraviruses

Tobacco rattle virus (TRV, genus *Tobravirus*), first described on tobacco in the 1930s, is now seldom reported on tobacco crops. Symptoms of rattle on tobacco are systemic necrotic flecks and line patterns, and death or stunting of shoots. It was known as *Mauche*, *ratel*, *Streifen und Kräuselkrankheit* in Germany, its geographic origin. Distribution today is limited to Europe, Japan, New Zealand, and North America. The host range of TRV is very wide, as it infects over 400 species of both dicots and monocots, many of which are weeds and other wild plants. TRV causes important diseases of potato, pepper, and various ornamentals.

Biological vectors of TRV are nematodes in the genera *Paratrichodorus* and *Trichodorus* (Trichodoridae). *Nicotiana clevelandii* is recommended as a propagative host for TRV, and as a trap plant for testing nematode transmission characteristics. Transmissibility is mediated by read-through proteins encoded on RNA-2 of the bipartite, ssRNA genome which extend from the surface of rigid rod-shaped particles of various sizes. This region of RNA-2 has been exploited for expression of introduced genes, and the virus is now widely used as a virus-induced gene silencing (VIGS) vector for genetic experiments.

Necroviruses

Tobacco necrosis virus (TNV) is no longer associated with diseases of tobacco, but rather with bean stipple streak and tulip necrosis diseases. TNV is classified in the genus *Necrovirus* (family *Tombusviridae*). It is one of the few viruses transmitted by the fungus *Olpidium brassicae* and often occurs in irrigated soils and in greenhouses. Virus particles adsorb to the surface of resting spores, on which they do not survive for long periods. Symptoms on tobacco are localized necrosis, with very little systemic movement within infected plants. Electron microscopy of purified TNV revealed 26–28 nm isometric particles of $T = 3$ symmetry. Some cultures also had 17 nm particles, which were a satellite virus (satTNV) encoding a capsid protein that assembled into a $T = 1$ particle. satTNV is found in Europe and North America in association with bean, but not with tobacco.

Varicosaviruses

Tobacco stunt virus (TStV) is reported only from Japan, where it was found in the 1950s to cause severe stunting and necrosis in tobacco. This virus was among the first to be shown to be transmitted by a fungus, *O. brassicae* (order Chytridiales), in which it is borne internally in resting spores and persists for 20 years or more. Once soil is infested with spores containing virus, tobacco planted into the soil will become infected and show symptoms within 2 weeks. The RNA genome of TStV is encapsided as two segments in straight, rod-shaped, rather labile, particles. The genome is now classified as being negative sense and single-stranded, with genome organization like that of rhabdoviruses. Taxonomically, TStV is in the genus *Varicosavirus*, whose name comes from the enlarged (varicose) veins induced in lettuce by the virus now known as lettuce big-vein associated virus. Recent molecular analyses suggest that TStV is a strain of this virus, rather than a distinct species.

Luteoviruses and Umbraviruses

Diseases caused by luteoviruses alone

Tobacco necrotic dwarf virus (TNDV) of the genus *Enamovirus* (family *Luteoviridae*) causes severe disease symptoms in some tobacco fields in Japan. It is transmitted by the aphid *Myzus persicae* in a persistent manner, but not mechanically. Early infection causes stunting and premature yellowing or death of young leaves of tobacco, but distribution is apparently limited.

Tobacco rosette and other diseases with dependent transmission

An aphid-transmitted disease known as tobacco rosette was widespread in Zimbabwe in sub-Saharan Africa in the 1930s. Smith in 1946 discovered that the sap-transmissible tobacco mottle virus (TMoV) could only be transmitted by aphids if plants were co-infected with tobacco vein distorting virus (TVDV), making tobacco rosette the first disease complex associated with dependent transmission. TVDV, a member of the genus *Enamovirus*, is the assistor virus for TMoV, a presumed member of the genus

Umbravirus based on sap transmissibility and other biological properties. Sequence data of one of the two recognized strains of TMoV confirmed this assignment in 2001.

Two other diseases of tobacco have complex etiology presumed to involve an umbravirus–luteovirus complex. Tobacco yellow vein virus (TYVV), a tentative species of the genus *Umbravirus*, and tobacco yellow vein assistor virus, a tentative member of the family *Luteoviridae*, were described as causing a tobacco disease with chlorotic vein-banding and leaf malformation symptoms in Malawi. Tobacco bushy top disease occurring in Rhodesia since the early 1960s is known to be caused by TVDV and a different umbravirus, tobacco bushy top virus (TBTV), and is characterized by pale green, mottling, and extreme shoot proliferation. TBTV and TVDV have recently been detected in China in tobacco showing severe witches' broom symptoms, the etiology of which had been presumed to be phytoplasma. Sequence data from these viruses confirm their classification. The significance of this observation is that this is the first incidence of an umbravirus–luteovirus complex reported in China, and first outside of sub-Saharan Africa.

Tymoviruses

A virus was isolated from naturally infected tobacco in Brazil in 1996, and described as eggplant mosaic virus-tobacco strain (EMV-T), the first report of a virus of the genus *Tymovirus* (family *Tymoviridae*) from tobacco. The virus caused mosaic symptoms, but did not reduce plant productivity. It was experimentally transmitted by sap and by the chrysomelid beetle, *Diabrotica speciosa*. As this is the only report of its incidence in tobacco, EMV-T is of only minor importance in tobacco in a limited geographic region. EMV is a pathogen of eggplant and other solanaceous vegetables, and was limited in distribution to Trinidad and Tobago. It is closely related to Andean potato latent virus, but is considered a distinct species. Genomic relationships between EMV and EMV-T have not been reported.

Nucleorhabdoviruses

Eggplant mottled dwarf virus (EMDV, genus *Nucleorhabdovirus*, family *Rhabdoviridae*) was found in tobacco plants in Greece. Plants showed severe stunting, leaf deformation, and vein clearing, and were not infected by other common tobacco viruses. Incidence was at less than 0.01%, mainly in plants near the edges of the field suggesting a weed reservoir for the virus, which has a cicadellid leafhopper vector, *Agallia vorobjevi*. EMDV has been known in the Mediterranean area since 1969 and was reported from tobacco in Italy in 1996 as tobacco vein yellowing virus, now a synonym of EMDV. EMDV infects other solanaceous crops, and appears to be spreading to a wider geographical range from Spain to the Middle East.

Glossary

Origin of assembly Stem–loop structure that is the site of initiation of virion assembly.
Pseudoknot An RNA structure with base pairing between a loop and other regions of the RNA.

Introduction

Early research in the late 1800s on the causal agent of the mosaic disease of tobacco led to the discovery of viruses as new infectious agents. Thus tobacco mosaic virus (TMV), the type species of the genus *Tobamovirus*, became the first virus to be discovered, and subsequently has had a significant role in many fundamental discoveries in virology. The first quantitative biological assay for plant viruses was the use of *Nicotiana glutinosa* plants, which produce necrotic local lesions when inoculated with TMV and many tobamoviruses. The resistance gene *N* that confers this hypersensitive response-type resistance to TMV was the first resistance gene against a plant virus to be cloned and characterized. TMV was the first virus to be purified and crystallized, which led to the discovery of the nucleoprotein nature of viruses and determination of the atomic structure of the coat protein and the virion. TMV was the first virus to be visualized in the electron microscope, confirming the predicted rigid rod-shaped virions. The genetic material of TMV was shown to be RNA, a property previously thought to be restricted to DNA. The first viral protein for which an amino acid sequence was determined was the coat protein of TMV. TMV was the first virus to be mutagenized and the subsequent determination of coat protein sequences from a number of strains and mutants helped to establish the universality of the genetic code. Methods of infecting plant protoplasts with viruses were developed with the tobacco–TMV system, creating a synchronous system to study events in the infection cycle. The TMV 30 kDa protein was the first viral protein shown to be required for virus movement.

Taxonomy and Classification

The genus *Tobamovirus* has not been assigned to a family. Currently, there are 23 recognized species within the genus *Tobamovirus* (**Table 1**). Several recently sequenced viruses are tentative members of new species (**Table 1**). Although tobamoviruses comprise one of the more intensively studied plant virus genera, taxonomy has often been confusing. Historically, plant viruses with rigid virions of approximately $18 \times 300\,\text{nm}^2$ and causing various diseases were all designated strains of TMV. Thus, many viruses originally referred to as TMV strains are now recognized as belonging to separate species. For example, the tobamovirus that was referred to as the tomato strain of TMV, and is approximately 80% identical to TMV at the nucleotide sequence level, is actually tomato mosaic virus. One criterion for distinguishing the members of separate tobamovirus species is a nucleotide sequence difference of at least 10%.

Virus Structure and Composition

Tobamovirus virions are straight tubes of approximately $18 \times 300\,\text{nm}^2$ with a central hollow core 4 nm in diameter. Virion composition is approximately 95% protein and 5% RNA. For TMV, approximately 2100 subunits of a single coat protein are arranged in a right-handed helix around a single genomic RNA molecule, with each subunit associated with three adjacent nucleotides. Protein–protein associations are the essential first event of virion assembly. Coat protein subunits assemble into several types of aggregates. Coat protein monomers and small heterogeneous aggregates of a few subunits are collectively referred to as 'A-protein'. The equilibrium between A-protein and larger aggregates is primarily dependent upon pH and ionic strength. Purified coat protein and viral RNA can assemble into infectious particles *in vitro*. Larger aggregates are disks composed of two individual stacked rings of coat protein subunits, and protohelices. Protohelices contain approximately 40 coat protein subunits arranged in a spiral around a central hollow core, similar to the arrangement within the virion. A sequence-specific stem–loop structure in the RNA, the origin of assembly (OAS), initiates encapsidation and prevents defective packaging that could result from multiple independent initiation events on a single RNA molecule. Virion assembly initiates as the primary loop of the OAS is threaded through a coat protein disk or protohelix with both ends of the RNA trailing from one side. The conformation of the coat protein protohelix changes as the RNA becomes embedded within the groove between the two layers of subunits. Elongation is

bidirectional, proceeding rapidly toward the 5′ end of the RNA as the RNA loop is extruded through the elongating virion and additional coat protein disks are added. There is disagreement about the mechanism of elongation toward the 3′ terminus of the RNA, but it appears that this slower process involves the addition of smaller protein aggregates.

Subgenomic mRNAs containing the OAS are encapsidated into shorter virions that are not required for infectivity. The OAS is located within the open reading frame (ORF) for the movement protein of most tobamoviruses. The level of accumulation of a particular subgenomic mRNA containing the OAS determines the relative proportion of that particular virion species. Thus, all tobamovirus virion populations contain a small percentage of movement protein subgenomic mRNAs. In some tobamoviruses, including cucumber green mottle mosaic virus, hibiscus latent Singapore virus (HLSV), kyuri green mottle mosaic virus, maracuja mosaic virus, sunn-hemp mosaic virus, zucchini green mottle mosaic virus, and cactus mild mottle virus, the OAS is located within the coat protein ORF. Thus, these so-called subgroup 2 tobamoviruses produce a significant proportion of small virions that contain coat protein subgenomic mRNA. Hybrid nonviral RNAs containing an OAS will also assemble with coat protein into virus-like particles of length proportional to that of the RNA.

Genome Organization

The genome of tobamoviruses consists of one single-stranded positive-sense RNA of approximately 6300–6800 nt (**Figure 1**(**a**)). There is a methylguanosine cap at the 5′ terminus, followed by an AU-rich leader 55–75 nt in length. The 3′ nontranslated end of the RNA consists of sequences that can be folded into a series of pseudoknot structures, followed by a tRNA-like terminus. The hibiscus-infecting tobamoviruses HLSV and hibiscus latent Fort Pierce virus contain a polyA stretch between the 3′ end of the coat protein ORF and the tRNA-like structure. The tRNA-like terminus can be aminoacylated *in vitro*, and in most cases specifically accepts histidine. The exception is the 3′ terminus of SHMV, which accepts valine and appears to have arisen by a recombination event between a tobamovirus and a tymovirus.

Four ORFs that are contained within all tobamovirus genomes (**Figure 1**(**a**)) correspond to the proteins found in infected tissue. Two overlapping ORFs begin at the 5′ proximal start codon. Termination at the first in-frame stop codon produces a 125–130 kDa protein. A 180–190 kDa protein is produced by readthrough of this leaky termination codon approximately 5–10% of the time. The remaining proteins are expressed from individual 3′ co-terminal subgenomic mRNAs, from which only the 5′ proximal ORF is expressed (**Figures 1**(**c**) **and 2**(**a**)). The next ORF encodes the 28–34 kDa movement protein, which has RNA-binding activity and is required for cell-to-cell movement. The 3′ proximal ORF encodes a 17–18 kDa coat protein. A subgenomic mRNA containing an ORF for a 54 kDa protein that encompasses the readthrough domain of the 180–190 kDa ORF has been isolated from infected tissue, although no protein has been detected.

Within the protein-coding regions of the genome, there are nucleotide sequences that also function as *cis*-acting elements for subgenomic mRNA synthesis, virion assembly, and replication. Gene expression from subgenomic mRNAs is regulated both temporally and quantitatively. The movement protein is produced early and accumulates to low levels, whereas the coat protein is produced late and accumulates to high levels. The regulatory elements for subgenomic mRNA synthesis are located on the genome-length complementary RNA overlapping the upstream ORF (**Figure 1**(**a**)). There is limited (40%) sequence identity between the TMV movement protein and coat protein subgenomic promoters. The TMV movement protein subgenomic promoter is located upstream of the movement protein ORF, flanking the transcription initiation site. Unlike the movement protein subgenomic promoter, full activity of the coat protein subgenomic promoter requires sequences within the coat protein ORF.

Viral Proteins

The tobamovirus 125–130/180–190 kDa proteins are involved in viral replication, gene expression, and movement. Both are contained in crude replicase preparations, and temperature-sensitive replication-deficient mutants map to these ORFs. The 125–130/180–190 kDa proteins contain two functional domains common to replicase proteins of many positive-stranded RNA plant and animal viruses (**Figure 1** (**b**)). The N-terminal domain has methyltransferase and guanylyltransferase activities associated with capping of viral RNA. The second common domain is a proposed helicase, based upon conserved sequence motifs. The readthrough domain of the 180–190 kDa protein has sequence motifs characteristic of RNA-dependent RNA polymerases. Both proteins are necessary for efficient replication, although the TMV 126 kDa protein is dispensable for replication and gene expression in protoplasts. The 125–130 kDa protein (or sequences within this region) of the 180–190 kDa protein are required for cell-to-cell movement. Additionally, these multifunctional proteins are symptom determinants, as mutations in mild strains map to these ORFs.

The 28–34 kDa movement protein has a plasmodesmatal binding function associated with its C-terminus and a single-stranded nucleic acid-binding domain associated with the N-terminus. The movement protein–host interaction determines whether the virus can systemically infect some plant species. Although principally a structural protein, the coat protein is also involved in other host interactions. Coat protein is required for efficient long-distance movement of the virus. Coat protein is also a symptom determinant in some susceptible plant species and an elicitor of plant defense mechanisms in other plant species.

Interactions between Viral and Host Proteins

Available evidence suggests that the interactions of viral proteins with host factors are important determinants of viral movement and host ranges. Amino acid substitutions in the movement protein and 125–130/180–190 kDa

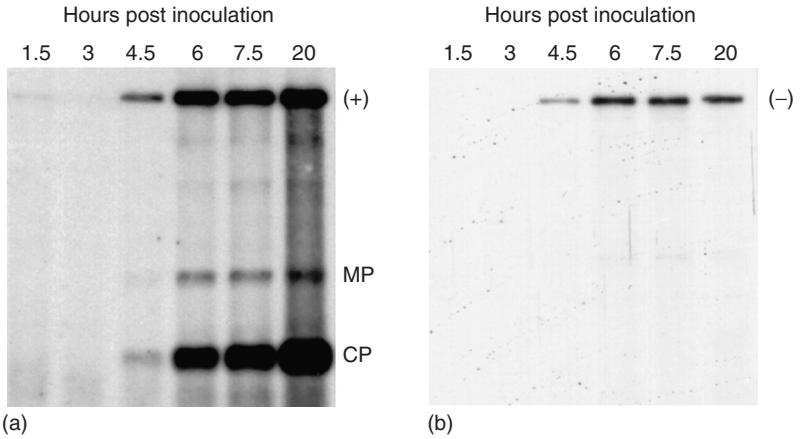

Figure 2 Time course of accumulation of TMV positive-stranded (a) and negative-stranded (b) RNAs in tobacco protoplasts. proteins can alter the movement function in different hosts. Some viruses, including tobamoviruses, can assist movement of other viruses that are incapable of movement in a particular plant species. These interactions suggest that there are more precise associations of viral proteins with host factor(s) than with viral RNA. Additionally, precise coat protein–plant interactions are required for movement to distal positions within the plant. The helicase domain of the 130–190 kDa proteins elicits the *N* gene-mediated resistance in *N. glutinosa.*

Virus Replication

Virions or free viral RNA will infect plants or protoplasts. Because tobamoviruses have a genome consisting of messenger-sense RNA that is infectious, one of the first events is translation of the 5′-proximal ORFs to produce the proteins required for replication of the genomic RNA and transcription of subgenomic mRNAs. When virions are the infecting agent, the first event is thought to be co-translational disassembly, in which the coat protein subunits at the end of the virion surrounding the 5′ end of the RNA loosen, making the RNA available for translation. Ribosomes then associate with the RNA, and translation of the 126/183 kDa ORFs is thought to displace coat protein subunits from the viral RNA. After the formation of an active replicase complex, a complementary negative-strand RNA is synthesized from the genomic positive-strand RNA template. Negative-strand RNA serves as template for both genomic and subgenomic mRNAs. Negative-strand RNA synthesis ceases early in infection, while positive-strand RNA synthesis continues. This results in an asymmetric positive- to negative-strand RNA ratio. Early in infection, genomic RNA functions as template for negative-strand RNA synthesis and as mRNA for production of the 126/183 kDa proteins. Later in the infection cycle, most of the newly synthesized genomic RNA is encapsidated into virions. Subgenomic mRNAs transcribed during infection function as mRNA for the 3′ ORFs. Within cells of an infected leaf, replication proceeds rapidly between approximately 16 and 96 h post infection within a cell, then ceases. Even though the infected cells become packed with virions, these cells remain metabolically active for long periods. During the early stages of infection of an individual cell, the infection spreads through plasmodesmatal connections to adjacent cells. This event requires the viral movement protein that modifies plasmodesmata to accommodate larger molecules and the 126/183 kDa proteins. Movement through plasmodesmata does not require the coat protein. A second function of the movement protein appears to be binding to the viral RNA to assist its movement through the small plasmodesmatal openings. The movement protein also appears to associate with the cytoskeleton. As the virus spreads from cell to cell throughout a leaf, it enters the phloem for rapid long-distance movement to other leaves and organs of the plant, a complex process that requires the coat protein.

cis-Acting Sequences

The 5′ nontranslated region contains sequences that are required for replication. This region is an efficient translational leader. The 3′ nontranslated region contains *cis*-acting sequences that are involved in replication. Certain deletions within the pseudoknots are not lethal, but result in reduced levels of replication. Exchange of 3′ nontranslated elements between cloned tobamovirus species has resulted in some lethal and nonlethal hybrids, suggesting a requirement for sequence specificity and/or secondary structure. The 3′ nontranslated region appears to be a translational enhancer, both in the viral genome and when fused to heterologous reporter mRNAs. Sequences encoding the internal ORFs for the movement and coat proteins are dispensable for replication. Duplication of the subgenomic promoters results in transcription of an additional new subgenomic mRNA. Heterologous tobamovirus subgenomic promoters inserted into the viral genome are recognized by the replicase complex and transcribed. Foreign sequences inserted behind tobamovirus subgenomic mRNA promoters have been expressed to high levels in plants and protoplasts.

Satellite Tobacco Mosaic Virus

Satellite tobacco mosaic virus (STMV), a tobamovirus-dependent satellite virus, was isolated from *Nicotiana glauca* plants infected with tobacco mild green mosaic virus (TMGMV). The STMV genome consists of one single-stranded positive-sense RNA of 1059 nt. The 240 3′ nucleotides share approximately 65% sequence identity with TMGMV and TMV, contain pseudoknot structures, and have a tRNA-like terminus. No sequence similarity with any tobamovirus exists over the remainder of the genome. Two overlapping ORFs that are expressed in *in vitro* translation reactions are present in the genomic RNA of most STMV isolates. The 5′-proximal ORF encodes a 6.8 kDa protein that has not been detected *in vivo* and is not present in all STMV isolates. The second ORF encodes a 17.5 kDa coat protein that is not serologically related to any tobamovirus coat protein. The 17 nm icosahedral virions are composed of a single STMV genomic RNA encapsidated within 60 STMV coat protein subunits. Replication of natural populations of STMV is supported by other tobamoviruses, but at lower levels than with the natural helper virus, TMGMV. The host range of STMV parallels that of the helper virus.

Tobravirus

S A MacFarlane, Scottish Crop Research Institute, Dundee, UK

© 2008 Elsevier Ltd. All rights reserved.

Taxonomy and Characteristics

The genus *Tobravirus* is comprised of three species, the type species *Tobacco rattle virus* (TRV) together with *Pea early-browning virus* (PEBV) and *Pepper ringspot virus* (PepRSV), which was previously referred to as the CAM strain of TRV. The genus has not been assigned to a virus family. Tobraviruses have a genome of two, positive-sense, single-strand RNAs that are packaged separately into rod-shaped particles. In some situations, the larger genomic RNA (RNA1) can cause a systemic infection in the absence of the second, smaller RNA (RNA2) and without the formation of virus particles. Tobraviruses are transmitted between plants by root-feeding nematodes of the genera *Trichodorus* and *Paratrichodorus*, and in some plant species are also seed transmitted.

Virus Particle Production and Structure

Tobravirus RNA1 is encapsidated into the L (long) particle with a length of 180–215 nm, depending on virus species, and RNA2 is encapsidated into S (short) particles which range in length from 46 to 115 nm, depending on virus isolate (**Figure 1**). Both L and S particles have an apparent diameter of 20–23 nm, depending on the technique used to examine them. *In vitro* translation experiments using RNA extracted from purified virus preparations, as well as studies with the TRV SYM isolate, which has an unusual genome structure, showed that some, if not all, tobravirus subgenomic (sg)RNAs are also encapsidated, in particles of various lengths. The tobraviruses encode a single coat protein (CP), molecules of which assemble in a helical arrangement around a central cavity with a diameter of 4–5 nm, and with a distance of 2.5 nm between successive turns of the helix. *In vitro* reconstitution experiments suggested that virus particle formation initiates at the 5′ end of the viral RNA, although the encapsidated sgRNAs do not carry the 5′ terminal part of the virus genomic RNAs. Peptide mapping showed that the major antigenic regions of the CP are, in descending order of strength, the C-terminal 20 amino acids (aa), 5 aa in the central region of the protein and 5 aa at the N-terminus. This and other spectroscopic analyses suggest that the N- and C-termini are exposed on the outer surface of the particle, while the central region is exposed in the central canal (where interactions of the CP with the viral RNA take place). The C-terminal domain appears to be unstructured and

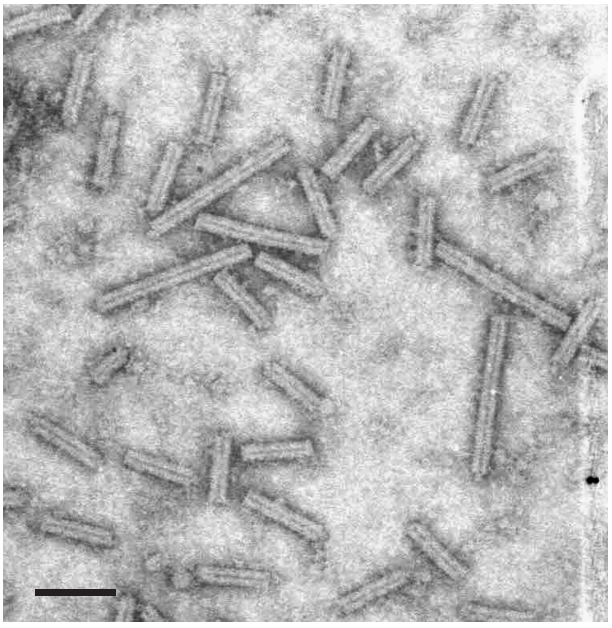

Figure 1 Electron micrograph of long and short particles of TRV isolate RH. Scale = 100 nm.

plays a role in interactions with other virus proteins that are involved in nematode transmission of the virus. Particularly with TRV, there is significant amino acid sequence difference between the CP of different virus isolates, resulting in many different serotypes of this virus.

M-Type and NM-Type Infections

In early studies with tobraviruses (usually with TRV), the infectivity of fractionated and purified L and S particles was examined, showing that L particles were infectious (producing local and systemic symptoms on particular hosts) but that S particles were not. However, plants infected with L particles did not contain virus particles, whereas plants infected with both L and S particles did contain (both) virus particles. This was explained by sequencing, which revealed that RNA1 encodes proteins for RNA replication and movement, whereas RNA2 encodes the CP. Because infections with RNA1 do not produce virus particles, they were very difficult to maintain by repeat inoculation of sap extracts, and were referred to as nonmultiplying (NM-type) infections. Infections derived from both RNA1 and RNA2 and producing virus particles were easily passaged and were referred to as multiplying (M-type) infections. Subsequently, it was found that extraction with phenol of RNA from NM-infected plants in fact produced highly infectious preparations.

Early observations also suggested that NM-type infections caused more severe symptoms than M-type infections and moved only slowly up the plant, giving rise to the theory that unencapsidated RNA1 could spread systemically only from cell to cell via plasmodesmata. However, experiments with TRV and PEBV carrying defined mutations in the CP gene demonstrated unequivocally that unencapsidated virus RNAs moved very rapidly via the vascular system in both *Nicotiana benthamiana* and *Nicotiana clevelandii* plants. In addition, with wild-type (encapsidated) virus, systemic infection always included both RNA1 and RNA2 but with the (unencapsidated) CP mutants RNA2 occasionally became separated from RNA1 and was not detected in some systemic leaves. One PEBV mutant carried only a small (28 aa) deletion at the C-terminus of the CP but did not produce virus particles or indeed any detectable CP in infected plants. Nevertheless, this mutant moved systemically as quickly as did wild-type virus and in this case RNA2 did not become separate from RNA1. This suggests, perhaps, that some form of CP but not incorporated into particles, which can be present at very low levels, ensures the coordinated transport of RNA1 and RNA2 through the phloem.

In another study, plants were infected with TRV RNA1 and two types of RNA2, one wild type and the second encoding a CP in which the 15 aa at the C-terminus were replaced with three nonviral residues. Both RNA2 species were encapsidated by the CP that they encoded but neither appeared to be encapsidated by the CP from the other RNA2. Apparently, although RNA1 is encapsidated *in trans*, RNA2 is only encapsidated *in cis*. The mechanism for this is not known but may be linked to the role of CP in the coordinated systemic movement of RNA1 and RNA2.

Genome Structure and Expression

The viral RNAs have a 5′ methylated guanosine cap. The 3′ end of the RNAs is not polyadenylated but folds into a tRNA-like pseudoknot structure that, in contrast to some other virus RNAs, cannot be aminoacylated. RNA1 is from 6.8 to 7 kb in size, and RNA2 varies between isolates from 1.8 to ~4 kb (**Figure 2**). Complete sequences have been obtained for RNA1 from four isolates of TRV, two isolates of PEBV, and one isolate of PepRSV. In addition, complete sequences have been obtained for RNA2 from 15 isolates of TRV, three isolates of PEBV, and one isolate of PepRSV. (Information on RNA sequences can be obtained from the eighth ICTV report.) Other than the sequencing, almost no further molecular studies have been carried out on PepRSV.

RNA Sequences

The larger RNA (RNA1) is highly conserved in nucleotide sequence between different isolates of the same virus (e.g., 99% identity between RNA1 of TRV isolates SYM and ORY), but there is much less identity between isolates of the different tobravirus species (e.g., 62% identity between RNA1 of TRV isolate SYM and PEBV isolate SP5). The smaller RNA (RNA2) varies considerably both in terms of overall nucleotide sequence identity as well as protein-coding capacity between isolates of the same

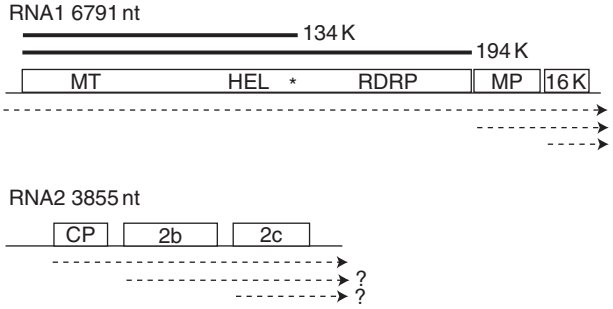

Figure 2 Genome diagram and expression strategy of TRV isolate PpK20. Open boxes denote virus genes. The solid lines above the RNA1 genes shows the location of the two, overlapping replicase genes. The 134K protein contains methyltransferase (MT) and helicase (HEL) motifs. The C-terminal part of the 194K protein contains an RNA-dependent RNA polymerase (RDRP) motif. The asterisk denotes the 134K gene termination codon where readthrough translation to produce the 194K protein occurs. The movement protein (MP) gene is also known as the 29K or 1a gene. The cysteine-rich 16K gene is also known as the 1b gene. For RNA2, CP denotes the coat protein gene. The dashed lines beneath each RNA denote the 3′ co-terminal subgenomic RNAs that are known or suspected to exist.

virus (TRV or PEBV), although phylogenetic analysis shows that the CPs of the different tobraviruses, which are encoded by RNA2, are more closely related to each other than to CPs from viruses in other genera. The tobraviruses are most closely related to tobamoviruses, in terms of particle structure, overall gene organization, and viral protein sequence homologies.

RNA1 has a 5′ noncoding region (NCR) of between 126 and 202 nt, and a 3′ NCR of 459–255 nt. RNA2 has a much larger 5′ NCR of 470–710 nt, and a 3′ NCR of 780–392 nt. There is almost no sequence homology between the 5′ NCRs of the tobraviruses; however, the 25 nt at the 3′ terminus of the TRV and PEBV RNAs are identical and there is 70% identity over the next 140 nt. Consequently, when recombinants were made between the RNA2 of TRV PpK20 and PEBV SP5, the replicase complex of both viruses could replicate RNA2 molecules carrying the 3′ NCR from either virus. However, RNA2 carrying the TRV 5′ NCR could only be replicated by a TRV replicase complex, and RNA2 carrying the PEBV 5′ NCR could only be replicated by a PEBV replicase complex.

Expression of Virus Genes

The 5′ proximal gene of RNA1, encoding viral replicase proteins, is expressed by direct translation of the genomic RNA. The two other RNA1-encoded genes (1a and 1b) are expressed from sgRNAs that start with the sequence AUA (within a conserved motif GCAUA) and that are co-terminal with the 3′ end of the genomic RNA.

The 5′ proximal gene of RNA2 of almost all tobravirus isolates encodes the CP. However, the CP gene is located at least 470 nt downstream of the 5′ terminus of RNA2, and this region contains numerous (at least six) AUG codons upstream of the translation initiation codon of the CP gene, that are inhibitory to CP expression. Experiments to delete parts of the 5′ NCR of PEBV RNA2 showed that only a very small amount of CP is translated *in vitro* from full-length (genomic) RNA2 but that translation is increased 25-fold when the 5′ NCR is removed. Thus, even though the CP gene is the 5′ proximal gene on RNA2, it (and the other genes on RNA2) is expressed from an sgRNA. Uniquely, the CP gene of TRV SYM is located near to the 3′ end of RNA2, downstream of another gene. The sgRNA for this CP is much shorter than genomic RNA2 and is encapsidated into a clearly identifiable VS (very short) virus particle.

A stem–loop sequence is found upstream of tobravirus sgRNA start sites, and is particularly conserved for the CP sgRNA. The introduction of mutations into this structure (8 bp stem, 4 nt loop) upstream of the PEBV CP gene showed that the stem–loop forms an essential part of the sgRNA promoter, and that the structure of the stem rather than its actual sequence is important for sgRNA synthesis *in planta*. The promoter regions for the TRV and PEBV CP genes could be used as a cassette and moved to other locations in RNA2 to express nonviral genes.

Recombination in Tobravirus RNAs

The large variation in the overall length of RNA2 from different tobravirus isolates reflects the fact that most are recombinant molecules, where the 3′ part of RNA2 has been replaced by sequences from the 3′ part of RNA1. The recombination junction can occur at any position in RNA2 that is downstream of the CP gene, and the recombinant may retain none, some, or even both of the other genes (2b and 2c) that might be considered RNA2 specific. The region of RNA1 that is transferred to RNA2 always includes the 3′ NCR, often includes the 1b gene immediately upstream of the 3′ NCR, and may occasionally include part of the 1a gene that is located upstream of the 1b gene. This means that many of these recombinant isolates carry two, probably both functional, copies of the 1b gene, one on RNA1 and the second on RNA2. The mechanism for recombination is not known but is speculated to be caused by template switching by viral replicase from RNA1 to RNA2 during minus-strand RNA synthesis. Sequences that resemble the 5′ terminus of tobravirus genomic RNAs (rich in A and U residues) are often found at or near the recombination junction, and conceivably could facilitate the recombination event. It is also not completely clear when tobravirus recombination occurs, though the feeling is that repeated passage of virus by mechanical inoculation in glasshouse-grown plants, bypassing the nematode transmission process, either encourages recombination or reduces selection against the survival of recombinants. Nevertheless, at least one known recombinant isolate, TRV PaY4, which was cloned after only a very limited period of multiplication in the glasshouse, did retain its ability to be nematode transmitted.

A different recombination process also occurs in which the CP and/or 2b gene in RNA2 of some TRV isolates appears to have been derived from PEBV. For this reason, serological analysis is not always successful in discriminating between the different tobraviruses. Attempts to reproduce this recombination by co-inoculating TRV and PEBV to plants in the glasshouse were not successful, suggesting that this may be only a rare occurrence, or may be stimulated by particular environmental conditions. Nevertheless, one report showed that 30% of the TRV isolates recovered from fields in the coastal bulb-growing region in the Netherlands were TRV/PEBV recombinants.

Viral Proteins

RNA1

RNA1 encodes proteins for virus RNA replication and intraplant movement (local and systemic). The 5′ half of RNA1 encodes a large (134–141 kDa) protein that contains methytransferase and helicase domains and is expected to be part of the viral replicase complex.

Readthrough translation of the stop codon of this protein produces a larger protein (194–201 kDa) that contains motifs associated with RNA-dependent RNA polymerase proteins. *In vitro* translation experiments showed that the opal (UGA) translation termination codon of the TRV 134 kDa protein is suppressed by tRNAs that incorporate tryptophan or cysteine at this position. Downstream of the replicase genes is the 1a gene encoding a 29–30 kDa cell-to-cell movement protein. Disruption of this gene prevents accumulation of TRV in inoculated leaves but can be overcome by co-inoculation with tobacco mosaic virus (TMV) or to transgenic plants expressing the TMV 30K movement protein. The C-terminal 1b gene encodes a 12–16 kDa cysteine-rich protein that is involved in seed transmission of PEBV in pea, pathogenicity of TRV and PEBV, and in cultured *Drosophila* cells suppresses RNA silencing. Deletion of the 1b gene prevents systemic movement of TRV in *N. benthamiana*, which can be recovered by co-expression, from TRV RNA2, of other cysteine-rich proteins from PEBV, soil-borne wheat mosaic virus, and barley stripe mosaic virus, as well as by the 2b silencing suppressor protein of cucumber mosaic virus.

RNA2

RNA2 encodes proteins for virus particle formation and transmission by nematodes. Several studies have identified the CP as being involved in the nematode transmission process, and deletion of part of the C-terminal domain of the CP prevented the transmission of PEBV without affecting virus particle formation. Infectious, nematode-transmissible clones of three TRV isolates and one PEBV isolate have been sequenced. In addition to the CP, these RNAs all carry two other genes encoding the 2b and 2c proteins, both of which (for PEBV) have been detected by Western blotting in extracts of virus-infected plants. Mutation studies showed that the 2b gene is necessary for transmission of TRV and PEBV, whereas the 2c protein was only required for transmission of PEBV. This difference may reflect the different species of nematode that transmitted the particular virus isolates used in these studies, rather than a clear mechanistic difference between TRV and PEBV transmission. A further, small open reading frame, encoding a putative 9 kDa protein immediately downstream of and in-frame with the CP gene, is present in PEBV-TpA56 and TRV TpO1. For PEBV, mutation of this gene greatly reduced nematode transmission frequency, although the protein was not detected by Western blotting.

The 2b proteins of the different tobravirus isolates share some amino acid sequence homology with each other, ranging from only 11% identity (TRV Umt1 vs. TRV PaY4) to 99% identity (TRV Umt1 vs. TRV OR2). They also range in size from 238 aa (TRV PaY4) to 354 aa (TRV PpK20). The TRV PaY4 2b protein has been show to act *in trans*, with nematode transmission of a 2b-mutant virus being complemented by co-infection with wild-type virus. However, this appears to be isolate specific, as the TRV PaY4 2b mutant was complemented only by wild-type TRV PaY4 and not by wild-type TRV PpK20.

The 2b protein may influence nematode transmission by more than one mechanism. In a microscopy study of the roots of *N. benthamiana* plants infected by PEBV, large numbers of particles of the wild-type virus were found in all regions of the root tip, which is where the vector nematodes preferentially feed, whereas virus particles of a mutant deleted for the 2b and 2c genes were present in roots only in much lower numbers. A similar enhancement was found in the efficiency of invasion of roots in *N. benthamiana*, as well as in leaves of *Arabidopsis thaliana*, when TRV carrying the 2b gene was compared with that of TRV lacking the 2b gene.

The 2b protein also physically interacts with the TRV CP (as examined by yeast two-hybrid (Y2H) analysis) and the virus particle (as examined by immunoelectron microscopy). One suggestion is that the 2b protein acts as a bridge to trap virus particles to specific sites of retention on the nematode esophageal cuticle. Aggregates of virus particles have been observed using the electron microscope to collect in this part of the nematode but the co-location of the 2b protein has not yet been demonstrated. It appears that interaction between the CP and 2b protein stabilizes the 2b protein, as in plants infected with wild-type TRV PaY4, carrying both PaY4 CP and PaY42b genes, the 2b protein was detected by Western blotting. However, with a recombinant TRV carrying the TRV PpK20 CP gene and the TRV PaY4 2b gene, the 2b protein could not be detected, possibly because these proteins from two different isolates cannot interact with one another. This is reinforced by results from the Y2H study, where the TRV PpK20 CP and PpK20 2b proteins were found to interact. Similarly, the PaY4 CP and PaY4 2b proteins interacted; however, the PpK20 CP did not interact with the PaY4 2b protein and the PaY4 CP did not interact with the PpK20 2b protein.

Although the 2c protein is involved in transmission of PEBV, little else is known about this protein. Amino acid sequence homologies between the 2c proteins of different TRV isolates range from almost none to over 95% identity. In a Y2H assay, the TRV PpK20 2c protein interacted with the PpK20CP, and removal of the CP C-terminal flexible domain did not affect the interaction.

Tobraviruses as Gene Expression/ Silencing Vectors

As RNA1 encodes all the proteins necessary for tobravirus replication and movement, the RNA2 can be modified to carry nonviral sequences without greatly affecting virus infection. Expression vectors have been constructed from all three tobraviruses, in which a duplicate CP

promoter sequence is inserted downstream of the native CP gene followed by restriction sites to allow the cloning of other sequences. Together, the tobraviruses can infect a wide range of plant species, often without causing particularly severe symptoms, features which increase their utility as expression vectors.

Plants infected with tobraviruses often undergo a rapid recovery in which infection symptoms and virus levels fall dramatically, although the plants do not become free of virus, most particularly in the meristem regions. However, these plants have developed a strong resistance to further infection by the same virus, most likely by an RNA silencing-based mechanism. Although not well understood, it seems that tobraviruses are potent triggers of RNA silencing but do not encode a strong silencing suppressor protein to counteract this host defense activity. A consequence of this is that when a host plant sequence is inserted into the virus genome, very strong silencing is initiated that targets expression of the host gene itself, a process known as virus-induced gene silencing (VIGS). TRV has become one of the most widely used VIGS vectors for studies of plant gene function, and recent work has shown that PEBV is also a very effective VIGS vector for studies in pea.

Diseases Caused by Tobraviruses

TRV is found in many regions (in Europe, North America, Japan, and Brazil) and has a particularly wide host range, infecting more than 100 species in nature and more than 400 species when tested in the glasshouse, although not all of these infections are systemic. As tobraviruses are transmitted by soil-inhabiting nematodes, infection may be limited in the field to the roots. Weeds may play an important role in the maintenance and spread of tobraviruses, with *Capsella bursa-pastoris*, *Senecio vulgaris*, *Stellaria media*, and *Viola arvensis* being the most commonly found weed hosts of TRV. Virus transmission in seed of these plants was also reported. Many crop plants are infected by TRV, the major diseases being those of potato and ornamental bulbs (narcissus, gladiolus, tulip, lily, and crocus). The symptoms of TRV infection in potato are the formation of arcs and flecks of brown corky tissue in the tuber which is referred to as spraing, and which can make the tuber unfit for sale. Both M-type and NM-type infections can produce spraing symptoms, the biochemical basis for which is not known. It was thought that potato cultivars that did not show spraing symptoms were resistant to TRV; however, recent work has shown that some infections can be symptomless. Nevertheless, even these symptomless infections lead to significant reductions in tuber yield and tuber quality. Inclusion of tubers carrying symptomless infection could have major consequences for the production and distribution of seed potatoes.

PEBV has been reported in several European countries (UK, Netherlands, Italy, Belgium, Sweden) as well as Algeria and Morocco. In the field, it infects mainly legumes, including pea, faba bean, French bean, lupin, and alfalfa. Several weeds and other crop plants may be infected, although often only in the roots.

PepRSV has only been reported from Brazil, where it infects pepper, tomato, and artichoke, as well as local weed species.

Glossary

Arbovirus A virus transmitted to vertebrates by hematophagous (blood-feeding) arthropods.

Cimicid A hemipteran bug of the family *Cimicidae*.
Encephalitis Acute inflammation of the brain.
Enzootic Infection or illness affecting or peculiar to animals of a specific geographic area.

Epidemic disease An illness that spreads rapidly and widely and affects many individuals in an area or a population at the same time.
Epizoodemic An extensive outbreak of a virus in both humans and other vertebrates.
Epizootic Infection or illness in a large number of animals at the same time within a particular region or geographic area, the number of affected animals being in clear excess of that which would be expected for the specific region and period of time.
Etiology The study of causes of diseases or pathologies.
Togavirus A virus of the family *Togaviridae*.

Introduction

In the 1930s, previously unrecognized viruses were isolated from diseased horses in California, Virginia, and New Jersey, and from an infected child in Caracas, Venezuela. These subsequently were named Western equine encephalitis virus (WEEV), Eastern equine encephalitis virus (EEEV), and Venezuelan equine encephalitis virus (VEEV), respectively. Since then, numerous isolations of these viruses have been obtained from infected mosquitoes and from horses, humans, and other vertebrates, mainly birds and rodents. In nature, these viruses are transmitted by hematophagous arthropods.

The virus family *Togaviridae* comprises two genera: *Alphavirus* and *Rubivirus*. Rubiviruses do not usually cause encephalitis and will not be discussed further in this article. Encephalitic alphaviruses are neuroinvasive and cause mild-to-severe neurological symptoms. The alphaviruses WEEV, EEEV, VEEV, and, more rarely, Ross River virus, Chikungunya virus, and Highlands J virus (HJV) can cause encephalitis in equines (see **Figure 1**) or humans.

The prototype alphavirus, Sindbis virus, does not typically cause encephalitis in humans and is encephalitic only under experimental conditions in mice. Therefore, this virus will also be discussed elsewhere. Among the naturally occurring alphaviruses, WEEV, EEEV, and VEEV, have widespread distributions in North, Central, and South America (see **Figure 2**). WEEV is distributed in the US from the mid-Western states of Michigan and Illinois to the West coast and in western Canada, and clinical cases have been reported in 21 states, whereas EEEV is distributed from Texas to Florida along the Gulf coast and from Georgia to New Hampshire along the Atlantic Coast and in eastern Canada, with cases reported in 19 states, including the mid-Western states of Wisconsin, Illinois, and Michigan. Transmission of VEEV occurs predominantly in Central and South America, with the exception of Everglades virus (formerly VEEV subtype II), which is found in Florida, and Bijou Bridge virus (formerly VEEV subtype IIIB), found in cimicid cliff swallow bugs (*Oeciacus vicarius*) in western North America.

Western Equine Encephalitis Virus

This virus was first isolated in 1930 from the brain of an encephalitic horse in California. According to the US Centers for Disease Control and Prevention, 639 confirmed human cases of WEE have occurred in the US from 1964 to 2005. Likely due to changes in irrigation practices and to successful mosquito control programs in the western US, the annual number of cases has been declining, with fewer than ten cases per year since 1988. Infections with WEEV are generally asymptomatic or result in mild disease after an incubation period of 2–7 days with nonspecific symptoms, for example, sudden onset of fever, headache, nausea, vomiting, anorexia, and malaise, although these can be followed by altered mental status, weakness, and signs of meningeal irritation, evidence of more serious infections. Encephalitis occurs in a minority of infected individuals and may lead to neck stiffness, confusion, tonic–clonic seizures, somnolence, coma, and death. Mild-to-severe neurological sequelae can be found in survivors of encephalitis, especially in those <1 year old, at rates between 5% and 30%. In addition, serological studies indicated that the relation of inapparent to apparent infections changes with age. In children <1 year old, the relation is about 1:1, between 1 and 4 years of age it is about 58:1, and in children >14 years old it is >1000:1. The overall case–fatality rate is about 3%. Encephalitis due to WEEV is characterized by vasculitis and focal hemorrhages mainly affecting the basal ganglia and the nucleus of the thalamus. Because small hemorrhages can occur in the white and gray substance throughout the central nervous system (CNS), they can be mistaken for resolved infarcts in elderly patients.

WEEV is maintained in an enzootic cycle between its natural vertebrate hosts, passerine birds, and its most common mosquito vector, *Culex tarsalis*, a species associated with irrigated agriculture and stream drainages in the western US. Transmission to horses and humans is mediated by so-called bridging mosquito vectors, including *Ochlerotatus melanimon* in California, *Aedes dorsalis* in Utah and New Mexico, and *A. campestris* in New Mexico (see **Figure 3**). Depending on the climate, the natural transmission cycle may be maintained throughout the year. In more moderate climate areas, WEEV may persist in yet-unrecognized hosts, or may be reintroduced annually by migratory birds that move great distances. Isolations of WEEV have been documented in the Veracruz region of Mexico and in South America. Genetic analyses of WEEV isolated in South America (Brazil and northern Argentina) revealed a level of nucleotide

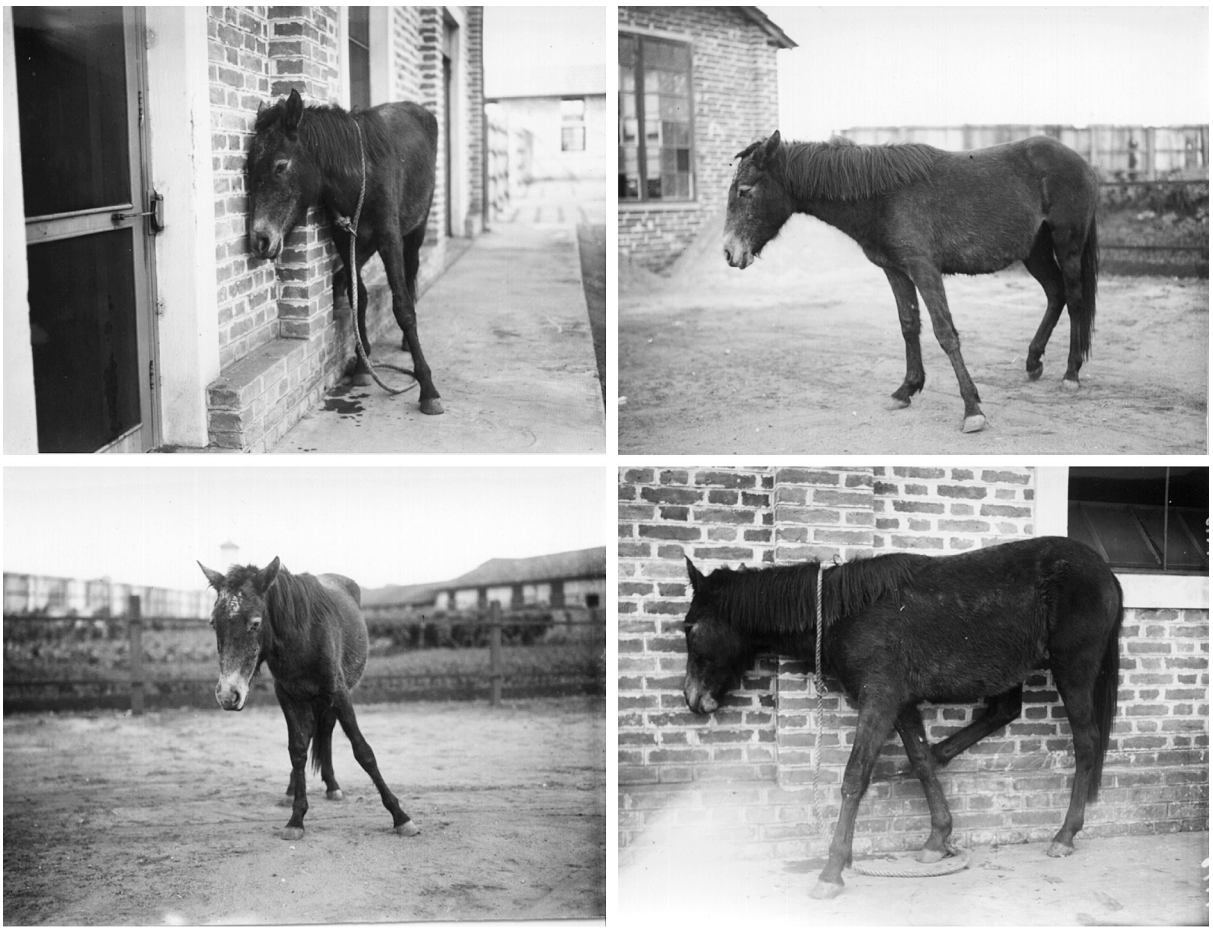

Figure 1 Western equine encephalitis in equines.

identity >90% in the E2/6K/E1 coding region when compared to isolates from California, Texas, and as far north as Montana, suggesting a monophyletic nature of the WEEV lineage, with an overall slow evolution. Hahn and colleagues showed that WEEV is a natural recombinant virus, with its capsid amino acid sequence similar to that of EEEV, while the remaining part of the structural polyprotein was more similar to that of Sindbis virus. Further phylogenetic analyses, including the nonstructural genes as well, confirmed that WEEV and the closely related Highlands J, Fort Morgan, and Buggy Creek viruses are recombinant viruses derived from an ancestor formed by an EEEV-like (5′ two-thirds of the genome) and Sindbis virus-like (3′ one-third of the genome) parental virus.

Eastern Equine Encephalitis Virus

The first isolates of EEEV were obtained in 1933 from infected horses in Virginia and New Jersey. The main EEEV transmission cycle occurs between birds and mosquitoes via *Culiseta melanura* mosquitoes. However, the principal arthropod vector for transmission of EEEV to humans or to horses are *Aedes*, *Coquillettidia*, and *Culex* mosquitoes which, unlike *Culiseta melanura*, tend to feed on both birds and mammals. Virus transmission occurs most commonly in and around freshwater hardwood swamps in the Atlantic and Gulf Coast states and in the Great Lakes region. Most cases of EEE have been reported from Florida, Georgia, Massachusetts, and New Jersey. In horses, in some bird species, and in dogs, EEEV can cause severe disease and experimental data suggest that equines can develop viremia upon experimental infection; however, it is believed that horses do not serve as amplifying hosts during epidemics.

According to the US Centers for Disease Control and Prevention, 220 confirmed cases of EEE have occurred in the US from 1964 to 2004. This virus is probably the most virulent of the encephalitic alphaviruses, with a case–fatality rate estimated at >33%. After a 4–10-day incubation period symptoms begin with sudden onset of fever, general muscle pains, and headache of increasing severity. In human cases of encephalitis, fever, headache, vomiting, respiratory symptoms, leucocytosis, hematuria, seizures, and coma may occur. Clinical studies of serologically confirmed and human EEEV infections using

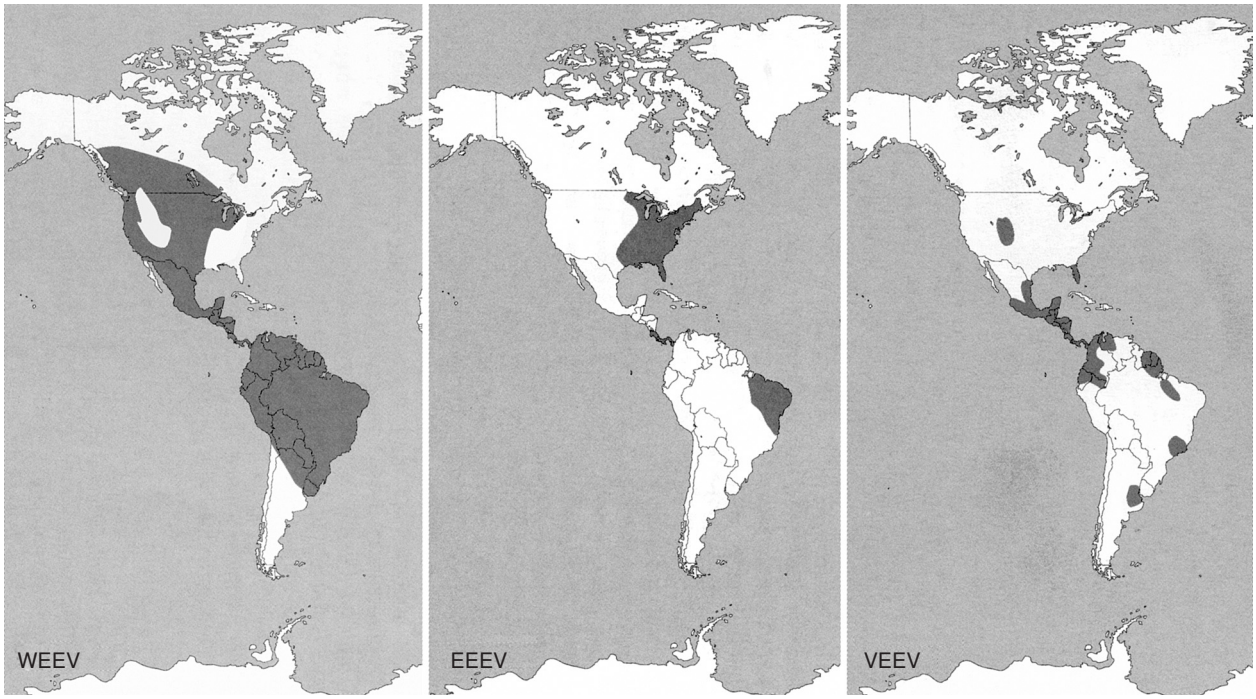

Figure 2 Geographic distribution of equine encephalitic togaviruses.

magnetic resonance imaging and computed tomography have shown changes in the basal ganglia and thalami, suggesting brain edema, ischemia, and hypoperfusion in the early stage of disease. Investigations of gross pathology of fatal human cases revealed brain edema with necrosis, facial or generalized edema, vascular congestion, and hemorrhage in the brain and visceral organs. The predominant micropathological manifestations in the brain include vasculitis, hemorrhage, and encephalitis.

The pathogenesis of EEEV is poorly understood; however, data from experimental infections of mice, guinea pigs, and rhesus monkeys, and from histopathological studies of equine and porcine cases are available. The mouse encephalitis model is well established for several alphaviruses, although it generally lacks the ability to reproduce the vascular component of the disease that is typical for EEE in humans. A hamster model of EEE, used to study acute vasculitis and encephalitis, was described recently. The virus penetrates the brain quickly in animal models and the neuronal phase of the disease develops rapidly. The virus is capable of establishing productive infection in all parts of the mouse or hamster brain. The experimental studies have suggested early infection of periventricular and perivascular neuronal cells in the basal ganglia and hippocampus. It is difficult to explain the early involvement of the basal ganglia and brainstem in experimental infections and to our knowledge no specific anatomic characteristics of these brain regions have been described that might help explain their susceptibility to early infection. In contrast to VEEV (see below), EEEV appears to rapidly invade the brain of infected animals via blood, and the first antigen-positive neuronal cells are located in the basal ganglia and brainstem in the hamster model. Certain findings in animal models, such as the hamster, are similar to early clinical manifestations of EEEV infections in humans. The inflammatory response in the brain is prominent in cases in which animals had survived for at least 5 days, and is produced by macrophages, lymphocytes, and neutrophils. Some of the animal models also display the peripheral pathological changes described in fatal human EEE cases, including congestion and numerous microhemorrhages in the liver, spleen, and lung.

Venezuelan Equine Encephalitis Virus

In 1938, the first isolation of VEEV was obtained from the brain of an encephalitic animal in Venezuela. Like WEEV and EEEV, VEEV is a zoonotic pathogen, transmitted between vector mosquitoes and vertebrate hosts, namely rodents and humans in enzootic cycles, and horses and humans in epidemic or epizootic cycles. Although during epizoodemics essentially any mosquito can be found infected with VEEV, *Ochlerotatus taeniorhynchus* is one of the principal vectors believed to be responsible for the transmission of VEEV during outbreaks, whereas *Culex* (*Melanoconion*) species mosquitoes transmit enzootic strains of VEEV. These viruses are also highly infectious via the aerosol route, and have been responsible for numerous laboratory accidents (>150 cases without an associated perforating injury) and have been developed as a biological weapon in the US and in the former Soviet

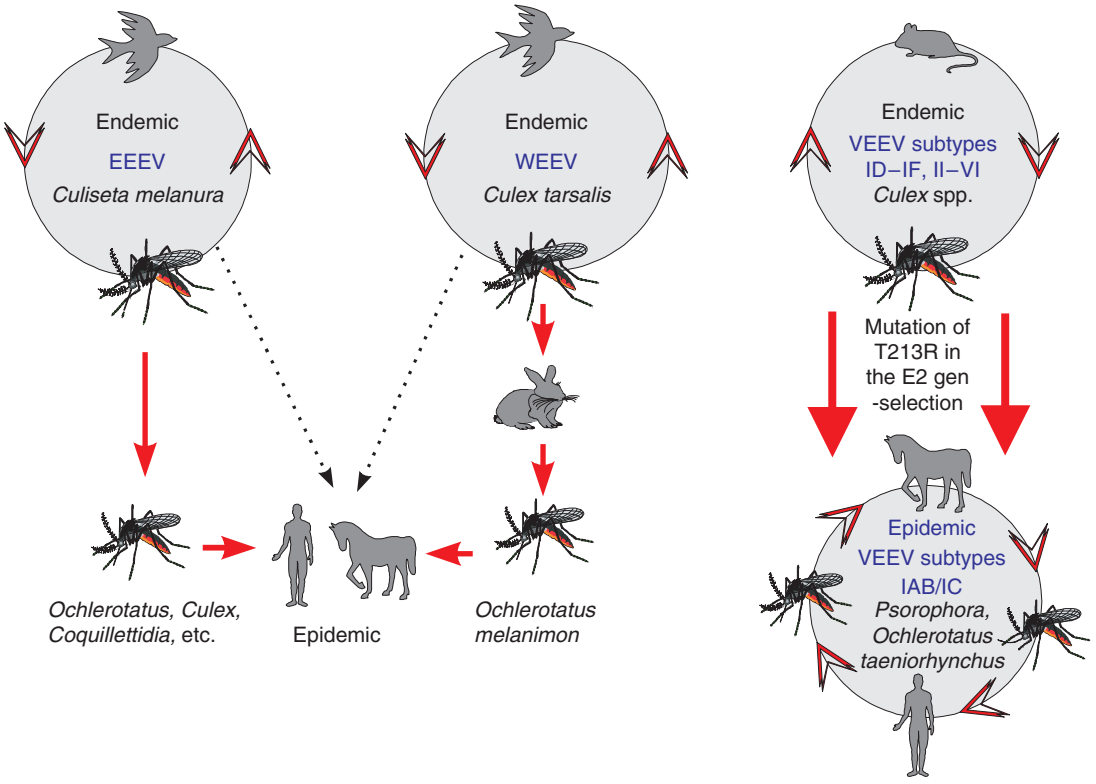

Figure 3 Epidemiology of equine encephalitic togaviruses. Ecological alterations lead to infections of horses and humans with Eastern equine encephalitis virus and Western equine encephalitis virus, but genetic shifts from subtype ID to IC Venezuelan equine encephalitis viruses trigger high viremia in horses, causing them to be virus amplifiers and sustaining epidemics/epizootics.

Union. VEEV infection has also been associated with abortion and fetal death in humans. Equids develop high-titer viremias, which serve as sources of infection for subsequently feeding mosquitoes. In recent years, spillover to humans during equine epizootics has resulted in epidemics of VEEV.

The VEEV antigenic complex, of which VEE virus is the prototype member, is divided into six distinct antigenic subtypes (I–VI). These subtypes correlate with human and equine pathogenicity but major human epidemics and equine epizootics have been associated almost exclusively with subtypes IAB and IC. Enzootic transmission is generally associated with subtypes ID and IE, which are less virulent for horses. In contrast, epizootic subtypes IAB and IC are highly pathogenic for horses, with case–fatality rates of up to 83% reported. The most recent major outbreak occurred in 1995 in Venezuela and Colombia in which 75 000–100 000 human cases occurred, and more than 300 fatal encephalitis cases were recorded. This epidemic was associated with VEEV subtype IC. In 1993, equine disease was associated with VEEV-IE in Mexico and in the period between 1993 and 1995, human cases of VEEV-ID-associated disease occurred in Peru.

Interferons (IFNs) have long been recognized as essential components of the innate immune response to various viral and bacterial infections. It is well established that IFN-α and IFN-β can protect against alphaviral disease and that the virulence correlates with the resistance to IFN-α and IFN-β. Previous studies with VEEV suggested that the IFN-α and IFN-β resistance or sensitivity phenotype correlated with epizootic potential and equine virulence, although others observed little or no difference.

Generally, severe encephalitis in VEEV infection is less common than with EEEV and WEEV infections, although VEEV-associated encephalitis is a more common outcome in children. In adults, VEEV infection usually results in flu-like symptoms and encephalitis is rare. In humans, while the case–fatality rate is low (<1%), neurological diseases, including disorientation, ataxia, mental depression, and convulsions, can be detected in up to 14% of infected individuals, especially children. Neurological sequelae in humans also are common. The predominant pathological findings in fatal human VEE cases include (1) in the CNS: edema, congestion, hemorrhages, vasculitis, meningitis, and encephalitis; (2) in the lungs: interstitial pneumonia, alveolar hemorrhage, congestion, and edema; (3) in lymphoid tissue: follicular necrosis and lymphocyte depletion; and (4) in the liver: diffuse hepatocellular degeneration.

A murine model for VEEV-induced encephalitis and lymphotropism has been established. Experimental studies have demonstrated that the murine model is

characterized by biphasic disease, which starts with productive infection of lymphoid tissue and ends in the destruction of the CNS by aggressive viral replication and a 'toxic' neuroinflammatory response, which is uniformly lethal. By the time encephalitis has developed in an infected mouse, infectious virus is usually absent from peripheral organs and blood. However, virus replicates to high titers in the brain and encephalitic mice die 5–7 days after infection. While the classical mouse model is useful to study lethal encephalitis in mice, it does not enable scientists to study VEEV clearance from the brain because naive mice uniformly succumb to CNS infection. To overcome that barrier, and to study the specific anti-VEEV immune response, as well as virus clearance from the brain, researchers use pre-immunized mice that are susceptible to VEEV infection of the CNS but survive the infection. In general, T cells have been shown to play essential roles in the hosts' defense against alphavirus infection, survival, encephalitis, and also in repair of neural damage and homeostasis in the brain. The brain has been proposed to be a distinct immune regulatory tissue, given its status as an immune-privileged site and that T-lymphocyte entry into the CNS under normal homeostatic conditions is thought to be restricted to memory T cells. Upon viral infection in the periphery and the onset of lymphopenic conditions (characteristic of VEEV infection) followed by entry into the brain, a combination of naive T cells and virus-specific memory T cells may migrate to sites of CNS infection. $CD4^+$ T cell effector functions in encephalitis may include a combination of Th1, Th2, and regulatory T cell ($CD25^+$, forkhead family transcription factor, $Foxp3^+$) activities.

$CD8^+$ T cells contribute to both recovery and pathology of encephalitic flavivirus infections, but their role in VEEV-induced encephalitis, immunopathology, and protection is unclear. In general, it has been hypothesized that cell-mediated cytotoxicity is less critical for control of cytopathic viruses such as VEEV, as compared to control of noncytopathic viruses. This general paradigm can be extended to the CNS where elimination of virus from neurons is thought to be via nonlytic mechanisms, due to the poor regenerative capacity of this cell type.

Once the blood–brain barrier is breached by the virus, local antibody production by B cells in the brain plays a role in prevention of viral entry into cells of the CNS and facilitates virus clearance via Fc receptors. Immunohistochemistry studies have shown that B cells are present in the brains of mice that are vaccinated and which survive for 1 month after challenge with VEEV via the intranasal route.

It is believed that VEEV pathogenesis, particularly the development of clinical signs of encephalitis, such as paralysis, depends both on the virus-mediated and immune-mediated neuronal cell death, and that the development of these encephalitic signs depends on two factors, direct damage of neurons and specific characteristics of the neuroinflammatory response. In addition, some studies have indicated that the early neuroinflammatory response in vaccinated animals (rapid adaptive response to infection) is incapable of controlling the initial replication of the challenge VEEV in the brain, which occurs at levels comparable to those measured in naive animals on the first 3 days after intranasal infection. Production of infectious VEEV in the brain of a vaccinated mouse is reduced 7 days after infection and is undetectable 1 month after infection in immunocompetent mice. It is likely that the reduction of VEEV replication in the brain of vaccinated animals on day 7 might impact survival. However, recent studies on genetically modified mice with preexisting anti-VEEV immunity have shown that a high level of replication in the brain over a period of 28 days is not lethal.

Protection from lethal encephalitis in mice appears to be dependent on the presence of αβ T-cell receptor (TCR)-bearing cells but not on γδ TCR-bearing cells. The relative degree of immune-mediated inflammation in various TCR-deficient mice does not fully correlate with viral clearance. Remarkably, vaccinated γδ TCR-deficient mice are protected from lethal viral challenge by intranasal inoculation but VEEV can persist up to 28 days post inoculation. Virus clearance is not affected in vaccinated, immunocompetent mice, or in surviving animals lacking functional IFN-γ receptor. Most notably, γδ T-cell-deficient mice tolerate (1) high levels of viral replication in the first 7 days after infection (acute phase), which is similar to levels observed in unvaccinated, immunocompetent mice that become paralyzed and succumb to infection; and (2) lower-level virus persistence for at least 28 days that is not observed in immunocompetent mice (asymptomatic, persistent phase). The virus can persist in the brain despite a moderate level of inflammation and cellular infiltration at the site of infection. Such viral persistence has not been observed in other animal models. Observations described in recent studies may provide opportunity in the future to dissect potential intervention points and, perhaps, to add prognostic markers that correlate with protection against VEEV encephalitis in vaccinated humans.

Highlands J Virus

As pointed out earlier, HJV is a member of the recombinant WEEV lineage. Therefore, it is not surprising that this virus initially was listed as a subtype of WEEV but later raised to the taxonomic level of 'virus' based on oligonucleotide and antigenic mapping. HJV is similar epidemiologically to EEEV in that (1) it is transmitted by the same freshwater swamp mosquitoes, *Culiseta melanura*; (2) it shares the same geographical distribution in the eastern parts of North America and as far west as Texas; and (3) its primary vertebrate hosts are passerine

birds. Curiously, however, with one recorded exception (an encephalitic horse from Florida in 1964), it has not been linked to equine or human diseases. HJV may cause severe disease in chickens (up to 7% mortality) and young turkeys, and it is responsible for severe losses in egg production in adult turkeys, but has not been detected in the brains of these diseased birds. Thus, the horse case may have had a co-morbidity that went unnoticed. In comparison of VEEV, EEEV, and WEEV, HJV has to be mentioned, but it is not considered an encephalitic alphavirus.

Diagnosis and Treatment

WEEV

IgM antibodies to WEEV usually are detectable at time of onset of the disease in either horses or humans, using 'IgM antibody-capture enzyme-linked immunosorbent assay' (MAC-ELISA) and within a few days after onset by hemagglutination-inhibition and neutralization assays. A fourfold or greater rise or fall in IgG antibody to WEEV in paired acute- and convalescent-phase samples taken at least 10 days apart also indicates infection with WEEV. Depending on the geographical origin of the suspected case or the particular travel history, a neutralization assay may be required to sort out cross-reacting antibodies against VEEV, EEEV, HJV, or other alphaviruses. If direct virus detection is required, virus can be isolated in a variety of vertebrate and mosquito cell lines; however, Vero cells (African Green Monkey kidney cells) are preferentially used. 'Reverse transcription-polymerase chain reaction' (RT-PCR) and real-time RT-PCR protocols for specific amplification of viral RNA are available. Immunohistochemical detection of viral antigen can be performed on brain tissues from dead horses. Clinical parameters usually are within the normal range, but cerebrospinal fluid (CSF) displays elevated levels of protein (90–110 mg dl^{-1}) and a leukocytosis (up to 500 cm^{-3}, mainly lymphocytes).

EEEV

EEEV infection is diagnosed using serological assays, especially by detection of IgM in serum and CSF in the presence of CNS or febrile disease, and neutralizing antibody testing of acute- and convalescent-phase samples. Virus isolation and detection of viral nucleic acid is possible, as described above for WEEV.

VEEV

Currently, VEEV infection is diagnosed principally by direct detection, for example, nucleic acid or virus isolation from acute-phase serum or spinal fluid or by serological assay, such as detection of VEEV-specific IgM in the CSF using MAC-ELISA or monoclonal antibody-based antigen-capture ELISA. The plaque-reduction neutralization test (PRNT), which like MAC-ELISA is useful in distinguishing VEEV infections from infections with other alphaviruses (see above), cannot be used to identify the serotype. Recently, a VEEV-specific blocking ELISA was described that also identifies serotype-specific antibodies against VEEV in sera of humans, equids, or rodents.

No effective antiviral treatment exists for these encephalitic arboviruses and treatment remains symptomatic.

Glossary

Analgesics Medications to relieve pain.
Arbovirus A virus transmitted to vertebrates by hematophagous (blood-feeding) insects and which replicates in the insect, as opposed to 'mechanical' transmission.
Arthritis Acute or chronic inflammation of one or more joints, usually accompanied by pain and stiffness, and sometimes swelling of the joint.
Fascia/fasciitis Fascia are bands or sheaths of connective tissues that support or connect parts of the body. Fasciitis is inflammation of these structures, most commonly the fascia of the sole of the foot and the wrist.
Maculopapular (referring to a rash) A mixture of flat red areas (macules) and small red raised spots (papules).
Nonsteroidal anti-inflammatory agents Medications used to relieve inflammation that are not corticosteroids, aspirin, or acetaminophen. Common ones include ibuprofen, naproxen, and indomethacin.
Sylvatic Involving wild animals.
Synovial Pertaining to the synovium, a thin membrane that lines joints and tendons and secretes synovial fluid.
Tenosynovitis Inflammation of tendons and the synovial membrane surrounding the tendon.
Teratogenic Causing malformations of an embryo or fetus.
Urticarial Characterized by pale or reddened irregular, elevated patches, and severe itching. An urticarial rash is also called 'hives'.

Introduction

Viruses of the family *Togaviridae* (togaviruses) are enveloped, positive-stranded RNA viruses of 60–70 nm diameter, and include viruses of two genera, *Alphavirus* and *Rubivirus*. The latter contains a single species, Rubella virus, a major cause of fever and rash internationally; it is discussed elsewhere in this series. Alphaviruses are distributed worldwide and cause illness in many hundreds of thousands of people each year. Clinical illness ranges from mild febrile illnesses to severe illnesses, such as encephalitis and hemorrhagic fever. One of the most common clinical manifestations of alphavirus infections is fever accompanied by rash and/or arthritis. The alphaviruses causing these illnesses are all closely related and belong to two major and one minor antigenic groups: the Semliki Forest virus (SFV) antigenic group (**Figure 1**), which includes SFV, Chikungunya virus (CHIKV), O'nyong-nyong virus (ONNV), and Ross River virus (RRV); and the Sindbis virus (SINV) virus group (**Figure 2**), comprising SINV and Mayaro virus (MAYV). Barmah Forest virus (BFV) is in its own antigenic complex but is genetically linked to the SFV complex viruses. The diseases they cause are usually named after the virus, though an antigenic subtype of SINV is the cause of Ockelbo disease, Pogosta disease, and Karelian fever, while the disease due to RRV has been called epidemic polyarthritis in the past. All are mosquito-borne viruses, but with differences in their ecology and epidemiology. However, there are significant similarities in the clinical aspects of the diseases caused by these viruses, likely reflecting common pathogenic features.

Clinical Manifestations

Many infected individuals will develop clinical illness, and symptomatic to asymptomatic infection ratios have been estimated at 2:1 to 4:1 for CHIKV, ONNV, and MAYV disease, from 1:80 to 3:1 or higher for RRV infections in Australia, and 1:20 to 1:40 for Ockelbo and Pogosta diseases (**Table 1**).

Infections occur at all ages and in both sexes. The male to female ratio varies in different studies but there are no major gender effects on clinical illness. Infection of children in endemic areas or during epidemics occurs commonly, but clinical disease is less common and usually milder than in adults, and arthritis is rare in children.

Acute Infection

Clinical illness presents mainly as joint pains and muscle pains, accompanied by fever and/or rash in a varying proportion of cases.

Patients typically present with joint pains and muscle pains that are usually preceded by a few days of fever, at least in those who become febrile. Sore throat and

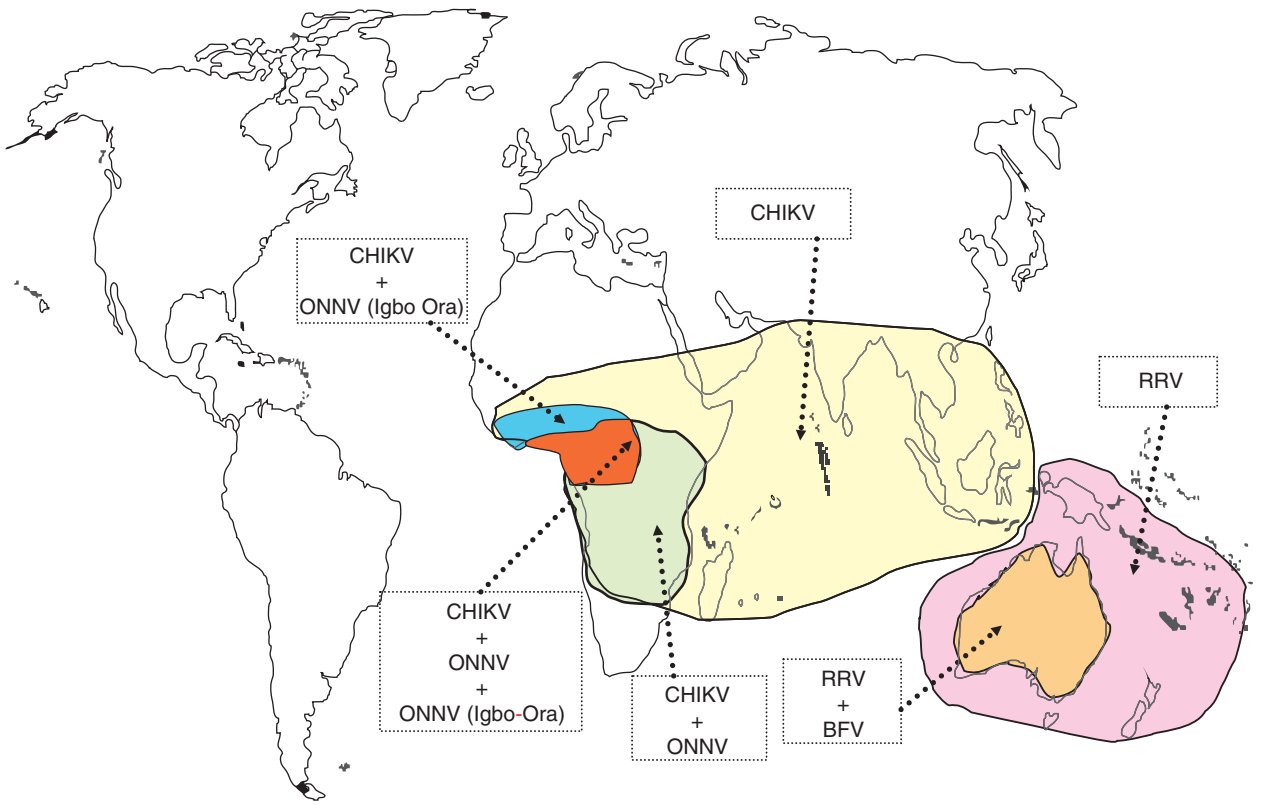

Figure 1 Geographical distribution of the major alphaviruses of the Semliki Forest virus antigenic complex that cause fever, rash, and arthritis in humans.

headache are also commonly reported, and conjunctivitis occurs occasionally. Rash generally follows the other manifestations by a few days, but can sometimes precede them or appear simultaneously. With illness due to RRV and BFV, fatigue is also a prominent clinical feature, and is probably a feature of the other alphaviruses as well. Lymphadenopathy is prominent with some of the alphaviruses, CHIKV causing generalized lymphadenopathy and ONNV causing enlarged posterior cervical lymph nodes.

The pattern of joint involvement is consistent across this group of alphaviruses, commonly involving the ankles, knees, fingers, wrists, elbows, and shoulders. Several joints are involved and the joint involvement is usually symmetric. Other joints including the jaw and the spine may also be affected and back pain is a common complaint. Pain is the most common feature, but most patients also have stiffness of the joints and, less frequently, swelling. The swelling can be due to effusion and/or synovial and soft tissue swelling. During recovery there is a gradual decline in both the number and severity of joint involvement. Inflammation of the fascia of the sole of the foot and the wrist is often reported with RRV and CHIKV infection. Pressure on nerves due to swelling of the fascia may cause tingling in the extremities. This is common with RRV, CHIKV, ONNV, and SINV disease. Muscle pain and tenderness is a prominent part of the clinical illness, usually involving the limbs and shoulders. This can sometimes be more troublesome than the joint pains and it is important to determine whether limb pain is arising from the joints or the muscles.

When rash occurs it is usually maculopapular and most florid on the face, trunk, and upper part of the limbs. However, it can involve the whole body surface, including the palms of the hands, the soles of the feet, and the scalp. Urticarial or vesicular rash occurs in some patients with SINV or BFV disease, but is rare in patients infected with the other viruses. Itchy rash is common with Pogosta disease and ONNV infection. Evidence from RRV and SINV studies suggests that the rashes probably result from presence of virus in the skin and the resulting local immune responses. The RRV rash shows a monocytic infiltrate with presence of RRV antigen within epidermal cells, while the rare purpuric rashes are associated with cytotoxic T-cell responses and capillary leakage.

Gastrointestinal symptoms such as vomiting, abdominal pain, and diarrhea have been reported with RRV and CHIKV illness, particularly in children. Severe illness is rare, other than hemorrhagic disease resembling dengue that can occur following CHIKV infection.

In summary, the majority of infections with the arthritogenic alphaviruses are benign but temporarily debilitating. Fever and rash, if present, usually last less than a week and most patients recover fully within 4 weeks. Joint pains, muscle pains, and lethargy are the slowest to resolve.

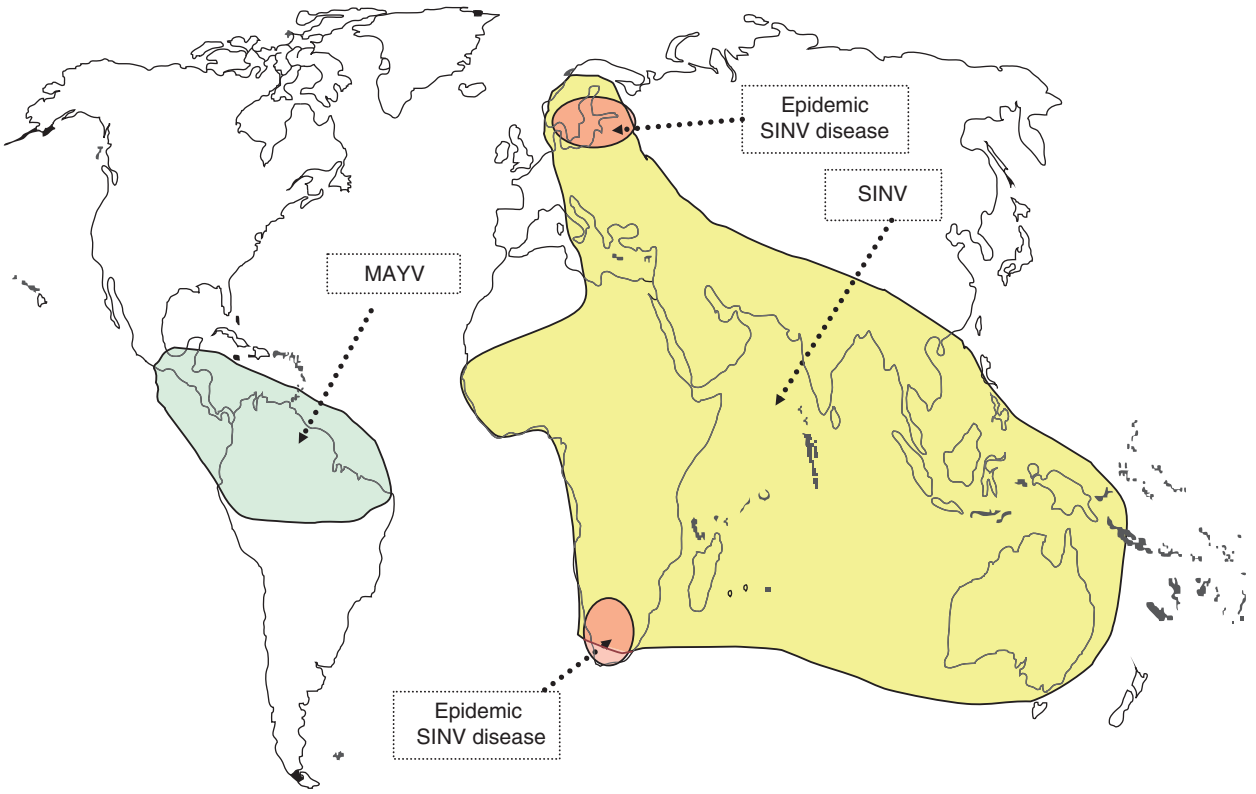

Figure 2 Geographical distribution of the major alphaviruses of the Sindbis virus antigenic complex that cause fever, rash, and arthritis in humans.

Chronic Illness Following Infection

One of the features of alphavirus arthritis is the frequency of prolonged illness, especially persisting joint pains. For SINV, joint pain lasting more than 2 years has been reported for 50% of cases in Finland (i.e., Pogosta disease) and for 25% of cases in Sweden (i.e., Ockelbo disease). Persisting joint pain is also common in Russian cases (i.e., Karelian fever). Similarly, joint pains commonly persist for many months following acute CHIKV infection, and have been reported to follow MAYV infection. Most RRV patients return to full physical activity within 3–6 months, but some suffer from persisting disability due to joint pains, muscle pains, fatigue, and depression. One study found that joint pain persisted for more than 3 months in about 70% of patients. A separate prospective case-controlled study found that at 12 months after onset 90% of patients still had joint pain, 80% had tiredness, 75% had joint stiffness, and 50% had muscle and/or tendon pain.

Infection in Pregnancy

Generally, infection in pregnancy has no special implications for the mother. RRV causes fetal and neonatal death in mice, but there is no evidence of this in humans. During outbreaks in the Pacific Islands possible congenital infection occurred in a small percentage of women, but there was no effect on length of gestation or fetal outcome, and no evidence of congenital malformation. In contrast, during the 2005 Indian Ocean outbreak of CHIKV, there was a 12% rate of transmission to the fetus, and most of these babies had either meningoencephalitis or a coagulation disorder.

Pathogenesis of Alphavirus Arthritis

The virus is introduced subcutaneously by a blood-feeding infected mosquito (**Table 2**) and initial replication probably occurs within subcutaneous tissue and local skeletal muscle. Little is known about the pathogenesis of the systemic manifestations of alphavirus infection, and interest has focused on the joint disease. RRV arthritis induces a predominantly monocytic inflammatory response in synovial fluid in humans. T-cell-derived interferon-γ has been found in joint fluid of RRV-infected humans, and is secreted by RRV-specific T cells of humans and mice. In animal models or *in vitro* a number of alphaviruses including RRV, BFV, CHIKV, and SINV infect synovial monocytes/macrophages and, in the case of RRV, can be found in synovial cells. A combination of release of inflammatory mediators from the infected monocytes/macrophages and the cytotoxic T-cell responses to viral antigens are the likely explanations for the synovial swelling, effusion, and joint pain experienced in acute alphavirus infection.

Table 1 The clinical features of the major alphaviruses causing fever, rash, and arthritis in humans

	Chikungunya virus	*O'nyong-nyong virus*	*Ross River virus*	*Barmah Forest virus*	*Sindbis virus (Pogosta)*	*Sindbis virus (Ockelbo)*	*Mayaro virus*
Incubation period	3–12 days, usually 2–7 days	>8 days	3–21 days, usually 7–9 days	7–9 days	<7 days	<7 days	up to 12 days, usually 6–12 days
Fever	100%	Similar to CHIK	45–55%	50%	45%	40%	100%
Joint pains	80–100%	Similar to CHIK	95–100%	70–85%	95%	95%	50%
Arthritis (Joint stiffness/swelling)	Usually, soft tissue	Similar to CHIK	80–90%	30%	45%	60%	NI[a]

Table 2 Summary of the major ecological characteristics of the arthritogenic alphaviruses

Virus	*Reservoir*	*Major vectors*	*Geographic distribution*
Chikungunya virus	Nonhuman primates, possibly rodents	Africa (rural): *Aedes africanus, Ae. furcifer, Ae. luteocephalus, Ae. taylori*; Asia: *Ae. aegypti, Ae. albopictus*	Africa, Saudi Arabia, SE Asia, Philippines
O'nyong-nyong virus	Unknown	*Anopheles funestus, An. gambiae* (and related species)	Uganda, Kenya, Tanzania, Zaire, Malawi, Mozambique, Senegal, Zambia, Cameroon, and the Central African Republic; Igbo Ora variant in Nigeria, the Central African Republic, Côte d'Ivoire.
Ross River virus	Marsupials, especially macropods	*Culex annulirostris, Ae. vigilax, Ae. camptorhynchus, Ae. notoscriptus, Ae. sagax*	Australia, New Guinea, Irian Jaya, Pacific Islands
Barmah Forest virus	Marsupials, especially macropods	*Cx. annulirostris, Ae. vigilax, Ae. camptorhynchus*	Australia
Mayaro virus	Possibly wild vertebrates	*Haemagogus* spp.	Central America, northern South America, the Amazon Basin, Trinidad
Sindbis virus	Range of wild and domestic birds	Northern Europe: *Ae.* spp., *Culiseta* spp., *Culex* spp.; Africa: *Culex* spp., *Aedes* spp., *Mansonia* spp., *Cx. univittatus* (in South Africa); Australia: *Cx. annulirostris*	Southern and northeastern Africa, Scandinavia, Finland, Russia, Central and Eastern Europe, Asia, Southeast Asia, and Australia

Attempts to isolate RRV from the joint fluid or tissues of patients with persisting joint disease following RRV infection have been unsuccessful, but RRV antigens have been detected within synovial fluid mononuclear cells. RRV RNA has been found within synovial tissue by polymerase chain reaction (PCR) and RRV can persist within macrophage cultures *in vitro* even in the presence of neutralizing antibodies. All this suggests that the chronic arthritis may result from a persistent, nonreplicative infection that induces an ongoing immune response to viral antigens.

There is also evidence that host factors are likely to influence outcomes. RRV joint disease in humans has been associated with HLA-DR7 positivity, which has a possible role in reducing the cytotoxic T-cell responses to the virus.

Diagnosis of Infection

A number of the alphaviruses produce a viremia detectable by culture or nucleic acid amplification during the early stages of infection, though most patients are not seen until after this period. Alphaviruses will grow in mosquito cells such as C6/36, AP-61, or TRA-284 incubated for 3–4 days at 28 °C, followed by blind passage to indicator cells, such as Vero, baby hamster kidney (BHK), or chick embryo cells that are incubated at 37 °C for a few days. The virus can be identified using monoclonal antibodies, by neutralization tests, or by amplification and characterization of viral nucleic acid using virus-specific primers, probes, or product sequencing.

Detection of viral RNA is significantly more sensitive than is culturing and has been used for detection of CHIKV, RRV, and SINV in blood, and occasionally from other clinical material. A variety of assays directed at NSP1 or E2 viral protein sequences have been used either in uniplex or multiplex formats and, more recently, DNA microarrays have been used for virus identification and characterization.

However, the culture and PCR-based methods are expensive, difficult to access, and negative in most cases. Therefore, diagnosis is almost exclusively done using serological tests. Most diagnostic testing uses the enzyme immunoassays (EIAs) or hemagglutination inhibition (HI) tests, with some use of indirect immunofluorescence antibody (IFA) assays. EIAs and IFA tests can be used to specifically detect either immunoglobulin G (IgG) or immunoglobulin M (IgM). HI will detect both IgG and IgM but is relatively insensitive for IgM detection. Neutralizing antibody titers are regarded as the most specific of the tests, but are confined to specialized laboratories.

IgM antibodies nearly always appear within 1 week of onset of illness, followed by a rise in IgG titer. It is characteristic of alphavirus infections that IgM persists for long periods of time. RRV IgM and BFV IgM usually persist for several months and sometimes years, independent of whether the patient has ongoing symptoms. Persisting IgM has also been documented for SINV and CHIKV, and is likely to be common to all the arthritogenic alphaviruses. Therefore detection of IgM does not, by itself, prove recent infection. That is best diagnosed either by seroconversion from IgG negative to IgG positive or by a fourfold or greater rise in rise in IgG titer between acute and convalescent samples tested in parallel.

False-positive IgM results may also occur occasionally and appear to be a problem particularly with EIA tests,

but can occur with other tests as well. They are due to either a nonspecific reaction of the assay or to cross-reaction with IgM produced in response to infection with a related virus. For example, false-positive BFV IgM is occasionally seen in patients with genuine RRV IgM, incorrectly suggesting a dual infection. Cross-reacting antibodies are more likely to occur between closely related viruses, such as ONNV and CHIKV, or MAYV and SFV, but also occasionally occur with rubella or with infectious and noninfectious conditions that cause polyclonal B-cell activation.

Therefore, the proper interpretation of alphavirus serology requires a good clinical history of the illness and knowledge of the viruses to which the patient may have been exposed. Nevertheless, standard serological tests performed in the correct clinical context have proved to be very reliable.

Treatment of Alphavirus Infections

There is a very limited literature on the treatment of alphavirus arthritis. Rest and gentle exercise assist many patients, and nonsteroidal anti-inflammatory agents and simple analgesics are commonly used and provide substantial benefit for the musculoskeletal manifestations.

There are currently no specific antiviral agents available for the treatment of alphavirus infections, nor are there likely to be any in the near future. Drugs used for treatment of rheumatoid arthritis help some patients. Hydroxychloroquine has shown a benefit for patients with post-CHIKV arthritis in one small trial, and corticosteroids have been used for acute RRV arthritis, but most practitioners remain reluctant to use these agents until there are more data about long-term benefits and safety.

Barmah Forest Virus

BFV was first isolated from *Culex annulirostris* in southeast Australia in 1974, then from mosquitoes in other areas of eastern and northern Australia. Human cases were not reported until the 1980s in southeastern Australia, Queensland, the far north of Western Australia, and in the Northern Territory. The virus was subsequently found to be endemic in the tropical areas of northern Australia. Since then there has been appearance of human disease in new areas both within the tropical north and in the more southerly temperate areas where RRV is also active. BFV activity in new areas has been marked by human epidemics of varying size, after which it settles into an endemic pattern that is similar to, but not always coincident with, RRV activity. Human infections have now occurred throughout mainland Australia, with seasonality and incidence varying between regions.

BFV has been isolated from many of the same mosquito species that carry RRV. It is assumed that the same marsupial hosts are important in maintenance and amplification of the virus, but the full range of vertebrate hosts remains to be determined. BFV shows genetic homogeneity across Australia, suggesting that the same strain of BFV spreads widely across the country.

BFV disease has been reported in people aged 5–73 years old, although most cases of both BFV disease and RRV disease occur between the ages of 20 and 60 years. Clinically it is very similar to RRV disease, though joint involvement is less common and less severe, while rash is more common and more likely to be vesicular or urticarial.

Chronic illness occurs following BFV arthritis, but there are few data regarding this. Chronicity is less common after BFV infection than following RRV infection and probably occurs in about 10% of patients.

Chikungunya Virus

CHIKV disease was first recognized following an outbreak of arthritis in Tanzania in 1952, and shortly after was isolated from human serum as well as from *Aedes* spp. and *Culex* spp. mosquitoes. The name is a Swahili word meaning 'that which contorts (or bends up)' and refers to the severe joint pains and stiffness associated with this illness.

The virus is widespread across sub-Saharan Africa, Saudi Arabia, the Indian subcontinent, and Southeast Asia, especially the Philippines. Two major genetic lineages exist, of which one is restricted to West Africa. The other is further subdivided into Asian and East African sublineages. While there are some biological differences between these lineages, it is not known whether these have any specific pathogenic implications. There are data to suggest that genetic diversity may be seen among CHIKV strains responsible for individual outbreaks in Africa and in adjacent areas. For example, during the recent Indian Ocean outbreak, the virus was from the East African sublineage, but showed evolution during the course of the outbreak. The Asian sublineage shows a much greater genetic conservation.

In Africa, the virus shows low-level endemic activity in rural areas, where it is believed to be maintained in a cycle involving *Aedes* spp. mosquitoes, nonhuman primates, and, possibly, rodents. The role of nonhuman mammalian hosts in Asia is not known, though seropositive primates have been described. Occurrence of epidemic disease in Africa and Asia is associated with the rainy season and increases in numbers of *Aedes aegypti* and, in Asia, *Ae. albopictus*. Urban outbreaks may continue over 2 or more years, but cases then typically disappear for several years. *Mansonia* spp. and *Culex* spp. have also been implicated as potential vectors in laboratory studies.

Epidemics occur either due to reemergence of the virus in an area of prior activity once sufficient time has passed for a susceptible population to reestablish, or due to movement of the virus into areas without previous activity. They may involve up to half the population. There have been regular occurrences of epidemics in Africa, with the most recent being in Kinshasa in 1999/2000. In Asia a number of outbreaks occurred in the 1960s, followed by a relatively quiescent period in the 1970s, reemergence in Indonesia in 1982, further spread within Malaysia in 1988–89, reemergence in Thailand in 1995, and in Indonesia in 2001–03. The most recent outbreak began in late 2004 in southwestern Indian Ocean islands and subsequently spread over the next couple of years to affect several hundred thousand people in that region, with the largest number of cases on Réunion, the Seychelles, and in several areas of India. Subsequently, small numbers of cases were detected worldwide in travelers returning from epidemic areas.

CHIKV acute illness is more severe than that seen with the other alphaviruses, with fever that is more frequent and higher, worse joint pain, a greater incidence of severe disease, and occasional deaths. While most patients recover within a few days or weeks, chronic joint pains lasting months to years occur in about 10% of patients.

Hemorrhagic manifestations, including petechiae and gingival bleeding due to CHIKV infection, are well described but rare and can lead to a misdiagnosis of dengue. This is complicated by the fact that these two viruses may co-circulate and patients may be simultaneously infected by both. Fatalities in the past have been extremely rare and were reported to occur in the very young or in those with severe hemorrhagic disease, though it is not certain that the fatalities were due to CHIKV. In the recent Indian Ocean outbreak, a number of cases of CHIKV encephalitis and deaths have been reported. The latter have occurred in the elderly or those with co-morbidities.

Mayaro Virus

MAYV was first isolated from a forest worker in Trinidad in 1954, and is now known to be widely distributed in Central America, northern South America, and the Amazon Basin. Transmission is primarily by forest-dwelling *Haemagogus* spp. mosquitoes, though *Mansonia venezuelensis* and *Ae. aegypti* are possible vectors. The virus is probably maintained in a sylvatic cycle between mosquitoes and wild vertebrates. There are two genotypes, one being widespread and the other found only in Brazil.

Occasional outbreaks and sporadic cases occur within the endemic areas following human contact with the forest environment. The illness is very similar to that caused by CHIKV, including hemorrhagic disease in some cases.

Una virus was initially classified as subtype of MAYV, but is now regarded as a separate species and has not been shown to cause human disease.

O'nyong-nyong Virus (Including Igbo-Ora Variant)

ONNV is closely related to CHIKV both virologically and clinically. The disease was first described in Uganda in 1959 and the name is a tribal word for painful joints. It was subsequently isolated from human serum and from mosquitoes. That epidemic eventually involved more than 2 million people in Uganda, Kenya, Tanzania, Zaire, Malawi, Mozambique, Senegal, and Zambia. Spread was thought to have occurred by movement of viremic humans. This virus has also been found in Cameroon and the Central African Republic. A variant called Igbo-Ora was later found in West Africa, in Nigeria, Central African Republic, and Côte d'Ivoire. ONNV disappeared for 35 years before reappearing in Uganda in 1996/1997, with subsequent cases in Kenya. Infections due to the major strain (i.e., not Igbo-Ora) have recently been reported from Côte d'Ivoire and Chad.

Transmission is by *Anopheles funestus* and *An. gambiae*. It is presumed that there is a nonhuman mammalian host to account for maintenance of the virus between epidemics, but it has not yet been identified.

The clinical illness is very similar to CHIKV disease, though fever is usually milder and there is prominent cervical lymphadenopathy. Joint pain persisting for several months has been noted, but the frequency is not known.

Ross River Virus

RRV was named after an area near Townsville in northeastern Australia, where it was first isolated from *Ae. vigilax* in 1966, from mosquitoes collected in 1959. It was isolated from the blood of a febrile child in 1973, then from a case of epidemic polyarthritis in 1979. It has since been found in Papua New Guinea, Irian Jaya, and the Solomon Islands. In 1979–80 an epidemic occurred in various Pacific Islands involving over 50 000 cases, probably originating from a viremic air traveler from Australia.

Three genotypes of RRV have so far been described. Genotype 1 was present in Queensland in northeastern Australia until the mid-1970s, after which it disappeared. Genotype 2 has always been the major type on the east coast of Australia and is now the major current circulating type throughout Australia. Genotype 3 was the dominant type in the southwest of Australia until 1996, since which it has largely been replaced by genotype 2 virus. Pacific Islands isolates belong to genotype 2.

RRV is primarily maintained in a cycle between mosquitoes and vertebrate hosts. Two salt-marsh mosquitoes, *Ae. vigilax* and *Ae. camptorhynchus,* are important in northern and southern coastal areas of Australia, respectively. In some coastal and inland areas, transmission to humans occurs from several freshwater breeding species, especially *Cx. annulirostris* but also *Ae. sagax* and *Ae. normanensis*, as well as *Ae. camptorhynchus* breeding in brackish and freshwater. Other species, such as *Coquillettidia linealis* and *Ae. notoscriptus*, may play significant roles in urban environments.

The major vertebrate hosts for both maintenance and amplification of RRV are the macropod marsupials (kangaroos, wallabies, and euros). Horses and small marsupials, such as possums, may be important in periurban and urban areas. There is circumstantial evidence that RRV may survive for years in desiccation-resistant eggs of some *Aedes* spp.

RRV disease is reported every year in Australia, with between 2000 and 8000 notified cases per annum. In the tropical northern parts of the country most activity is seen during the wet season from December to May. Further south in temperate regions, human infections occur predominantly in late spring, summer, or autumn. In those seasons, rainfall or tidal inundation of coastal breeding sites coupled with warm temperatures leads to an increase in vector numbers. Major outbreaks in these areas occur every 2–4 years. In the arid inland regions of Australia occasional outbreaks occur following heavy rainfall with flooding.

RRV disease has been reported in people ranging in age from less than 1 year old to 88 years old, although most cases occur between the ages of 20 and 60 years. Clinical illness appears to be uncommon in children. The clinical illness is typical of these alphaviruses, though tenosynovitis and fasciitis are more common. Joint pains, muscle pains, and fatigue persist for months or years in 70–90% of patients.

Semliki Forest Virus

SFV was first isolated in 1942 from mosquitoes in Uganda and is distributed across sub-Saharan Africa. Serological surveys show that human infection is common in endemic areas, but it has only been associated with a single reported human outbreak of fever, headache, and joint pains that occurred in the Central African Republic in 1987.

Sindbis Virus (Including Ockelbo Virus)

SINV was first isolated from *Culex univittatus* at Sindbis in Egypt, and subsequently from a wide range of species of mosquitoes and vertebrates in Europe, the Middle East, Africa, India, Asia, the Philippines, and Australia. It was not until 1961 that it was isolated from the blood of a febrile human in Uganda, and then linked to human disease in South Africa in 1963.

SINV is the most widely distributed arbovirus causing human disease. It is found throughout southern and northeastern Africa, Northern, Central, and Eastern Europe, Asia, Southeast Asia, and Australia, but clinical disease is largely restricted to Sweden (Ockelbo disease), Norway (Ockelbo disease), Finland (Pogosta disease), Russia (Karelian fever), and South Africa. Clinical disease has only rarely been reported in Asia. Only isolated cases of illness in humans have been reported from Australia, although serological studies have indicated that human infections occur regularly.

Many species of birds and of other vertebrates have been shown to be capable of being infected with SINV, but disease has been identified only in humans. Mosquitoes feeding on birds appear to be the primary source of human infection. In Sweden the virus has been found primarily in the fieldfare (*Turdus pilaris*), redwing (*T. iliacu*), and song thrush (*T. philomelos*), and in Norway game birds also carry the virus. Transmission to humans is via *Aedes*, *Culiseta*, and *Culex* spp. in Sweden, Norway, and Finland. In Africa *Culex*, *Aedes*, and *Mansonia* spp. are important, with *Cx. univittatus* being the primary human vector in South Africa. In Australia, *Cx. annulirostris* is the dominant vector species, but it is also been isolated from *Aedes* spp. No maintenance cycles involving nonhuman vertebrates have been identified as yet in any country.

Two major lineages circulate: the Paleoarctic/Ethiopian and the Oriental/Australian. It is believed that migratory birds are responsible for the spread of the two lineages, though within each there is a genetic heterogeneity consistent with local adaptation and evolution of the virus. Studies in Australia have shown that there is also temporal evolution of the virus within a lineage, presumed to be due to periodic introduction of new variants by migratory birds. A third unique lineage has been identified in the southwest of that country.

The restricted distribution of human epidemics suggests that the Paleoarctic/Ethiopian lineage has a greater ability to cause disease than does the Oriental/Australian lineage. However, the ecology of SINV and the pathogenesis of disease are still poorly understood, so other factors may account for the unusual disease patterns.

Epidemics of Ockelbo disease and Pogosta disease occur during summer and autumn in northern Europe, coincident with the peak mosquito breeding period. Ockelbo occurs each year, while Pogosta disease has shown a consistent periodicity of 7 years since it was first recognized in 1974, the reasons for which are uncertain. Summer–autumn SINV epidemics have also been described in South Africa. Patients usually recover within a few weeks but chronic joint pains are common.

The Future

Alphavirus infections impose a substantial human health and economic burden, without any immediate prospect of antiviral therapy or vaccines. Further research is needed to understand the ecology and epidemiology of these viruses and the pathogenesis of disease.

Glossary

Cohabitation experiment Fish needle-inoculated with wild-type salmonid alphaviruses (SAVs) are placed in the same tank with naive fish to determine whether SAV can be transmitted from infected to uninfected fish via cohabitation. Alternatively, fish immunized with inactivated SAVs are placed in the same tank as naive fish and then fish experimentally inoculated with wild-type SAVs are introduced to determine whether immunized fish can passively transfer SAV immunity to naive individuals in the same water.

Lice Any of numerous small, flat-bodied, wingless biting or sucking insects of the orders Mallophaga or Anoplura, many of which are external parasites of vertebrates.

Smolt A young salmon at the stage intermediate between the parr and the grilse, when it becomes covered with silvery scales and first migrates from freshwater to the sea.

Introduction

The virus family *Togaviridae* comprises two genera, *Alphavirus* and *Rubivirus*. The latter includes only Rubella virus and will be discussed elsewhere in this encyclopedia. The alphavirus-type species is Sindbis virus which, as do many other alphaviruses, causes fever with rash. There are many medically important alphaviruses, including Eastern equine encephalitis virus, Western equine encephalitis virus, and

Venezuelan equine encephalitis virus; these also will be discussed elsewhere in this encyclopedia.

Most alphaviruses are transmitted by hematophagous arthropods to susceptible terrestrial mammals and, as mentioned, can cause diseases in them ranging from simple fevers to fatal encephalitides. The exceptions are alphaviruses that have not been associated with human rash and fever or encephalitis, or occur only in fish. These and certain other viruses are outlined below and summarized in **Table 1**.

Humans in South America have been shown to have antibody to the mosquito-borne alphaviruses Una virus (UNAV, Semliki Forest antigenic complex) and Trocara virus (not placed in an antigenic complex); these viruses have not been associated with human disease. However, UNAV is closely related to Mayaro virus, a known human pathogen. Antibody to Ndumu virus (NDUV) was found in humans in South Africa in the 1950s and NDUV isolates from *Mansonia* and *Aedes* mosquitoes cause encephalitis in mice; NDUV has not been associated with human disease. Cabassou virus (CABV), a member of the Venezuelan equine encephalitis virus complex, has been isolated from mosquitoes, marsupials, and birds in French Guiana; human disease caused by CABV has not been observed. Whataroa virus (WHAV; Western equine encephalitis virus complex) has been isolated from mosquitoes, birds, and marsupials in New Zealand and from mosquitoes in Australia. Neutralizing antibody to WHAV has been detected in humans in those countries as well; human disease caused by WHAV has not been recorded. Bebaru virus (BEBV), a Semliki Forest complex virus, has been isolated from *Culex* (*Lophoceraomyia*) spp. and *Aedes butleri* mosquitoes in Malaysia and Australia. Neutralizing antibody to BEBV has been detected in Malaysians. Relatively little is known about these six viruses. They have not often been isolated from mosquitoes and their transmission cycles are not defined.

Neutralizing antibodies to Middelburg virus (MIDV), a member of the Middelburg virus complex, have been detected in humans in South Africa, Mozambique, and Angola; no human disease has been associated with MIDV. Neutralizing antibodies to MIDV have been detected in cattle, goats, sheep, and horses in South Africa. However, it is unknown whether livestock participate in the natural transmission of MIDV. Numerous MIDV isolates have been made from *Aedes* and *Mansonia* mosquitoes and virus transmission by *Aedes caballus* has been documented. Experimentally infected *Ae. caballus* successfully transmitted MIDV to lambs starting 4 days post-infection, and the lambs developed viremia and a stiff gait. Despite this, MIDV has not been associated with disease in livestock.

Getah virus (GETV), a member of the Semliki Forest virus complex, was first isolated from mosquitoes in Malaysia and subsequently from mosquitoes in other Asian countries, Australia, and eastern Russia. The first recognition of disease caused by GETV was in racehorses in Japan in 1978. Antibody to this virus has been detected not only in horses but also in humans, pigs, and other mammals in Asia and Australasia. Pathogenicity of GETV is relatively mild and appears to be limited to horses and pigs. Several outbreaks of GETV disease in horses have been reported in Japan and India. Disease is principally characterized by fever, rash, and limb edema and also includes (India) depression, anorexia, and lymphocytopenia. The rash may be caused by immune complex-mediated hypersensitivity. Horses recover completely. Pigs are highly susceptible to GETV infection, with occasional deaths of newborn piglets or fetuses occurring by transplacental infection; adult pigs are less likely to be symptomatic. Because Japanese encephalitis virus, a flavivirus, also causes deaths of fetal pigs, laboratory diagnosis is required to distinguish between infections caused by these two viruses.

Fort Morgan virus (FMV), a Western equine encephalitis complex virus, was first isolated in 1973 from *Oeciacus vicarius* (Hemiptera: Cimicidae) bugs in a nest of cliff swallows occupied by house sparrows (*Passer domesticus*). Subsequently, numerous FMV isolates, plus isolates of a closely related subtype, Buggy Creek virus, were made from *O. vicarius* bugs, house sparrows, and cliff swallows (*Petrochelidon pyrrhonota*); no human disease caused by FMV has been observed. Experimentally infected *O. vicarious* transmitted FMV to nestling sparrows 1 month after infection and for up to 312 days after being held at temperatures simulating hibernation. Mosquitoes of certain *Culex* and *Culiseta* species were refractory to FMV infection, suggesting that transmission is likely mediated only by *O. vicarius*.

Until recently, knowledge of alphaviruses was limited to viruses affecting terrestrial mammals and birds. The recent discovery of alphaviruses in lice parasitizing elephant seals (family Phocidae, genus *Mirounga*) and in fish indicates that alphaviruses occur in both terrestrial and marine environments. It is unknown whether louse-borne Southern elephant seal virus (SESV) causes disease in elephant seals, but outbreaks of sleeping disease and pancreas disease (PD), both caused by salmonid alphaviruses (SAVs), are widespread in farmed fish throughout Western Europe and North America and cause major economic losses to aquaculture industries.

Southern Elephant Seal Virus

SESV was first isolated in 2001 from seal lice, *Lepidophthirus macrorhini*, collected from southern elephant seals (*Mirounga leonina*) on Macquarie Island, 2000 km south of the Australian mainland. Whereas the vector competence of *L. macrorhini* has not been evaluated, Macquarie Island has no mosquitoes and ticks are rare

Table 1 Alphaviruses not associated with human disease or that occur only in fish or have been associated with marine mammals

A question mark indicates a postulated host.

on elephant seals, further suggesting that lice are vectors of this virus. SESV has not been isolated from elephant seals, but the prevalence of neutralizing SESV antibody is high in a population of elephant seals on Macquarie Island and is higher in older animals.

Genetic comparisons have revealed that SESV is most closely related to Australasian alphaviruses in the Semliki Forest complex, but antigenic studies showed that SESV is only very distantly related to other members of the Semliki Forest complex. That alphaviruses may be vectored by lice on migrating elephant seals traveling long distances, including between Australasia and South America via Antarctica, suggests that dispersal of some alphaviruses may be by such mechanisms, although seal populations other than those on Macquarie Island have not been sampled for evidence of SESV infection.

Salmonid Alphaviruses

Alphaviruses enzootic in fish include salmon pancreas disease virus (SPDV), sleeping disease virus (SDV), and Norwegian salmonid alphavirus (NSAV). These viruses cause morbidity and mortality in farmed salmon and trout. The SAV shares only ~33% amino acid identity with other alphaviruses, the basis for considering them as quite distinct from other alphaviruses.

Salmon Pancreas Disease Virus

PD has been reported in farmed Atlantic salmon, *Salmo salar*, in Western Europe and the United States since 1976 and causes up to 50% mortality in salmon smolts. Affected smolts develop necrosis of the exocrine pancreas, cardiomyopathy, skeletal myopathy that causes infected fish to swim sluggishly, and inappetance, all of which lead to stunted growth and, sometimes, death. Infected salmon smolts experience a triphasic disease including: (1) a preacute stage characterized by pancreatic exocrine necrosis and basophilia of pancreatic acinar cells; (2) an acute phase marked by hemorrhagic pancreatic necrosis and occasional liver and kidney lesions as well as inappetance and inactivity; and (3) a post-acute phase in which the pancreas recovers histopathologically, although survival and weight are lower than in uninfected fish of the same age.

For many years the causative agent of this disease was not known, and attempts to isolate a virus from moribund fish were unsuccessful. The strongest evidence that PD was transmissible came from experimental studies in which PD developed in naive fish injected with spleen homogenates from diseased salmon and from experiments in which naive fish that cohabited in tanks with PD-afflicted fish developed the disease. The etiological agent of PD was identified in 1999 as the alphavirus SPDV on the basis of sequence analysis of viral RNA extracted from tissues of infected farmed salmon. Ectoparasitic sea lice of salmon, *Lepeophtheirus salmonis*, have been postulated as vectors but SPDV-infected lice have not been reported and experimental vector competence studies are lacking. Since PD has been reported only in salmon smolts, natural reservoirs of SPDV presumably are fish. Cohabitation experiments suggest that transmission can occur via direct horizontal spread among salmon in the absence of arthropod vectors, although whether lice were eliminated from experimentally infected salmon is unclear. Further, the stability of SPDV in seawater of various temperatures or evidence of contact transmission among fish or via their excreta has not been evaluated.

As with other alphaviruses, SPDV contains a single-stranded positive-sense RNA genome of approximately 12 kbp. SPDV shares fundamental biological properties with other alphaviruses, although it replicates more slowly in cell cultures than do other alphaviruses and only infects select fish cells. Salmon smolts experimentally infected with SPDV develop hemorrhagic pancreatic necrosis consistent with lesions observed in wild fish. Smolts immunized with inactivated cultured SPDV are protected against cohabitation challenge with wild-type SPDV, indicating that tissue-culture adapted SPDV may have potential as a vaccine candidate to protect against PD.

Sleeping Disease Virus

Outbreaks of SDV have been recognized since 1985 in farmed freshwater rainbow trout, *Oncorhynchus mykiss*, in France, Great Britain, and Norway. Diseased trout lay on their sides at the bottom of their tanks, reminiscent of a sleeping state. Lesions of diseased fish include the sequential development of pancreatic atrophy, cardiac necrosis, and, ultimately, skeletal muscle degeneration. Sleeping disease has been estimated to affect 30% of fish farms in northern France. However, estimates are based on behavioral observations and scant histological studies of moribund fish, and it is difficult to discriminate between pancreatic lesions induced by SDV and those occurring in the similar disease caused by the salmonid birnavirus infectious pancreatic necrosis virus. As with SPDV, mechanisms of SDV transmission are not well understood. One SDV isolate was made from rainbow trout farmed in seawater in close proximity to diseased salmon in Norway, suggesting water-borne transmission. Another possibility is vector-borne transmission via an arthropod or another unrecognized organism that associates with both trout and salmon.

Until 2000, efforts to isolate and characterize SDV proved unsuccessful because the virus does not produce cytopathic effects (CPEs) in most fish cell lines. Isolation of SDV typically requires incubating SDV-infected fish organ homogenates with rainbow trout or Chinook salmon embryo cells at 10 °C for 7–11 days, with CPE generally only becoming evident after several passages. Rainbow trout inoculated intraperitoneally with SDV have detectable viremias within 1 week after inoculation and develop neutralizing antibody to the virus.

Although it exhibits unique ecological characteristics, SDV is presently classified as a strain of SPDV. Genetic analyses of isolates revealed that SDV resembles mammalian alphaviruses with respect to genome organization, conserved nucleotide sequence elements, and amino acid motifs. However, the SDV E3 protein lacks glycosylation. The SDV E1 and E2 glycoproteins diverge genetically from other alphaviruses by 66–70%. This genetic diversity between SDV (and the other SAV) and all other alphaviruses is greater than the degree of diversity between any two mammalian alphaviruses, indicating that the SAVs are the most genetically divergent alphavirus species known. Both SDV and SPDV share only 26% envelope 2 (E2) gene amino acid identity with SESV, a level similar to the identities that SDV and SPDV share with respect to E2 proteins of other alphaviruses. This lack of sequence similarity between marine alphaviruses is evidence against a common aquatic origin of alphaviruses. Comprehensive sequence comparisons using all available SAV sequences with members of other alphavirus complexes are needed if we are to clarify the phylogenetic relationships between SAVs and other alphaviruses, including SESVs.

Sequence comparisons of SDV isolated from geographically distant areas in Europe revealed that strains fall into three genotypes according to location of isolation, but these genetic distinctions are not accompanied by detectable antigenic differences. Even with newly developed monoclonal antibody-based immunoperoxidase detection assays, SDV isolates cannot be differentiated antigenically from one another or from SPDV. Due to difficulties in distinguishing SDV isolates from each other and from SPDV, and to the similar clinical presentations of the three SAVs and infectious pancreatic necrosis virus, definitive diagnosis of SAV is achieved by comparisons of sequenced strains.

Comparative studies revealed that SDV and SPDV share 91% amino acid identity and that SPDV has a 24 nt insertion at the C-terminus of the nsP3 gene that encodes a protein involved in viral RNA synthesis; the phenotypic relevance of this insertion is unknown. Given the rapid and artificial evolution of alphaviruses in cell culture, genomic analyses of SAV that are customarily recovered after extensive fish cell passage should be interpreted with caution. For example, the first published SPDV sequence, derived from virus subjected to repeated passage, contained cell-culture-adapted variant sequences that were not representative of sequences generated from low or unpassaged SPDV isolates.

Norwegian Salmonid Alphaviruses

In 2005, a genetically distinct SAV, NSAV, was identified in diseased salmon and rainbow trout in Norway. NSAV differs genetically from SDV by ~7% and from SPDV by ~9%. Fish infected with NSAV experience disease similar to PD and SD. Unlike certain terrestrial alphaviruses that use small rodents as reservoirs, isolates of NSAV collected from geographically dispersed Norwegian farms raising saltwater fish do not segregate phylogenetically according to physical proximity, suggesting either extensive gene flow within the fish reservoir or a common source of virus. Given that farmed smolts do not migrate in open water, movement of fish by humans for aquaculture is one possible means of NSAV dispersal.

Glossary

Alphavirus A virus in the genus *Alphavirus*.
Clade All of the descendants of a common ancestor (also known as a monophyletic group).
Genotype Genetic composition of individuals; used to delineate relatedness of a group of individuals.

Introduction

The alphaviruses are a group of antigenically related arthropod-borne viruses (arboviruses) that were first isolated in the 1930s. The arboviruses were originally divided into one of three serological groups (A, B, or C) based upon results of hemagglutination inhibition (HI) tests as performed by Casals and Brown. Later characterization of the viruses based upon genetic and virion properties led to the inclusion of those viruses clustered in group A in the genus *Alphavirus*.

Alphaviruses can be broadly categorized into three distinct groups based upon the type of illness they produce in humans and/or animals. Disease patterns include: (1) febrile illness associated with a severe and prolonged arthralgia, (2) encephalitis, or (3) no apparent or unknown clinical illness. Any particular alphavirus will fit into only one of the above profiles but additional symptoms such as demyelination may also be present. Additionally, some of the viruses can induce abortion or stillbirth in animals, decreased egg production in avians, or mortality in vertebrates. Further, a small number of alphaviruses, those strains belonging to the Salmon pancreas disease virus (SPDV) species, infect and cause illness only in fish. The alphaviruses have a wide geographic distribution and are present virtually everywhere on the earth. However, patterns of illness do not correlate with geography as viruses causing any given disease syndrome are found under diverse climatic and ecological conditions. Rather, distribution of a particular virus is tied to vertebrate reservoir and invertebrate vector availability.

Taxonomy and Classification

The genus *Alphavirus* is one of two genera within the family *Togaviridae*. While the second genus, *Rubivirus*, contains only a single species (*Rubella virus*), there are 29 recognized species in the genus *Alphavirus* currently divided into at least eight antigenic complexes (**Table 1**).

Evolutionary Relationships

Numerous phylogenetic studies have been performed on members of the genus *Alphavirus* since the advent of sequencing and genetic analyses. Overall, these derived evolutionary relationships closely agree with the antigenic relationships associated with the surface glycoproteins that have been established for members of this group based upon serological techniques. Evolutionary relationships have not been found to vary with the gene(s) or sequences examined with the exception of the members of the western equine encephalitis (WEE) antigenic complex. When viruses in the WEE complex are examined, they are found to be associated with the WEEV genotype when comparing E2 or E1 glycoproteins, while genetic comparisons of other gene regions result in alignment with viruses in the eastern equine encephalitis virus (EEEV) genotype. This unique feature is a result of the fact that most New World WEE complex viruses

[a]Classification according to the most recent report of the ICTV; antigenic complexes according to SIRACA.

are descendants of an ancestor that arose by recombination of an EEEV with a Sindbis (SIN)-like virus. This recombination event was a double crossover event that combined the E2/E1 genes of the SINV-like ancestor with the other genes and noncoding regions of an EEEV ancestor.

Phylogenetic analyses have been most useful in the study of the Old World viruses which have been studied in far less detail than the encephalitic alphaviruses that only exist in the western hemisphere. Partial genome sequence analyses have produced conflicting topologies, particularly in the placement of Middelburg virus (MIDV), which has been not been extensively characterized. However, the use of longer sequences in phylogenetic comparisons and evaluations of tree topologies using likelihood tests provides the best estimates of evolutionary relationships given the data available. A phylogeny based upon distance matrix analysis of the E1 gene of representatives of each virus is presented in **Figure 1** demonstrating the monophyletic clustering of viruses within a given antigenic complex. Significantly, the clades generated by all phylogenetic analyses accurately reflect associations of viruses that share medically important characteristics. For example, the encephalitic alphaviruses cluster together and are more closely related to each other than those viruses that express other disease patterns providing evidence of the ancient relationships that exist among the alphaviruses.

Phylogenetic relationships cannot conclusively verify the geographic origin of the alphaviruses as New World and Old World origins are equally parsimonious with each requiring three transoceanic introduction events. Internal branch lengths of distance matrix trees also suggests that the most basal alphaviruses are those that infect

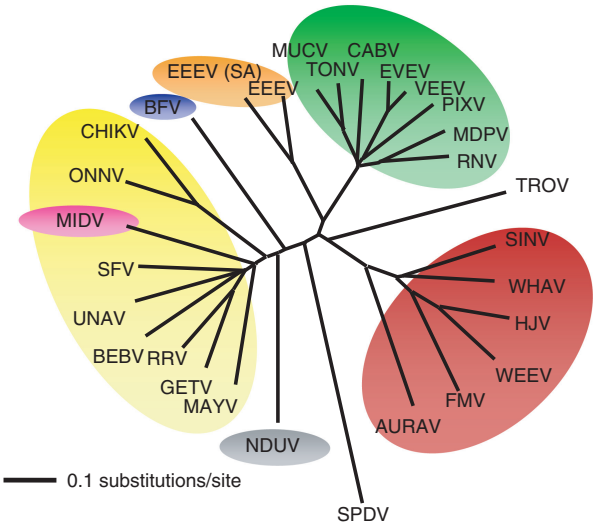

Figure 1 Unrooted phylogenetic tree of all *Alphavirus* species generated from the E1 nucleotide sequences using the F84 algorithm of the neighbor-joining program (SESV is not included because no homologous sequence for this region was available). Virus abbreviations are from **Table 1**. Antigenic complexes are indicated by colored circles.

fish indicating that an ancestral alphavirus adapted to infect fish. Other lineages of alphaviruses evolved as insect-borne viruses as most alphaviral species are recognized to be. Even the southern elephant seal virus (SESV), which has been found to infect lice, supports this hypothesis.

Virion Structure

Alphavirus virions are small (60–70 nm in diameter), icosahedral particles exhibiting $T=4$ symmetry. The single-stranded RNA genome is contained within a capsid core comprised of the virally encoded C protein. This nucleocapsid is then encased in a lipid envelop acquired by budding from the host cell plasma membrane making the virions sensitive to ether and detergents. The envelop membrane also contains the viral E1 and E2 glycoprotein heterodimers that are arranged as trimers on the surface. Binding to cellular receptors occurs via the E2 glycoprotein after which conformational changes in the glycoprotein trimers result following endocytosis.

Genome Organization and Replication

The alphaviruses have a genome consisting of a linear, positive-sense, single-stranded RNA molecule of approximately 11.2–11.8 kbp in size depending upon the species (**Figure 2**). The nonstructural proteins, required for viral replication, are encoded in the 5′ two thirds of the genome, while the structural genes are collinear with the 3′ one third.

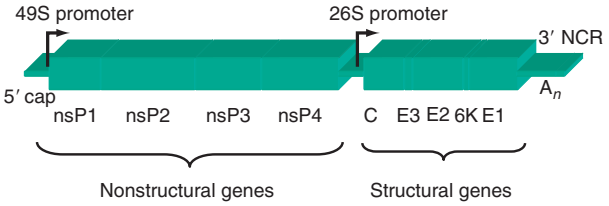

Figure 2 Organization of the alphavirus genome showing genes, promoter elements, and noncoding regions (NCRs).

The 5′ end of the genome has a 7-methylguanosine cap, while on the 3′ end a polyadenylation tail is present. Just upstream of the poly A tract is a 3′ noncoding region of varying length depending upon the virus. This region contains specific repeat elements that are distinctly associated with each of the different viruses. There are secondary structures associated with this noncoding region that may be involved in replication, host specificity, or virulence patterns.

There are four nonstructural genes, designated nsP1–4, which are necessary for viral replication; each has specific functions during the replication process. The nsP1 protein is required for initiation of synthesis of minus-strand RNA and also functions as a methyltransferase to cap the genomic and subgenomic RNAs during transcription. The second gene, nsP2, encodes a protein that has RNA helicase activity in its N-terminus while the C-terminal domain functions as a proteinase for the alphavirus nonstructural polyprotein. Cleavage of the nonstructural polyprotein by both nsP2 and polyproteins containing nsP2 occurs at three distinct sites and depends upon the composition of the polyprotein. This differential cleavage serves as a regulatory action leading to alternative processing pathways at different times during the infectious process to modulate the rate of replication. For example, early during infection, P123 and P1234 (made by readthrough translation of a stop codon present between the nsP3 and nsP4 genes) are produced by translation of the genomic mRNA. As the infection proceeds, P123 cleaves between nsP1 and nsP2 to produce nsP1 and P23. The P23 polyprotein is autoproteolytic and cleaves itself to generate the individual nsP2 and nsP3 proteins (**Figure 3**). The nsP3 gene encodes a protein consisting of two domains, a widely conserved N-terminal domain and a hypervariable C-terminus, whose functions are not fully understood. The C-terminal region has been shown to tolerate numerous mutations, including large deletions or insertions, and still produce viable viral particles in vertebrate cells. It is possible that some of these nsP3 mutations may play a role in defining cell type and invertebrate vector specificity. The final nonstructural protein, nsP4, encodes the viral RNA-dependent RNA polymerase (RdRp) and contains the characteristic GDD motif associated with this highly conserved element.

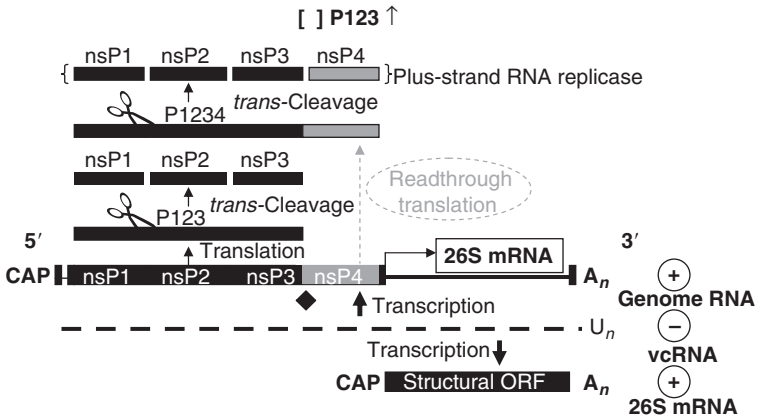

Figure 3 Model for the processing of the alphavirus nonstructural polyprotein during replication. When low levels of P123 are present, *cis*-cleavage of P1234 generates the minus-strand RNA replicase of the virus. This results in primarily negative-sense RNA being generated from the incoming genomic RNA of the virus (upper panel). As the level of the *trans*-acting protease P123 rises in the infected cell, cleavage in *trans* generates other RNA replicase complexes. This results in a shift by the virus from the production of primarily negative-sense RNA to primarily positive-sense RNA. Eventually, replicase complexes capable of producing negative-sense RNA will no longer be present in the infected cell resulting in the complete cessation of negative-sense RNA synthesis (lower panel). The presence of a leaky opal termination codon (depicted as a black diamond) in the virus genome is believed to lead to a more rapid buildup of P123 in the infected cell, and thus a more rapid conversion to the production of positive sense RNA by the virus. Courtesy of Dr. Kevin Myles.

A second polyprotein is generated by translation of a subgenomic mRNA that is generated from an internal promoter immediately downstream of the nonstructural open reading frame. This polyprotein encodes the structural proteins and is processed to produce a capsid protein, the two major envelope surface glycoproteins (E1 and E2) and two small peptides (E3 and 6K) that are not associated with intact virions. E1 and E2 are post-transcriptionally modified in the endoplasmic reticulum and Golgi apparatus before being transported to the plasma membrane where they maintain a close association with each other forming a dimeric spike structure. As virion formation proceeds, the nucleocapsids present in the cytoplasm are moved to the cell membrane. Here, they bind to the surface glycoproteins before budding from the cell. In terms of function, the E2 protein has been found to be an important determinant of antigenicity and cell receptor binding in both the vertebrate host and the insect vector for other alphaviruses. The other major structural protein, E1, has been found to contain domains associated with membrane fusion.

Transmission

The alphaviruses as a whole are transmitted to vertebrate hosts by a broad range of mosquito species. There are some alphaviruses that have non-mosquito invertebrate vectors; Fort Morgan virus (FMV) is transmitted by a cimicid bug (*Oeciacus vicarious*) and SESV is postulated to be transmitted by lice (*Lepidophthirus macrorhini*). Further, the fish alphavirus, salmon pancreas disease virus (SPDV), is not known to have an invertebrate vector. However, for the mosquito-borne alphaviruses, any given virus tends to be transmitted enzootically by only a single or small number of invertebrate species; these very specific host–virus interactions are related to geography and ecological dynamics associated with the mosquito vectors. In contrast to enzootic maintenance, epidemic or epizootic outbreaks may utilize numerous species of mosquitoes but transmission by these species rarely continues once the outbreak subsides. A few of the virus–vector–host interactions have been extensively studied and are described below.

The most well studied alphaviral transmission cycles are those of the equine encephalitides: EEEV, Venezuelan equine encephalitis virus (VEEV), and WEEV. Curiously, all of these viruses, even though they cause encephalitis, exist only in the New World, and are more closely related to each other than other members of the genus *Alphavirus*, utilize extremely different invertebrate vectors in their transmission cycles. EEEV is maintained in North America in a transmission cycle including *Culiseta melanura* mosquitoes and avians. However, this species of mosquito rarely feeds on mammals so epidemic or epizootic transmission to humans or equines typically involves multiple other species of mosquitoes in several genera. The South American cycle of EEEV transmission is not well characterized but isolates of virus have been obtained from *Culex* (*Melanoconion*) mosquitoes implicating them as the likely enzootic vectors. The majority of the viruses within the VEE complex circulate in continuous enzootic habitats between small vertebrate rodent hosts and mosquitoes of the subgenus *Culex* (*Melanoconion*). However, outbreaks of VEEV are a result of

transmission by a number of different mammalophilic mosquitoes in the genera *Aedes* and *Psorophora*. Finally, like North American EEEV, WEEV is transmitted in cycles involving avian hosts; however, the predominant mosquito species that vectors this virus is *Culex tarsalis* in North America. WEEV virus may be vertically transmitted by *Aedes* species mosquitoes in temperate climates where year-round maintenance of the virus does not occur.

Of the arthralgic-causing alphaviruses, only a few have well-characterized transmission cycles. Chikungunya virus (CHIKV) (prevalent throughout Africa as well as Southeast Asia and parts of Oceania) appears to be maintained in sylvatic cycles involving wild nonhuman primates and forest-dwelling *Aedes* spp. mosquitoes including *Aedes furcifer*, *Aedes taylori*, *Aedes luteocephalus*, *Aedes africanus*, and *Aedes neoafricanus* in western and central Africa. However, while forest-dwelling mosquito species are primary vectors in west and central Africa, the urban mosquito *Aedes aegypti* has been found to be the most significant vector in Asia with virtually all Asian mosquito isolates coming from this species. Urban or large outbreaks in east Africa are also likely associated with the presence of *Ae. aegypti* mosquitoes. Other common peridomestic species (*Aedes albopictus*, *Aedes vittatus*, and *Anopheles stephensi*) that have been found in abundance in CHIKV endemic areas have also been found to be competent vectors in the laboratory. Both humans and wild nonhuman primates are likely to be the vertebrate reservoirs for CHIKV. The most closely related virus to CHIKV, o'nyong nyong virus (ONNV), is unique among the alphaviruses in that the primary epidemic mosquito vectors are members of the genus *Anopheles*. The virus was isolated from collections of *Anopheles funestus* and *Anopheles gambiae* obtained from epidemic areas and entomological studies have further implicated *An. funestus* as a principal outbreak vector because it was the most abundant species from which isolates of ONNV were obtained during one outbreak. The identity of the vector of ONNV during interepidemic periods remains unknown as does any vertebrate reservoir. Another arthritis-causing alphavirus, Ross River virus (RRV), has been isolated from over 30 different species of mosquitoes; however, the most likely vectors of public health concern are *Aedes vigilax*, *Aedes camptorhynchus*, and *Culex annulirostris* due to their abundance during outbreaks, the number of isolates of virus obtained from these species, and their temporal and spatial association with outbreaks of RRV disease. The vertebrate hosts of RRV are not defined with certainty. Based upon serosurveys, virus isolations, and experimental infection studies, marsupials, macropods, livestock, domestic pets, birds, and humans have all been postulated to play a role either in maintenance or amplification of the virus. Further studies correlating human disease with reservoir status would prove useful in clarifying the role of each of these vertebrates in RRV transmission.

Epidemiology

The epidemiological patterns of the alphaviruses are as diverse as their geography and ecological characteristics. Generally, outbreaks of human or animal illness due to alphavirus infections coincide with peak mosquito seasons in temperate zones while they occur year-round in tropical climates. The magnitude of each outbreak can vary dramatically depending upon whether the outbreak was localized to urban or rural settings. However, in both ecologies, the attack rates can be significant if a virulent alphavirus is the etiological agent. For example, morbidity rates between 30% and 70% are typical during CHIKV epidemics and mortality rates for EEEV outbreaks can reach as high as 70%. The seropositivity rates often correlate with the vector infectivity and transmissibility rates as well as host preference of the mosquito. In general, disease is often more severe in young children and elderly patients and rates of immunity are lower in young children. This indicates that many alphaviruses produce long-lived antibodies that are presumably protective for life. Occupational exposure differences to mosquitoes are likely the cause of any higher incidence rates that may be associated with males compared with females.

Glossary

Arbovirus Virus maintained in an infection cycle involving hematophagous arthropods and vertebrate hosts.

Encephalitis Inflammation of the brain associated with cognitive changes.

History

Nomenclature of the encephalitic alphaviruses recognizes the characteristic geographic distribution of each and the initial identification of the viruses as causes of encephalitis in horses. The first clear record of epidemic equine encephalitis is from 1831, when an outbreak in Massachusetts, USA, resulted in the deaths of 75 horses. Over the next 100 years, several local epidemics of encephalitis in horses occurred along the Atlantic seaboard. The virus of this eastern encephalitis (EEEV) was first isolated from the brain of an affected horse in 1933 by Tenbroek and Merrill. However, 2 years earlier, Meyer, Haring, and Howitt had isolated a virus from central nervous system (CNS) tissues of two horses involved in an epidemic of equine encephalitis in the San Joaquin Valley of California. The EEEV and the western equine encephalitis virus (WEEV) virus were shown to be antigenically distinct. Both diseases occurred in summer epidemics, and, in 1933, Kelsor showed that WEEV could be transmitted by mosquitoes; shortly thereafter, mosquito transmission of EEEV was shown. In 1938, both EEEV and WEEV were isolated from humans with encephalitis occurring in the same regions as the equine cases. In 1936, an epidemic of equine encephalitis occurred in the Goajira region of Venezuela and the virus causing this epidemic, isolated independently by Beck and Wyckoff and Kubes and Rios, was not neutralized by sera from animals immunized with EEEV or WEEV and was designated Venezuelan equine encephalitis virus (VEEV).

Taxonomy and Classification

In 1954, three serologic groups (A, B, and C) of arthropod-borne viruses had been distinguished by Casals and Brown on the basis of cross-reactivity in hemagglutination inhibition (HI) tests. EEEV, WEEV, and VEEV constituted the original group A arboviruses. A second cross-reacting set, including dengue, St. Louis encephalitis, and yellow fever viruses, constituted the group B arboviruses, and the other viruses, mostly from Brazil, were designated group C viruses. As viruses became classified on the fundamental properties of the virion, the group A viruses became the alphaviruses (genus *Alphavirus*) within the family *Togaviridae* of enveloped RNA viruses. HI was used to classify alphaviruses into six broad antigenic complexes; EEE, WEE, and VEE form three of these complexes. The EEE and VEE complexes contain only EEEV and VEEV. The WEE complex includes several viruses in addition to WEEV (e.g., Whataroa, Kyzylagach, Highlands J, Fort Morgan, Aura, and Sindbis), distinguished from each other by complement fixation, neutralization, or other tests.

Viruses within each complex have been subtyped using reactivity with monoclonal antibodies, kinetic HI (EEEV, VEEV), or neutralization (WEEV, VEEV) assays. EEEV and WEEV viruses each have North American and South American subtypes. WEEV and VEEV also can be subdivided into epizootic and enzootic strains. The VEE viruses are differentiated by HI and neutralization tests into subtypes I (VEEV), II (Everglades), III (Mucambo), IV (Pixuna), V (Cabassou), and VI (Rio Negro). Epizootic strains of VEEV are equine virulent and fall within subtype I, which is further subdivided antigenically into IAB and IC (epizootic strains) and ID, IE, and IF (enzootic strains). Sequence information has confirmed the validity of most of these distinctions.

Virion and Genome Structure

Properties of the Virion

Alphavirus virions are 60–65 nm in diameter. The RNA is enclosed in a capsid formed by a single protein arranged as an icosahedron. The nucleocapsid is enclosed in a lipid envelope derived from the host cell plasma membrane and which contains the viral-encoded glycoproteins, E1 and E2. These proteins form heterodimers that are grouped as trimers to form knobs on the virion surface that are arranged with a $T=4$ symmetry. Glycoproteins are arranged with 240 copies of each protein interacting with 240 copies of capsid protein. The virion is sensitive to ether and detergent. Infectivity can be inactivated by heat or acid. The viruses are stable at −70 °C for long periods.

Properties of the Genome

The 49S genome is a single-stranded, nonsegmented, capped, and polyadenylated message-sense RNA that is

infectious. Complete sequence information is available for representative members of all three virus complexes. The genomes contain approximately 11 700 nucleotides and have the nonstructural proteins at the 5′-end and the structural proteins at the 3′-end. Highly conserved regions of genome are the 19 nucleotides at the 3′ terminus, important for negative-strand synthesis, and 21 nucleotides at the junction between the nonstructural and structural genes, important for synthesis of the subgenomic RNA. Analysis of codon usage shows an underutilization of the dinucleotide CpG.

Properties of the Viral Proteins

Five potential structural proteins (C, E3, E2, 6K, and E1) are encoded in the 3′-end of the genome. The capsid protein is 259 (EEEV, WEEV) to 275 (VEEV) amino acids long. The N-terminal portion is conserved, basic, and binds the genomic RNA, and the C-terminal portion interacts with the cytoplasmic tail of E2 and with other capsid proteins to form the nucleocapsid. The E3 protein is 59 (VEEV), 60 (WEEV three serologic groups, A, B, and C), or 63 (EEEV) amino acids long, serves as a signal sequence for E2, and, *in vitro*, is shed into the supernatant fluid after cleavage by a furin-like protease in the *trans*-Golgi network. The E2 glycoprotein is a transmembrane protein that is 420 (EEEV) to 423 (WEEV, VEEV) amino acids long and has two (EEEV) or three (WEEV, VEEV) N-linked glycosylation sites. The intracytoplasmic portion has a second stretch of hydrophobic amino acids. The 6K protein is 55 (WEEV, VEEV) or 56 (EEEV) amino acids long and serves as a signal peptide for E1. By analogy to Sindbis virus, small amounts are probably incorporated into the virion. The E1 protein is 439 (WEEV), 441 (EEEV), or 442 (VEEV) amino acids long and has one or two N-linked glycosylation sites. E1 has a short (one or two residue) intracytoplasmic tail and a positionally conserved internal hydrophobic stretch of amino acids in the N-terminal portion of the protein that serves as the fusion peptide for virion entry into the cell. The 5′-end of the genome encodes four nonstructural proteins that function in replication of viral RNA and in production of the genomic and subgenomic RNA.

Replication

For the most part, knowledge of the replication of EEEV, WEEV, and VEEV is based on the extensive studies of Sindbis and Semliki forest viruses. Initial attachment to the cell may involve interaction of the E1 glycoprotein, which has hemagglutination activity, with phospholipids on the cell surface. Efficient subsequent entry involves binding of E2 to cellular proteins followed by receptor-mediated endocytosis. Within the acidified endosomal compartment, the glycoprotein spikes undergo a conformational change that results in fusion with the endosomal membrane and release of the nucleocapsid into the cytoplasm. Acidified endosomes may not be essential for infection of mosquito cells. Once released from the nucleocapsid, the virion RNA serves as mRNA and translation of the nonstructural proteins is initiated. Cytopathic vacuoles form and negative-strand 49S RNA, positive-strand 49S RNA, and positive-strand 26S subgenomic RNA are transcribed. The 26S RNA represents the 3′-portion of the genome from which the structural proteins are translated as a polyprotein. After translation of the capsid protein is complete, it is autocatalytically cleaved from the nascent chain. E2 and E1 are transported into the endoplasmic reticulum, cleaved by cellular proteases, and processed through the Golgi. At the plasma membrane, nucleocapsids align with regions containing the E1–E2 heterodimers and bud from the cell surface. The process may be different in mosquito cells, where intracytoplasmic compartments containing mature virions are seen *in vitro*. However, these structures have not been seen during ultrastructural studies of alphavirus infection in mosquitoes.

Geographic and Seasonal Distribution

The encephalitic alphaviruses are geographically restricted. With few exceptions, alphaviruses are transmitted primarily by mosquitoes and, therefore, transmission is restricted to warm months of the year. EEEV is endemic in eastern Canada and from New Hampshire along the Atlantic seaboard and Gulf Coast to Texas in the United States, in the Caribbean, Central America, and along the north and east coasts of South America. Inland foci exist around the Great Lakes. In the northern part of the range, cases occur between July and October, while in the southern region cases can occur throughout the year. Viruses of the WEE complex are widely distributed throughout the Americas as three closely related but antigenically distinct viruses (WEEV, Highlands J virus, and Fort Morgan virus). Highlands J virus is endemic on the East Coast of the United States in the same areas as EEEV. WEEV is widely distributed in the western plains and valleys of the United States and Canada and is found in South America. Enzootic VEE viruses are perennially active in subtropical and tropical areas of the Americas (subtype II in Florida; ID and IE in Central America; IF and III–VI in South America). Epizootics have appeared in Venezuela, Colombia, Peru, and Ecuador at approximately 10 year intervals.

Host Range and Virus Propagation

The life cycle of the encephalitic alphaviruses involves replication in invertebrate vectors, primarily mosquitoes,

and in reservoir vertebrate hosts, primarily birds (EEEV and WEEV) or small mammals (VEEV). In epidemic periods, additional hosts, such as horses and humans, are infected. EEEV causes encephalitis in humans, horses, pigeons, and pheasants. Many birds are susceptible to infection but remain asymptomatic, despite prolonged viremia. The amplifying species for EEEV in North America are wading birds and migratory song birds. In South America, forest-dwelling rodents and marsupials become infected and may provide additional reservoirs. Infection has also been reported in turtles and snakes. In invertebrates, virus is most consistently recovered from *Culiseta melanura* in North America, *Culex taeniopus* in the Caribbean, and *Culex* (*Melanconion*) spp. in South America. Mosquitoes of many species can serve as bridge vectors to mammals.

WEEV may cause encephalitis in horses and humans. The enzootic cycle in North America involves domestic and wild birds and *Culex tarsalis* for WEEV in the western United States and songbirds and *Culiseta melanura* for Highlands J virus in the eastern United States. Serosurveys and virus isolations have demonstrated evidence of natural infection in chickens and other domestic birds, passerine birds, pheasants, rodents, rabbits, ungulates, and snakes.

Epizootic strains of VEEV can cause disease in horses and in humans. The enzootic strains of VEEV can infect horses but these infections are asymptomatic and may protectively immunize horses against epizootic strains. Enzootic strains produce mild disease in humans. A variety of wild birds are susceptible to infection, but small mammals serve as an important reservoir, with efficient transmission of infection by *Culex* (*Melanconion*) spp. mosquitoes.

In addition to the native hosts, a number of laboratory animals are susceptible to infection. All three viruses cause encephalitis in monkeys, mice, rats, guinea pigs, and hamsters. Disease is generally age dependent, so that young animals more often develop fatal infections than do adult animals. Primary isolates of these viruses are often made in newborn mice.

In vitro, the viruses are routinely propagated in cultures of chick embryo fibroblasts, BHK-21 cells, or Vero cells. Most strains will form plaques in these cells and plaque assays provide the usual basis for virus quantitation. Mosquito cell lines support replication, often without cytopathic effect. Many other cell lines (e.g., L-cells, HeLa cells) support replication as well.

Genetics

Alphaviruses show genetic changes by accumulation of point mutations in the genomic RNA, but this occurs at a rate that is much slower than that predicted for other RNA viruses. Recombination is infrequent, but can be demonstrated *in vitro* and occurs at least occasionally in nature because sequence analysis has shown that WEEV is the result of recombination between EEEV and Sindbis-like viruses.

Evolution

The alphaviruses derive from a single unknown protoalphavirus and are part of the alphavirus superfamily of viruses. Viruses in this superfamily have a similar genetic organization and include many RNA plant viruses. In general, amino acids important in secondary structure (e.g., cysteine) have been conserved for the structural glycoproteins E1 and E2, suggesting that the three-dimensional structure is similar for all alphaviruses. Sequence analyses suggest that the encephalitic alphaviruses evolve slowly in nature. The capsid protein and E1 glycoprotein are the most conserved of the structural proteins, whereas the E2 glycoprotein is more divergent. EEEV has evolved independently in North and South America over the last 1000 years and there is currently one group in North America and the Caribbean and three groups in South America, one in the Amazon River basin, one on the coasts of South and Central America and the third in Brazil. North American EEEV isolates are highly conserved, varying by less than 2% over 63 years. South American isolates are evolving more rapidly, perhaps locally within different vector–host relationships. Rates of divergence of WEEV and Highlands J virus of 0.1–0.2% per year have been estimated. It is hypothesized that short transmission seasons and limited host mobility constrain genetic diversity in a geographic region.

Epidemiology

EEEV causes localized outbreaks of equine, pheasant, and human encephalitis in the summers. Cases of equine encephalitis are usually the first indicators of an outbreak. In North America, the primary enzootic cycle is maintained in shaded freshwater swamps where the vector is the ornithophilic swamp mosquito *Culiseta melanura* and the reservoir hosts are migratory passerine songbirds. Young birds are probably most important for virus amplification because they are more susceptible to infection, have a prolonged viremia, and are less defensive toward mosquitoes. Human and equine cases usually occur within 5 mi (8.045 km) of the swamp, with virus being transmitted by epizootic vectors such as *Coquillittidia perturbans*, *Aedes sollicitans*, and, potentially, *Aedes albopictus*. The enzootic vector in the Caribbean is probably *Culex taeniopus* and in South America *Culex (Melanoconion)* spp. Epizootics appear approximately every 5–10 years and are usually associated with heavy rainfall that increases the populations

of enzootic and epizootic mosquito vectors. The mechanism of overwintering in northern areas is not known. There is no evidence for overwintering in mosquitoes. Human infections are unusual, with an average of 5–10 cases per year in the United States (**Figure 1**). Serological surveys in the northeastern United States suggest that there are approximately 23 inapparent infections for every case of encephalitis, but children are more susceptible and this declines to only 8:1 for children under 4 years of age.

WEEV is maintained in an endemic cycle involving domestic and passerine birds and *Culex tarsalis*, a mosquito particularly adapted to irrigated agricultural areas. Interseasonal persistence occurs in saltwater marshes, where vertical transmission of WEEV in *Culex tarsalis* has been demonstrated. Occasional isolations have been made from *Culex stigmatosoma, Aedes melanimon*, and *Aedes dorsalis*, also competent vectors. Transmission from this enzootic cycle has resulted in small numbers of cases of encephalitis in humans. However, periodically, there have been widespread summer epidemics of equine encephalitis in North America with significant extension into humans. The estimated case to infection ratio is 1:58 in children under 5 years and 1:1150 in adults. Recently, for reasons that are not completely clear, cases of equine and human cases have declined (**Figure 2**). In the eastern United States, Highlands J virus has been isolated from ornithophilic mosquitoes (*Culiseta melanura*, the enzootic vector for EEEV) in freshwater swamp habitats along the Atlantic coast, as well as from birds. Ecologic restriction and limited pathogenicity may explain the paucity of human and equine disease caused by Highlands J virus. The lack of significant human disease during equine outbreaks of WEE in South America may be related to the feeding habits of the vector or to a difference in virulence for humans of the South American strains.

VEEVs are maintained in enzootic cycles by *Culex (Melanoconion)* spp. mosquitoes that live in tropical and subtropical swamps throughout the Americas and breed near aquatic plants. They feed at dawn and dusk on a wide variety of rodents, birds, and other vertebrates. Humans living in these areas have a high prevalence of antibody, but little-recognized disease. Epizootic strains of VEEV arise by mutation from enzootic strains and are isolated only during outbreaks. Epizootics have occurred primarily in Latin America in cattle ranching areas during the rainy season. Formalin-inactivated vaccines containing residual live virus are suspected to be responsible for initiating the 1969–72 outbreak in Central America and which extended to Texas by 1971. During epizootics, horses are an important amplifying species. Virus has been isolated from several species of mosquitoes including *Aedes taeniorhynchus, Aedes aegypti, Mansonia dubitans*, and *Psorophora confinnis*. The incidence of encephalitis in clinically ill humans is generally less than 5% and the overall mortality less than 1%.

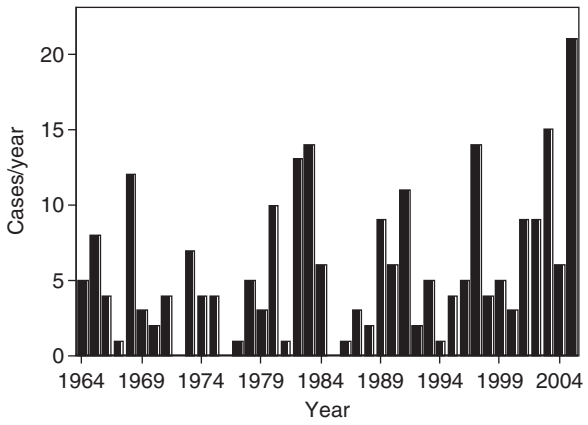

Figure 1 Numbers of human cases of eastern equine encephalitis reported in the United States from 1964 to 2005. Data are from the Centers for Disease Control and Prevention.

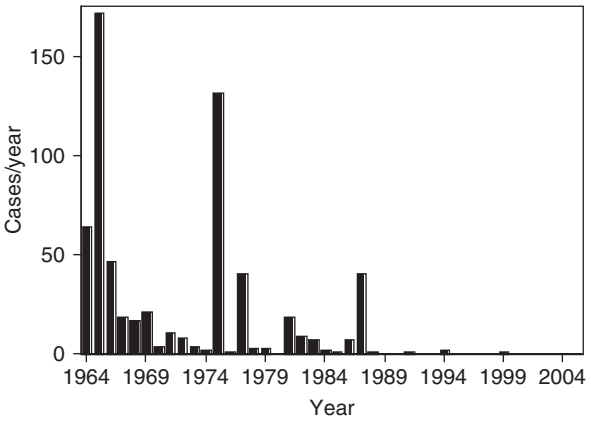

Figure 2 Numbers of human cases of western equine encephalitis reported in the United States from 1964 to 2005. Data are from the Centers for Disease Control and Prevention.

Transmission and Tissue Tropism

The primary mode of alphavirus transmission to birds and mammals is through the bite of an infected mosquito which inoculates virus extravascularly. Mosquitoes become infected by feeding on a viremic host, are able to transmit the virus 4–10 days later (extrinsic incubation), and remain persistently infected. Maintenance of this cycle requires an amplifying host that develops a viremia of sufficient magnitude to infect mosquitoes feeding on it. Other modes of transmission are of occasional importance. EEEV persists in the feather follicles of infected pheasants and secondary transmission among penned pheasants can occur through feather picking and cannibalism. VEEV can be transmitted by the respiratory route between infected horses and to humans in the laboratory. WEEV and VEEV can be transmitted transplacentally.

In mammals, EEEV replicates primarily in muscle and in neurons and glial cells of the CNS, with occasional involvement of liver and lymphatic tissue. Skeletal and myocardial muscle and the CNS of infected birds contain virus. In mosquitoes, there is infection of the midgut, muscle, and salivary glands without involving the nervous system. WEEV replicates primarily in skeletal and cardiac muscle, brown fat, and the choroid plexus, ependyma, and neurons in the CNS of mammals. Little is known of the tissue tropism of WEEV in birds. Epizootic strains of VEEV infect the upper respiratory tract, lymphatic and myeloid tissue, pancreas, liver, and CNS to varying degrees in different mammals. Mosquito infection is initiated in the midgut epithelial cells and spreads through the hemolymph to the salivary glands and flight muscles.

Pathogenicity

EEEV strains vary in their pathogenicity for horses (and presumably for humans), with South American strains being less virulent than North American strains. The molecular basis of these differences have not yet been defined. The North American strains of EEEV are among the most virulent of the alphaviruses, causing severe encephalitis in humans, horses, dogs, pigs, pigeons, emus, quail, and pheasants. The case–fatality rate in humans is 30–50%, up to 90% in horses and 50–70% in pheasants. Laboratory studies indicate a similar neurovirulence of EEEV for monkeys, mice, and hamsters. Hamsters also develop hepatitis and lymphatic organ infection. At 3–4 weeks of age, mice become relatively resistant to peripheral, but not intracranial, inoculation. Birds vary in their susceptibility, with birds of some species developing disease, while birds of many other species show no morbidity or mortality, despite a prolonged viremia. Pheasant deaths are caused by encephalitis while young chickens develop myocarditis. Mosquitoes develop persistent infection of the fat body and salivary glands.

WEEV in the western United States causes epidemics of encephalitis in humans, horses, and emus, but the case–fatality rate of 10% for humans, 20–40% for horses, and 10% for emus is lower than for EEEV in the eastern US. Highlands J virus has been reported to cause rare fatal disease in horses and turkeys. South American strains of WEEV cause fatal encephalitis in horses, but little disease in humans. Epizootic strains are neurovirulent and neuroinvasive in adult mice, whereas enzootic strains are not. Highlands J virus is intermediate in virulence between North and South American strains of WEEV. With increasing age mice become relatively resistant to fatal infection, whereas hamsters remain susceptible to Highlands J virus.

Infection of horses with epizootic strains of VEEV frequently is fatal. Disease is associated with leukopenia and a high-titered, prolonged viremia. In contrast to EEE and WEE, encephalitis is not always apparent and virus is shed in nasal, eye, and mouth secretions as well as in urine and milk. Experimental infection of laboratory animals produces a variety of disease patterns. In guinea pigs and rabbits, VEEV produces necrosis in lymph nodes, spleen, thymus, intestinal, and conjunctival lymphoid tissue, liver, and bone marrow. Hamsters develop encephalitis and pancreatitis in addition to widespread involvement of myeloid and lymphoid tissue. In rats and mice, there is more limited destruction of lymphoid and myeloid tissue and death is usually due to encephalitis. Virus enters the CNS through the olfactory tract and causes neuronal infection and apoptosis. Neonatal mice show extensive replication in many tissues, including brain, myocardium, and pancreas. Comparative studies of the virulent TRD and avirulent TC-83 strains of IA serotype VEEV and construction of recombinant viruses have led to identification of the 5′-noncoding region and the E2 envelope glycoprotein as important determinants of virulence for mice, whereas changes in nsP3 and E2 determine virulence for horses.

Clinical Features of Infection

EEEV is the most virulent of the encephalitic alphaviruses, causing a high mortality due to encephalitis. Prodromal symptoms of fever, headache, and myalgias are common. The onset of encephalitis tends to be fulminant and is associated with continued fever, increased headache, meningismus, obtundation, and seizures. The overall case–fatality rate is 30% in recent studies, with higher rates in children and the elderly. Recovery is more likely in those individuals that have a long (5–7 day) prodrome and do not develop coma. Sequelae are common, with more than 80% of survivors having significant neurological residua, including paralysis, seizures, and mental retardation. The diagnosis is usually made by detection of antibody in serum or cerebrospinal fluid.

WEEV can cause encephalitis with signs and symptoms similar to those caused by EEEV. There is a 3–5 day prodrome of fever and headache that may progress to irritability, nuchal rigidity, photophobia, and altered mental status. Severe disease, seizures, fatal encephalitis, and significant sequelae are more likely to occur in infants and in young children.

Infection with epizootic strains of VEEV usually causes relatively mild disease in humans. Illness in adults usually is manifested by fever, headache, myalgias, and pharyngitis 2–5 days after exposure. Severe diseases, including fulminant reticuloendothelial infection and encephalitis, may occur in young children. Children recovering from encephalitis may be left with neurological deficits. Fetal abnormalities and spontaneous abortions may occur in infections during pregnancy.

The cerebrospinal fluid during alphavirus encephalitis usually shows a moderate (up to 4000 cells mm^{-3}) pleocytosis with predominance of either polymorphonuclear or mononuclear cells. Protein is usually elevated and the glucose is normal. The electroencephalogram and magnetic resonance imaging scans are usually abnormal, but computed tomographic scans may be normal or indicative only of edema.

Pathology and Histopathology

Initial CNS infection with EEEV in experimental animals is of the capillary endothelial or choroid plexus epithelial cells and spread within the CNS can be cell to cell or through cerebrospinal fluid. The targeted cell within the CNS is the neuron and damage to this cell may be severe and irreversible. Histopathology demonstrates a diffuse meningoencephalitis with widespread neuronal destruction, neuronophagia, gliosis, and perivascular inflammation, with polymorphonuclear and mononuclear leukocytes early, and vasculitis and vessel occlusion late. Hamsters also exhibit necrosis of hepatocytes and lymphatic tissue accompanied by local infiltration of mononuclear leukocytes. Initial infection of mosquitoes is of midgut epithelial cells. Infection is facilitated when virus in the serum is concentrated next to these cells as the infected blood meal clots. Infected midgut epithelial cells subsequently degenerate and slough, and this process may facilitate penetration of the virus into the hemocoel and rapid dissemination of the infection.

Pathological examination of brains from fatal human cases of WEE demonstrates early perivascular extravasation of blood followed by endothelial hyperplasia, perivascular mononuclear and polymorphonuclear inflammation, and parenchymal necrosis. Areas of neuronal degeneration, glial nodules, and demyelination are found. Neonatal mice develop acute inflammation and necrosis in skeletal and smooth muscle, cartilage, and bone marrow. In vertebrate animals with encephalitis, the brain shows multifocal areas of necrosis and widespread lymphocytic infiltration of the leptomeninges and perivascular regions of the brain parenchyma. The heart shows a necrotizing, inflammatory myocarditis. Infiltration of mononuclear leukocytes into areas of lung, liver, and brown fat also occurs.

The pathology of VEE in horses includes cellular depletion of bone marrow, spleen, and lymph nodes, pancreatic necrosis, and, in cases with encephalitis, swelling of vascular endothelial cells, edema, and mononuclear cell cuffing of cerebral vessels and meningitis followed by the later appearance of demyelinating lesions. Small mammals with widespread involvement of the reticuloendothelial system may develop ileal necrosis.

Both innate and adaptive immune responses are induced by infection. Interferon-α/β (IFN-α/β) is produced quickly after infection. Virus-specific IgM is often detectable by enzyme immunoassay or by virus neutralization very early after onset of the disease in both serum and cerebrospinal fluid and provides a means for rapid diagnosis of infection. IgG antibody appears 10–14 days after onset and can be measured by enzyme immunoassay, HI, or neutralization. Many lines of evidence suggest that recovery from infection is primarily dependent on the antibody response. Extensive experimental studies to define the antibody specificity and the mechanisms of recovery and protection have been done using VEEV and Sindbis virus, a member of the WEE complex. Neutralizing and non-neutralizing antibodies are protective. Multiple epitopes on the E1 and E2 glycoproteins induce neutralizing, HI, and protective antibody. Sequencing of monoclonal antibody escape mutants has localized one neutralization domain to E2 residues 180–210 in VEEV. Immunization with peptides has shown that an antibody response to residues 1–25 of the VEEV E2 glycoprotein is also protective.

Cellular immunity has received more limited study, but virus-specific lymphoproliferative and cytotoxic responses have been documented and a mononuclear inflammatory response is common. The importance of cellular immune responses for recovery or for contribution to fatal disease has not been established but IFN-γ can contribute to virus clearance from the CNS. Prior infection with VEEV increases subsequent antibody responses to unrelated antigens. Antithymocyte globulin extends time to death in mice infected with VEEV, suggesting a T-cell-mediated immunopathogenic component to fatal disease.

Prevention and Control

Prevention of infection relies on efforts to control mosquito populations by spraying and reduction of breeding places. Individual use of protective measures such as mosquito repellents and protective clothing are important. Vaccines against EEEV, WEEV, and VEEV are available for horses and against EEEV for birds. Experimental human vaccines against EEEV, WEEV, and VEEV also are available for laboratory workers exposed to these agents. Most of these vaccines consist of formalin-inactivated virus, but TC-83 is a successful live attenuated vaccine against VEEV for use in horses. TC-83 is also used as a vaccine for humans, although side effects are common. No antiviral agents are of proven usefulness in treatment of these infections.

Future

Construction of full-length cDNA alphavirus clones that can be transcribed into infectious RNA provides tremendous potential for understanding the functions of

various genes and their importance for replication and virulence in the multiple hosts necessary for maintenance of these viruses in their natural cycles. An understanding of the folding and three-dimensional structures of each of the structural and nonstructural proteins is needed for interpretation of much of the sequence and virulence data that has been acquired. Further information on virulent and avirulent strains and functional analysis of the nonstructural proteins are likely to provide the next level of understanding of virus–host relationships and the conditions that lead to outbreaks.

Glossary

Alphavirus A virus in the genus *Alphavirus*.
Arbovirus A virus transmitted to vertebrates by hematophagous (blood-feeding) insects.
Endemic A disease constantly present in a community in a defined geographic region.
Enzootic A disease constantly present in an animal community in a defined geographic region.
Epidemic Outbreak of human disease above the normal (endemic) incidence.
Epizootic Outbreak of disease in animals above the normal (enzootic) incidence.
Vector An arthropod (mosquito in the case of most alphaviruses) that transmits an arbovirus.
Zoonotic A human disease whose causative agent is maintained in populations of wild animals.

Introduction and History

The *Togaviridae* is a family of enveloped, single-stranded, plus-strand RNA viruses that occur nearly worldwide. The family includes the genus *Alphavirus*, a group of zoonotic viruses maintained primarily in rodents, primates, and birds by mosquito vectors. Human disease occurs when people intrude on enzootic transmission habitats and are bitten by infected mosquitoes, or when the virus emerges to cause epizootics and epidemics. The other genus in the family *Togaviridae* is *Rubivirus*, with Rubella virus, the etiologic agent of 3-day measles (German measles), as its only member.

The first togaviruses to be isolated were the alphaviruses Western equine encephalitis virus (WEEV) and Eastern equine encephalitis virus (EEEV) in 1930 (although EEEV was not described until 1933), followed by Venezuelan equine encephalitis virus (VEEV) in 1938. Serologic tests using hemagglutination inhibition (HI) later indicated that these three viruses were antigenically related, and in 1954 Casals and Brown designated two groups of arboviruses: 'Group A' included WEEV, EEEV, and VEEV, Semliki Forest virus (SFV), and Sindbis virus (SINV), while 'Group B' is now known to include scores of flaviviruses. The HI test also indicated degrees of relatedness within viruses of Group A, with cross-reactions between EEEV and VEEV stronger than reactions between these viruses and WEEV, SFV, or SINV. These interrelationships, which formed the basis for the definitions of the antigenic complexes of alphaviruses, have generally stood the test of time, and are reflected in the phylogenetic relationships described below. Other assays including complement fixation (CF) and neutralization (NT) tests were used in some cases to define relationships on a finer scale. The introduction of the kinetic HI test later allowed further discrimination of certain alphaviruses, such as the antigenic varieties within the VEE complex and between North American and South American EEEV strains. The serological interrelationships among the alphaviruses were later determined to reflect the envelope glycoproteins in the

case of HI and NT, and a mixture of structural and nonstructural proteins in the case of CF.

For some time, the *Togaviridae* included four genera: *Alphavirus, Rubivirus, Flavivirus,* and *Pestivirus*. Not until the morphology, RNA genome organizations and coding strategies, as well as the protein and nucleotide sequences were determined for representatives was it recognized that the former two genera differ dramatically from the latter two. The flaviviruses and pestiviruses were then placed into a distinct family, the *Flaviviridae* (now with three genera), and the *Alphavirus* and *Rubivirus* genera were retained in the family *Togaviridae*.

Structure, Systematics, and Evolution

The basis for grouping the alphaviruses and Rubella virus into the *Togaviridae* is that they have very similar genome organizations and coding strategies, as well as primary sequence homology that can be detected in short motifs in the nonstructural protein genes (**Figure 1**). Alphavirus virions have been visualized at high resolution using cryoelectron microscopy. The E1 envelope glycoprotein domain that lies outside of the lipid envelope has been crystallized and its structure solved to atomic resolution. The folds of the alphavirus E1 protein are very similar to those of the flavivirus envelope protein, indicating that these proteins are homologous (share a common ancestral gene) and that the togaviruses and flaviviruses share a distant, common ancestor, at least for the E1/E protein genes which, due to their extensive divergence, cannot be detected from the nucleotide or amino acid sequences.

Alphavirus virions are about 70 nm in diameter; the nucleocapsid, which forms in the cytoplasm of infected cells, includes one molecule of genomic RNA and 240 copies of the capsid protein arranged in hexons and pentons in a $T = 4$ lattice. This icosahedral structure dictates the arrangement of the envelope proteins in the virion. Outside of the plasma membrane-derived lipid envelope, trimeric envelope spikes on the surface of the virion are composed of E1/E2 heterodimers, with the E2 protein most exposed and believed to interact with cellular receptors. The Rubella virion appears as a spherical particle, 60–70 nm in diameter, in electron micrographs. Rubella virus differs from alphaviruses in that the electron translucent zone between the nucleocapsid and envelope proteins is wider and the rubiviruses have a $T = 3$ icosahedral symmetry.

The alphaviruses and rubiviruses are quite distantly related and both share sequence homology with several taxa of plant viruses, some of which are transmitted by insects. These relationships suggest that the ancestor of these viruses was an insect virus that underwent a process called modular evolution that led to several genome rearrangements, including segmentation.

Before the era of molecular genetics, the alphaviruses were grouped into several antigenic complexes based on cross-reactivity in serologic assays including HI and CF (but generally not plaque reduction neutralization; PRNT) (**Table 1**). Within some of these complexes, the VEE complex, for example, differentiation of antigenic subtypes and varieties, some of which have fundamental and critical epidemiological and virulence differences, was accomplished using specialized forms of HI and, in some cases, PRNT. Direct genetic evidence of homology

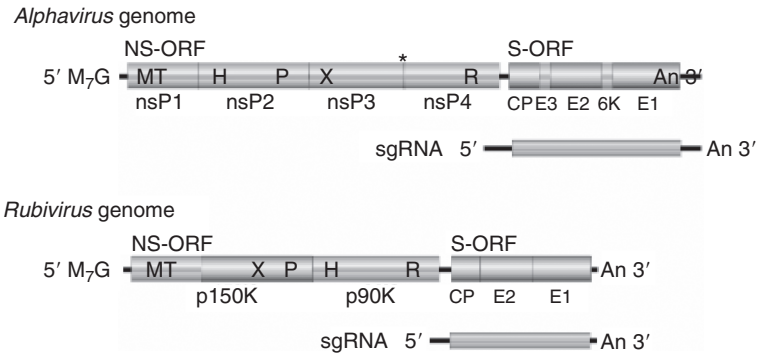

Figure 1 Togavirus genomic coding strategies. Shown are comparative schematic representations of the alphavirus and rubivirus genomic RNAs with untranslated regions represented as solid black lines and open reading frames (ORFs) as open boxes (NS-ORF, nonstructural protein ORF; S-ORF, structural protein ORF). Within each ORF, the coding sequences for the proteins processed from the translation product of the ORF are delineated. The asterisk between nsP3 and nsP4 in the alphavirus NS-ORF indicates the stop codon present in some alphaviruses that must be translationally read through to produce a precursor containing nsP4. Additionally, within the NS-ORFs, the locations of motifs associated with the following activities are indicated: MT, methyltransferase; P, protease; H, helicase; X, unknown function; and R, replicase. The sequences encompassed by the subgenomic RNA (sgRNA) are also shown. Reproduced from Weaver SC, Frey TK, Huang HV, *et al.* (2005) *Togaviridae*. Table 1 Members of the genus *Alphavirus*

Antigenic complex	*Virus*	*Antigenic subtype*	*Antigenic variety*	*Clinical syndrome in humans*	*Distribution*
Barmah Forest	Barmah Forest virus (BFV)			Febrile illness, rash, arthritis	Australia
Eastern equine encephalitis (EEE)	Eastern equine encephalitis virus (EEEV)	I–IV		Febrile illness, encephalitis (none recognized in Latin America)	North, Central, South America
Middelburg	Middelburg virus (MIDV)			None recognized	Africa
Ndumu	Ndumu virus (NDUV)			None recognized	Africa
Semliki Forest	Semliki Forest virus (SFV)			Febrile illness	Africa
	Chikungunya virus (CHIKV)			Febrile illness, rash, arthritis	Africa
	O'nyong-nyong virus (ONNV)			Febrile illness, rash, arthritis	Africa
	Getah virus (GETV)			None recognized	Asia
	Bebaru virus (BEBV)			None recognized	Malaysia
	Ross River virus (RRV)	Sagiyama		Febrile illness, rash, arthritis	Australia, Oceania
	Mayaro virus (MAYV)			Febrile illness, rash, arthritis	South and Central America, Trinidad
	Una virus (UNAV)			None recognized	South America
Venezuelan equine encephalitis (VEE)	Venezuelan equine encephalitis virus (VEEV)	I	AB	Febrile illness, encephalitis	North, Central, South America
			C	Febrile illness, encephalitis	South America
			D	Febrile illness, encephalitis	South America, Panama
			E	Febrile illness, encephalitis	Central America, Mexico
	Mosso das Pedras virus (MDPV)		F		
	Everglades virus (EVEV)			Febrile illness, encephalitis	Florida (USA)
	Mucambo virus (MUCV)	III	A	Febrile illness, myalgia	South America, Trinidad
			C	Unknown	Peru
			D	Febrile illness	Peru
	Tonate virus (TONV)	III	B	Febrile illness, encephalitis	Brazil, Colorado (USA)
	Pixuna virus (PIXV)			Febrile illness, myalgia	Brazil
	Cabassou virus (CABV)			None recognized	French Guiana
	Rio Negro virus (RNV)			Febrile illness, myalgia	Argentina
Western equine encephalitis	Sindbis virus (SINV)			Febrile illness, rash, arthritis	Africa, Europe, Asia, Australia
		Babanki		Febrile illness, rash, arthritis	Africa
		Ockelbo		Febrile illness, rash, arthritis	Europe
		Kyzylagach		None recognized	Azerbaijan, China
	Whataroa virus (WHAV)			None recognized	New Zealand
	Aura virus (AURAV)			None recognized	South America
	Western equine encephalitis virus (WEEV)	Several		Febrile illness, encephalitis	Western North, South America
	Highlands J virus (HJV)				Eastern North America
	Fort Morgan virus (FMV)	Buggy Creek		None recognized	Western North America
Trocara	Trocara virus (TROV)				South America
Salmon pancreas disease	Salmon pancreas disease virus (SPDV)			Pancreatic disease (salmon)	Atlantic Ocean and tributaries
	Sleeping disease virus (SDV)			Sleeping disease (trout)	Worldwide
Southern elephant seal virus	Southern elephant seal virus (SESV)			None recognized	Australia

among the alphaviruses, and later between the alphaviruses, rubella virus, and some plant viruses, came first from direct protein sequencing, followed by nucleotide sequencing. Eventually, nucleotide sequencing largely replaced the serological tests for determining relationships among the alphaviruses, although the latter remain useful from an epidemiological standpoint.

Nearly complete phylogenetic trees can now be constructed from homologous E1 envelope glycoprotein gene nucleotide or deduced amino acid sequences (**Figure 2**). These trees largely agree with the original antigenic groupings, with the exception of Middelburg virus, which genetically belongs within the SF complex. The relationships of the New World members of the WEE antigenic complex have more complex relationships when the nonstructural protein genes are analyzed; these viruses group more closely with EEEV than with the Old World SINV-like members of the WEE complex or with the New World member, Aura virus. These relationships reflect an ancient recombination event between a SINV-like ancestor and a virus closely related to an ancestor of EEEV (**Figure 2**). The recombinant ancestor later gave rise to the WEE, Highlands J, and Fort Morgan virus ancestors.

Most estimates for the rate of RNA sequence evolution among alphaviruses are on the order of 10^4 substitutions per nucleotide per year, similar to those of other arboviruses and lower than those of most vertebrate viruses that do not use arthropods as vectors. These low rates may reflect constraints imposed by alternate replication on disparate hosts, as well as by persistent infection of mosquito vectors. However, the timescale for evolution of the togaviruses and alphaviruses is difficult to determine from sequence data because the ability of phylogenetic

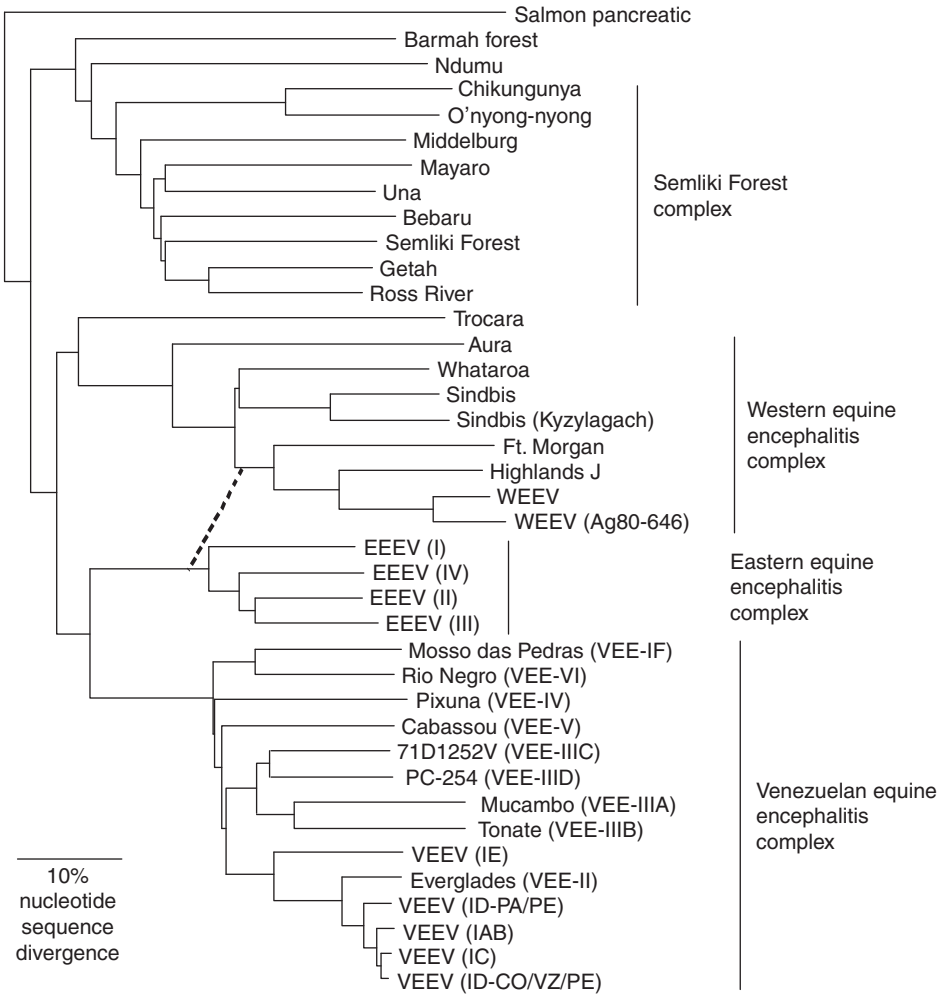

Figure 2 Phylogenetic tree of all alphavirus species except southern elephant seal virus (the homologous sequence region is not available), and selected subtypes and variants, generated from partial E1 envelope glycoprotein gene sequences using the neighbor joining program with the HKY distance formula. Antigenic complexes are shown on the right. The dashed line indicates the ancestral recombination event that led to Highlands J, Fort Morgan, and Western equine encephalitis viruses. Rubella virus cannot be included in this analysis because there is no detectable primary sequence homology with alphavirus structural protein sequences.

methods to compensate for sequential substitutions of the same nucleotides or amino acids is unknown.

Phylogenetic studies of alphaviruses generally point to purifying selection as dominating their evolution, presumably because most mutations are deleterious, especially when efficient replication in widely divergent hosts (mosquitoes and vertebrates) is required. Experimental evolutionary studies employing cell culture model systems also indicate that most adaptive mutations are host cell specific, supporting the hypothesis that the alternating host replication cycle constrains adaptation to new hosts by alphaviruses. The mobility of reservoir hosts appears to influence patterns of alphavirus evolution and their phylogeography. Viruses that use avian hosts, such as EEEV, WEEV, SINV, and Highlands J virus, tend to evolve within a relatively small number of sustained lineages that have very wide geographic distributions. For example, some lineages of WEEV have been sampled from California to Argentina. The efficient dispersal of these viruses by their highly mobile reservoir hosts presumably allows competition among different sympatric lineages to limit virus diversity. In contrast, alphaviruses that use hosts with more limited mobility, such as VEE complex viruses that rely on rodents and other small mammals, tend to exhibit more genetic diversity and lineages confined to smaller, nonoverlapping geographic regions.

Transovarial transmission from infected adult females to their offspring has been documented for a few alphaviruses, but it is not known whether this is important for maintenance of these viruses in nature. Persistent infection of vertebrate hosts also appears to be rare and is not known to be involved in long-term maintenance of alphaviruses. However, mechanisms for the overwintering of alphaviruses in temperate regions, which has been suggested by several genetic studies, remain enigmatic and could include transovarial transmission and/or persistent infection of reservoir hosts.

Compared to the alphaviruses, rubella virus is relatively conserved genetically, with only one serotype described. However, phylogenetic analyses indicate the existence of at least two genotypes, with genotype I isolates predominant in Europe, Japan, and the Western Hemisphere, and the more diverse genotype II isolated in Asia and Europe. There is considerable geographic overlap between these genotypes and subgenotypes, presumably reflecting the efficient dispersal of Rubella virus by infected people.

Diseases

Most of the alphaviruses cause febrile disease in humans and/or domestic animals. However, a few alphaviruses have not been associated with any disease, including Aura, Trocara, Middelburg, Ndumu, Ft. Morgan, and Una viruses. The most severe alphaviral feature, encephalitis, is caused by the New World viruses EEEV, VEEV, and WEEV. In humans, apparent:inapparent infection rates range from very low for EEEV (*c.* 1:23) to *c.* 10:1 for VEEV. However, mortality rates in apparent human infections are inversely correlated with these ratios, with *c.* 50% for EEEV and less than 1% for VEEV. In equids, most infections are apparent, with high mortality rates (*c.* $\geq$50%) for all three viruses. Any of these viruses can also cause disease in a wide range of other domesticated and wild animals, with EEEV documented as the etiologic agent of severe disease in pigs, deer, emus, turkeys, pheasants, cranes, and other birds. Everglades virus is also known to cause neurologic disease in humans, and Highlands J virus has caused documented disease in domestic birds and in a horse.

Several of the Old World alphaviruses including Chikungunya (CHIKV), O'nyong nyong (ONNV), Ross River, and Barmah Forest viruses cause an arthralgic disease syndrome often accompanied by rash. Mayaro virus (MAYV), another member of the SF complex that was probably introduced into South America from the Old World, is the exception to the relationship between hemispheric distributions and disease syndromes. The arthralgic disease caused by these alphaviruses can be highly incapacitating and chronic, with affected persons unable to work or function normally for several months or longer.

Rubella virus is the etiologic agent of rubella, also known as German or 3-day measles, a generally benign infection. Occasionally, more serious complications such as arthritis, thrombocytopenia purpura, and encephalitis can occur. Congenital transmission to the fetus during the first trimester of pregnancy can lead to serious birth defects that comprise congenital rubella syndrome. Congenitally infected children suffer a variety of autoimmune and psychiatric disorders in later life, including a fatal neurodegenerative disease known as progressive rubella panencephalitis. Rubella has been largely controlled through vaccination in most developed countries, although it remains endemic worldwide.

Transmission Cycles

All alphaviruses are zoonotic, and the vast majority have transmission cycles involving mosquito vectors and avian or mammalian reservoir and/or amplification hosts. Exceptions include the fish viruses, sleeping disease virus, and salmon pancreatic disease virus; southern elephant seal virus was isolated from lice and may use these insects as mechanical, rather than biological, vectors, although transmission has not been documented. The mosquito-borne alphaviruses often have relatively narrow vector ranges, relying on one or a few principal mosquito vectors

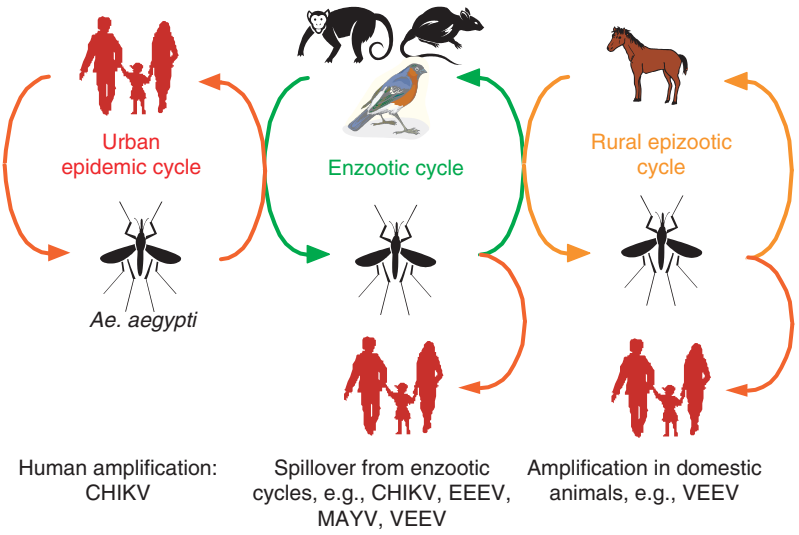

Figure 3 Cartoon showing mechanisms of human infection by alphaviruses. At the center is an enzootic cycle, typically involving avian, rodent, or nonhuman primates as amplification and/or reservoir hosts and mosquito vectors. Humans become infected via direct spillover when they enter enzootic habitats and/or when amplification results in high levels of circulation. Transmission to humans may involve the enzootic vector or bridge vectors with broader host preferences. Right panel: Secondary amplification involving domestic animals can increase circulation around humans, increasing their chance of infection via spillover. In the case of VEEV, mutations that enhance equine viremia are needed for secondary equine amplification. Left panel: CHIKV can use humans for amplification, resulting in urban epidemic cycles and massive outbreaks. Expanded form of virus abbreviations is provided in **Table 1**. Reproduced from Weaver SC (2005) Host range, amplification and arboviral disease emergence. *Archives of Virology* 19(supplement): 33–44, with permission from Springer-Verlag.

(**Figure 3**). Spillover to humans and domesticated animals results in epidemics and epizootics, with the affected animals (including humans) usually not generating sufficient viremia to participate in the transmission cycle (i.e., acting only as dead-end hosts). VEEV temporarily adapts via mutation to utilize equids as highly efficient amplification hosts (with high viremias), resulting in hundreds to several thousands of horses, donkeys, and mules affected during epizootics, and increased spillover to humans that results in epidemics of similar proportions. CHIKV and ONNV cause major epidemics by using humans as amplification hosts and, as vectors, mosquitoes that live in close association with humans, such as *Aedes aegypti, Ae. albopictus* (CHIKV), and *Anopheles* spp. (ONNV). Some alphaviruses, including EEEV, probably use secondary ('bridge') vectors during epidemics and epizootics because the primary mosquito vector (e.g., *Culiseta melanura* for EEEV) has a very narrow host range limited mainly to the animals serving as the reservoir hosts (**Figure 3**).

The infection of mosquito vectors by alphaviruses begins with the ingestion of a blood meal from a viremic vertebrate host. Susceptibility and minimum infectious doses for alphavirus infection of mosquitoes vary dramatically. Following the passage of ingested blood into the posterior midgut of the alimentary tract during feeding, infection of epithelial digestive cells occurs, presumably before the deposition of the peritrophic matrix around the blood meal, which begins with hours of feeding. Recent studies indicate that typical VEEV infections begin with fewer than 100 of the approximately 10 000 epithelial cells becoming infected, and thus the initial midgut infection may represent a bottleneck in alphavirus populations. After replication in the midgut epithelial cells, alphaviruses bud principally from the basal plasma membrane and somehow traverse the basal lamina to enter the hemocoel, or open body cavity of the mosquito. Then, transported by the hemolymph, the virus has access to many internal organs including the salivary glands, where replication leads to virus shedding into the saliva. Upon a subsequent blood meal from a naive host, transmission can occur via saliva deposited extravascularly during probing to locate a blood vessel, or intravascularly during engorgement. The amount of virus transmitted during blood feeding also varies widely, but rarely exceeds 100 infectious units of VEEV, again representing a bottleneck for virus populations. The extrinsic incubation period from an infectious blood meal to transmission by bite can occur in as little as 3 days, depending on the virus, mosquito, and temperature of incubation. However, mosquitoes generally do not re-feed until egg development and oviposition has occurred, which can require a week or more.

The sites of initial alphavirus replication in the vertebrate host are generally known only from studies using subcutaneous or intradermal needle inoculations, rather

than by mosquito feeding, and can include Langerhans cells, dendritic cells, dermal macrophages, and fibroblasts in the skin. Because virus is also deposited intravascularly during mosquito feeding, other sites could be important in natural infections. Secondary replication and amplification sites also vary, including lymph nodes, spleen, myocytes, chondrocytes, osteoblasts, and neurons.

Rubella virus is transmitted via the respiratory route among infected humans, with no vector involvement. Transplacental transmission can result in severe complications and sequelae.

Alphaviruses of Greatest Medical and Veterinary Importance

The majority of alphaviruses can cause at least mild disease in humans, and most exceptions are lesser-known viruses that have not been well studied epidemiologically. Recent studies of 'dengue-like' illness in several locations have revealed that several alphaviruses such as VEEV, MAYV, and CHIKV account for a significant number of cases diagnosed clinically as dengue. Proper serological testing or virus detection is needed to accurately determine the cause of many tropical fevers that present with nonspecific 'flu-like' signs and symptoms. Brief descriptions of the most important alphaviruses follow.

Chikungunya Virus

CHIKV is probably the most important alphaviral pathogen worldwide, although it rarely causes fatal disease. CHIKV, named after a local Makonde word meaning 'that which bends up', refers to the characteristic posture assumed by patients suffering severe joint pains. The virus probably occurs in most of sub-Saharan Africa, as well as in India, Southeast Asia, Indonesia, and the Philippines. In Africa, a sylvan transmission cycle between wild primates and arboreal *Aedes* spp. mosquitoes has been characterized, and the virus probably occupies a niche similar to that of the flavivirus, yellow fever virus. In Asia and nearby islands, and recently on islands off the eastern coast of Africa in the Indian Ocean, urban and suburban CHIKV epidemics usually have been associated with *Ae. aegypti* and/or *Ae. albopictus* transmission among human amplification hosts. Explosive epidemics have affected hundreds of thousands to millions of people, and many cases are probably unrecognized because CHIKV infection is difficult to distinguish clinically from dengue. Because CHIKV infection of humans is sporadic, and no reservoir hosts or sylvatic vectors are known from Asia, it is not known whether the virus is zoonotic outside of Africa, where it is believed to have originated. Although CHIKV historically has been regarded as a nonfatal human pathogen, recent fatal cases on islands off the eastern coast of Africa in the Indian Ocean indicate a possible increase in virulence, although improved surveillance is an alternative explanation.

Eastern Equine Encephalitis Virus

In human cases, North American strains of EEEV are the most virulent of the alphaviruses with case–fatality rates generally exceeding 50%. Fortunately, only 220 confirmed cases occurred in the US from 1964 to 2004. A wide variety of domesticated mammals and birds also suffer fatal infections in North America. In South and Central America, EEEV is widespread and equine outbreaks are common, but human EEE is rare, probably due to lower human virulence in the genetically distinct strains that occur there. Attack rates in North America tend to be highest in young children and the elderly.

Transmission cycles of EEEV in North America involve *Culiseta melanura* as the principal enzootic mosquito vector, and passerine birds as reservoir hosts in hardwood swamp habitats. Bridge vectors in the genera *Aedes*, *Coquillettidia*, and *Culex* may be responsible for most transmission to humans and domestic animals. Foci occur in swamps along the eastern seaboard and the coast of the Gulf of Mexico, but have also been documented as far west as Texas and the Dakotas. In South and Central America, the ecology and epidemiology of EEEV are poorly understood. Isolates from mosquitoes suggest that the most important enzootic vectors are members of the subgenus *Culex* (*Melanoconion*), which are also enzootic vectors of most of the VEE complex viruses. Reservoir hosts are not well understood, but may include mammals or birds.

Mayaro Virus

Mayaro virus has been isolated from persons suffering from an arthralgia with rash in Surinam, French Guiana, Colombia, Panama, Brazil, Peru, and Bolivia, and probably occurs in lowland tropical forests throughout much of South America. As are infections with many other alphaviruses, clinical diagnosis of MAYV infection is unlikely and many cases are misdiagnosed as dengue. Sporadic and focal infections usually occur in people living near or working in tropical forests, and forest-dwelling mosquitoes in the genus *Haemagogus* are probably the principal vectors. Wild primates probably serve as reservoir hosts. Mayaro virus activity is often detected during investigations of outbreaks of sylvan yellow fever, probably because both viruses share the same mosquito vectors.

Mayaro virus infection is characterized by a sudden onset of fever, headache, myalgia, chills, and arthralgia, sometimes accompanied by dizziness, photophobia, retro-orbital pain, nausea, vomiting, and diarrhea. Though not known to be fatal, the arthralgia may be severe, may

persist for up to 2 months, and usually affects the wrists, ankles, and toes, and less commonly the elbows and knees. Approximately two-thirds of patients develop a fine maculopapular rash on the trunk and extremities.

O'nyong-nyong Virus

ONNV, a close relative of CHIKV, derives its name from the description by the Acholi tribe, meaning 'joint breaker'. The virus was first isolated and characterized in 1959 during an epidemic involving *c.* 2 million people in Uganda, Kenya, Tanzania, Mozambique, Malawi, and Senegal. Since that epidemic ended in 1962, only a single major epidemic (1996, in the Rakai, Mbarara, and Masaka districts of southwestern Uganda and bordering Bukoba district of northern Tanzania) and a few sporadic reports of virus isolation have been reported. ONNV causes an arthralgia-rash syndrome that can persist for months, and all age groups are affected. Epidemic transmission involves *Anopheles funestus* and *An. gambiae* mosquitoes, which also transmit malaria parasites in Africa. ONNV is the only known alphavirus with *Anopheles* spp. vectors.

Ross River Virus

Ross River virus (RRV) infection has been recognized in Australia since 1928 as associated with epidemic polyarthritis. The disease there may involve up to thousands of people annually, and occurs mainly during the summer and autumn as sporadic cases and small outbreaks, usually among vacationers and other persons living or traveling in rural areas. RRV is maintained in Australia primarily among marsupials and other wild vertebrates, with *Culex annulirostris* and *Aedes vigilax* and other mosquitoes serving as vectors. Human cases and explosive epidemics also have been documented in islands of the South Pacific. Epidemiologic studies implicated *Ae. polynesiensis* as a vector and suggested that humans may have served as amplification hosts.

Following 3–21 days of incubation, disease begins suddenly with headache, malaise, myalgia, and joint pain. Joints may be swollen and tender. Multiple joints are involved; the most commonly affected are the ankles, fingers, knees, and wrists. Pain and loss of function usually last for several weeks, but some patients have persistent or recurrent arthralgia and arthritis for up to a year. About one-half of epidemic polyarthritis patients develop a maculopapular rash, usually lasting 5–10 days; 30–50% also have low-grade fever. Persons 20–50 years of age are most commonly affected, and the incidence is higher in females. Viremia is transient and may precede the onset of arthritis. The skin rash and joint swelling may be due to a local cell-mediated immune response rather than to immune complexes or complement-mediated reaction. The synovial exudate contains no detectable virus and consists almost entirely of mononuclear leukocytes.

Venezuelan Equine Encephalitis Virus

VEE was recognized first in Venezuela in 1936. The etiologic agent, VEEV, has caused explosive equine epizootics and epidemics in many regions of the Americas. The last major epidemic in northern Venezuela and Colombia in 1995 involved approximately 100 000 persons. VEEV strains use two distinct transmission cycles: enzootic, and epidemic or epizootic. The enzootic cycles generally rely on small rodent reservoir hosts and mosquito vectors in the subgenus *Culex* (*Melanoconion*), and occur in tropical forest and swamp habitats from Florida to Argentina. These viruses and subtypes are generally avirulent for equids, but are pathogenic for humans and can cause fatal disease. In contrast, epidemic or epizootic VEEV (subtypes IAB, IC) are virulent for both equids and humans, but have only temporary, unstable transmission cycles involving *Aedes* and *Psorophora* spp. mosquitoes, which transmit the virus among equids circulating high levels of viremia (**Figure 3**). People generally become infected by mosquitoes that previously engorged on viremic equids. VEE outbreaks are believed to occur following mutations of enzootic subtype ID viruses, which result in the transformation to an equid-virulent, IAB or IC subtype.

Following an incubation period of 1–4 days, symptoms of human VEE include fever, lethargy, headache, chills, dizziness, body aches, nausea, vomiting, and/or prostration. Symptoms usually subside after several days, but may recrudesce. Disease occurs in all age groups and both sexes, but severe neurologic signs, including convulsions and seizures, occur primarily in children (4–14% of pediatric cases) and usually late in the illness. Case–fatality rates are estimated at 0.5%.

Western Equine Encephalitis Virus

WEEV was first isolated from a horse brain in the Central Valley of California during a major epizootic in 1930. Like EEEV, WEEV was not established as an etiological agent of human disease until 1938. Later, WEEV was identified nearly throughout the Americas including the eastern US, but more detailed antigenic and genetic studies eventually elucidated other members of the WEE antigenic complex including Highlands J virus in eastern North America and Fort Morgan virus in the central United States. The distribution of WEEV is now believed to include western North America through Central and South America to Argentina. Virus strains from this wide range are remarkably conserved genetically, suggesting efficient transport by birds during migrations.

Antigenically and genetically distinct WEEV subtypes with more limited distributions in South America have also been identified, and some are less virulent in murine models. All of these WEEV-related New World viruses are believed to have descended from an ancient, recombinant alphavirus that obtained its nonstructural and capsid protein genes from an EEEV-like ancestor and its envelope glycoprotein genes from an ancestor of SINV.

In the western US, WEEV is transmitted primarily in agricultural habitats by *Culex tarsalis* mosquitoes among passerine birds, principally sparrows and house finches. A secondary cycle involving *Aedes* spp. mosquitoes and lagomorphs has also been described in central California, and *Aedes* mosquitoes have been implicated as equine epizootic vectors in Argentina. Human infections with WEEV range from inapparent (the vast majority) to a flu-like syndrome to life-threatening encephalitis and meningitis. Symptomatic infection typically includes a sudden onset with fever, headache, nausea, vomiting, anorexia, and malaise, followed by cognitive symptoms, weakness, and meningeal involvement. Young children tend to be affected more severely than adults, and 5–30% suffer permanent neurologic sequelae. The overall human case–fatality rate is about 3%. WEEV also causes encephalitis in equids, with case–fatality rates of 10–50%. Despite a history of producing epidemics with thousands of human cases, WEEV has apparently declined as a human pathogen since the 1970s, probably due in part to irrigation, mosquito control, and culturally reduced human exposure to mosquitoes.

Alphavirus Pathogenesis

Detailed pathogenesis studies of alphavirus infections have been performed for only a few members of the genus. Although they do not normally cause encephalitis in humans or domestic animals, SINV and SFV have served as models for other alphaviruses because they can cause encephalitis in young mice yet require lower levels of biocontainment than the human-virulent members of the genus. In the experimental encephalitis model these viruses cause apoptotic death of neurons after intracerebral inoculation. Studies with these and other aphaviruses described below indicate that the type 1 interferon response is critical for the initial control of infection, and that humoral immunity is most important for clearance of primary infection and for protection against subsequent infections. Cell-mediated immunity has been regarded as less important, and elimination of alphaviruses from the central nervous system is thought to occur via noncytolytic mechanisms.

Among the highly human-pathogenic alphaviruses, VEEV pathogenesis has received the most attention. The murine model produces uniformly fatal encephalitis following all routes of infection. Following subcutaneous infection, dendritic cells are believed to be infected in the dermis, followed by migration to the draining lymph node where high levels of replication result in viremia and lymphodepletion. Also associated with infection is a vigorous innate immune response that may contribute to neuroinvasion and/or febrile illness. VEEV typically invades the central nervous system via olfactory neurons. Encephalitis develops by day 5–7, when the virus has been cleared from the periphery by the adaptive immune response. However, VEEV continues to replicate to high titers in the brain and paralysis is quickly followed by death. Clinical encephalitis probably results from both virus- and immune-mediated neuronal cell death.

The pathogenesis of EEEV is poorly understood, but appears to differ fundamentally from that of VEEV in the murine model; EEEV also produces a biphasic disease, but the initial phase involves replication in fibroblasts, osteoblasts, and skeletal muscle myocytes. Invasion of the central nervous system probably occurs by a vascular route. Hamsters appear to more accurately reproduce the vascular component of EEE, which is prominent in human infections.

Among the alphaviruses that cause rash/arthralgia syndromes, only RRV has received much study as an etiological agent. In the murine model, initial targets of subcutaneous infection are similar to those of EEEV, including bone, joint, and skeletal muscle, with severe associated inflammation involving macrophages, natural killer cells, and CD4+ and CD8+ T lymphocytes. Recent studies with mice deficient in T lymphocytes indicate that the adaptive immune response does not play a critical role in the development of arthritic disease.

Diagnosis and Treatment

Diagnosis of alphavirus infections is rare because clinical signs and symptoms are similar to those caused by many other viral pathogens, including dengue and influenza viruses. Definitive diagnosis generally requires virus isolation from blood taken during the first 2–4 days of illness, or serologic confirmation as described below. Most alphaviruses can be isolated by intracerebral inoculation of newborn mice (usually fatal), and cause cytopathic effects in cells of a variety of mammalian and avian lines. Serodiagnosis can be made by detecting a fourfold or greater change in antibody titers in acute-phase and convalescent-phase serum samples drawn 1–3 weeks apart, using an enzyme-linked immunosorbent assay (ELISA), immunofluorescence, hemagglutination inhibition, CF, or NT. Detection of antiviral immunoglobulin M (IgM) using ELISA has more recently been applied for this purpose and is now the standard assay.

Treatment of most alphavirus infections is symptomatic and supportive. Anticonvulsive therapy may be effective in severe cases of encephalitis, especially in children. Lymphoid depletion caused by VEEV may lead to bacterial infection of the gastrointestinal tract, and antibiotic therapy should be considered in severe cases. Pneumonia secondary to VEE and EEE also is common. Neurologic sequelae occur following severe EEE, VEE, and WEE, including headache, amnesia, anxiety, and motor impairment.

Control of Disease

As is the case for many other arboviruses, control of alphaviral diseases relies upon interruption of transmission by mosquito vectors, and sometimes on vaccination of amplification hosts such as equids in the case of VEE. Mosquito vector control during epidemics and epizootics usually relies upon aerial application of insecticides such as malathion, optimally applied soon after floodwater species emerge from the aquatic immature stages, prior to dispersal, extrinsic infection, and transmission. People present during epidemics should avoid exposure to mosquitoes through limitation of outdoor activities and the use of repellents containing the active ingredient meta-*N*,*N*-diethyl toluamide (DEET) or picaridin. Persons entering sylvatic or swamp habitats where enzootic EEEV or VEEV circulate in the Americas, as well as forests of Africa enzootic for CHIKV, should also take these precautions. The diel periodicity of mosquito vectors should also be considered when planning outdoor activities and control measures. For example *Haemagogus* mosquitoes, the principal vectors of MAYV, feed during the daytime in forested neotropical habitats, and bed nets and window screens therefore do not effectively protect people. *Aedes aegypti*, an important urban vector of CHIKV, readily enters and rests in homes, and outdoor applications of adulticides are largely ineffective in controlling epidemics.

Glossary

Apoptosis A cascade of cellular responses to a stimulus (e.g., virus infection) resulting in cell death.
Cytopathic effect Destructive changes in cell morphology, structure, or metabolic processes resulting from virus infection.

Full-length cDNA clone A copy of an RNA virus genome that has been reverse-transcribed into DNA and placed into a subcloning vector. With positive-sense RNA viruses, infectious genomic RNA is generally directly synthesized from bacteriophage transcription promoters located upstream of the virus sequences.

Host cell shut-off Interruption or cessation of host transcription, translation, or other processes that occurs within virus-infected cells.
Interferon A pro-inflammatory cytokine that is produced after virus infection and stimulates antiviral activities in cells expressing the IFNAR receptor complex.
Interferon-stimulated gene (ISG) A gene whose transcription is increased after interferon signaling. Some ISGs are directly antiviral and can inhibit virus transcription or translation.
Positive-sense RNA genome The genomic material of the virus resembles a cellular messenger RNA and the open reading frame can be translated on host ribosomes.
Receptor Structures (e.g., protein, sulfated polysaccharide, phospholipid) found upon the surface of host cells that interact with virus attachment proteins and mediate attachment of virus particles to cell surfaces. These structures may also mediate subsequent events in cell entry such as viral protein rearrangements leading to membrane fusion.
Replicon system A replication-competent but propagation-incompetent form of a cloned virus. In many replicon systems, the replicon genome can be packaged into a virus-like particle by *trans*-expression of structural proteins.
RNA-dependent RNA polymerase (RdRp) The primary RNA synthesis enzyme for RNA viruses which uses viral genomic RNA as a template for transcription/replication.

Introduction

The family *Togaviridae* includes the genera *Alphavirus* and *Rubivirus*. The genus *Alphavirus* is comprised of 29 virus species segregated into five antigenic complexes, most of which are transmitted between vertebrate hosts by mosquito vectors and are capable of replicating in a wide range of hosts including mammals, birds, amphibians, reptiles, and arthropods. In contrast, the sole member of the genus *Rubivirus* is Rubella virus, which is limited to human hosts and is primarily transmitted by respiratory, congenital, or perinatal routes. Together, the viruses are a significant worldwide cause of human and livestock disease. Alphavirus disease ranges from mild to severe febrile illness, to arthritis/arthralgia and fatal encephalitis, while Rubella virus is an important cause of congenital abnormalities and febrile illness frequently accompanied by arthralgia/arthritis in the developing world. At the molecular level, the togaviruses are relatively uncomplicated, small, enveloped virions with single-stranded, positive-sense RNA genomes encoding two polyproteins, one translated from the genomic RNA and the other from a subgenomic mRNA transcribed during replication. However, their replication is very tightly regulated and intimately associated with host cell metabolic processes. Currently, an important aspect of togavirus research is designed to exploit their molecular biology for therapeutic and gene therapy applications. Here, we summarize major aspects of togavirus structure, genome organization, replicative cycle, and interactions with host cells.

Virion Structure and Genome Organization

Togavirus virions are small and enveloped, comprising an icosahedral nucleocapsid composed of 240 capsid (C) protein monomers, cloaked in a lipid envelope studded with membrane-anchored glycoprotein components, E1 and E2. Their tightly packed, regular structure has been revealed by high-resolution reconstruction of the particles by cryoelectron microscopy (**Figure 1**). The envelope glycoproteins of alphaviruses are similarly arranged on the outer surface of particles. E1 and E2 form a stable heterodimer, and three heterodimers interact to form 'spikes' distributed on the virion surface in an icosahedral lattice that mirrors the symmetry of the nucleocapsid. The regularity of the spike distribution is determined by the direct hydrophobic interaction of the E2 glycoprotein tail with a pocket on the surface of the C-protein. E2 projects outward from the virion to form the spikes that interact with host-cell attachment receptors, while the E1 glycoprotein, which mediates fusion with host cell membranes, appears to lie parallel to the lipid envelope. The E2 and E1 proteins are glycosylated at one to four positions, depending on the virus strain, during transit through the host-cell secretory apparatus.

The encapsidated alphavirus genome consists of a nonsegmented, single-stranded, positive-sense RNA molecule of approximately 11–12 kb with a 5′-terminal methylguanylate cap and 3′ polyadenylation, resembling cellular mRNAs (**Figure 2**). The genome is divided into two major regions flanked by the 5′ and 3′ nontranslated regions (NTRs) and divided by an internal NTR: (1) the 5′-terminal two-thirds of the genome encode the four nonstructural proteins (nsPs 1–4); and (2) the 3′ one-third of the genome encodes the three structural proteins (C, precursor E2 [PE2], and precursor E1 [6K/E1]). Overall, the capped and polyadenylated 9.5 kb Rubella virus genome is similarly organized (**Figure 2**), but the 5′-proximal open reading frame (ORF) encodes only two nsPs (P150 and P90) and three structural proteins are encoded by the 3′ ORF (C, E1, and E2).

Infection and Replication Cycle

The togavirus genome encodes very few but, therefore, necessarily multifunctional proteins. The replication of these viruses is very tightly regulated and as little as a single nucleotide change can alter susceptibility to cellular defense mechanisms. The following section outlines molecular aspects of togavirus infection and replication pertinent to the virus–cell interaction. Replication processes of viruses of the family *Togaviridae* have been most extensively studied for the alphaviruses, Sindbis virus (SINV) and Semliki Forest virus (SFV), and extrapolated to the other family members.

Virus Attachment, Entry, and Uncoating

The entry pathways of Rubella virus have undergone only limited study, but there is some evidence that a glycolipid molecule serves as an attachment receptor on some cell types. The nature of the receptor for naturally circulating, 'wild-type' alphaviruses has been examined more extensively, but remains controversial, as is the case with many arthropod-borne viruses. Typically, arthropod-borne viruses are thought to interact either with a single, evolutionarily conserved molecule expressed on most cells, or to utilize different receptors in different hosts and with cells derived from different tissues. The 67 kDa high-affinity laminin receptor (HALR) has been identified as an initial attachment receptor for cell culture-adapted, laboratory strains of SINV and an antigenically related molecule has similarly been identified for Venezuelan equine encephalitis virus (VEEV). In addition, receptor activity for particular cell types has been attributed to several other, as yet uncharacterized, proteins. However, more recent studies have indicated that efficient cell binding by many laboratory strains of alphaviruses is due to interaction with heparan sulfate (HS), a sulfated glycosaminoglycan molecule, and that this phenotype is conferred by positively charged amino acid substitutions in E2 that accompany adaptation to cultured cells. Currently, it is unclear whether or not the 67 kDa HALR or other identified receptor proteins act in concert with HS to bind cell culture-adapted alphavirus strains or if any of these molecules function in the natural replication cycle of wild-type alphaviruses. Moreover, it has become clear that many noncell culture-adapted alphavirus strains bind only weakly to commonly used cell lines, such as those derived from fibroblasts. Recently, DC-SIGN and L-SIGN, C-type lectins, were found to bind carbohydrate modifications on E1 and/or E2 proteins of both HS-binding and non-HS-binding strains of SINV and VEEV, promoting infection. The interaction of the lectins with virion carbohydrates is greatly enhanced by replication of viruses in mosquito cells, most likely due to the retention of high mannose carbohydrate structures, which are processed to complex carbohydrates in mammalian cells. Therefore, C-type lectins may be important attachment receptors for alphaviruses when transmitted by mosquitoes, and receptor utilization could be determined, at least in part, by the cell type in which alphaviruses replicate. Since DC-SIGN and L-SIGN receptors are expressed by a subset of alphavirus-permissive cells, these results further suggest that infection by alphaviruses may be mediated by different receptors on different cell types.

Following receptor interactions, which may initiate uncoating-related conformational changes in E1 and E2, alphavirus and Rubella virus virions enter acidified endosomes via a dynamin-dependent process. The decreasing pH in the endosome results in more dramatic

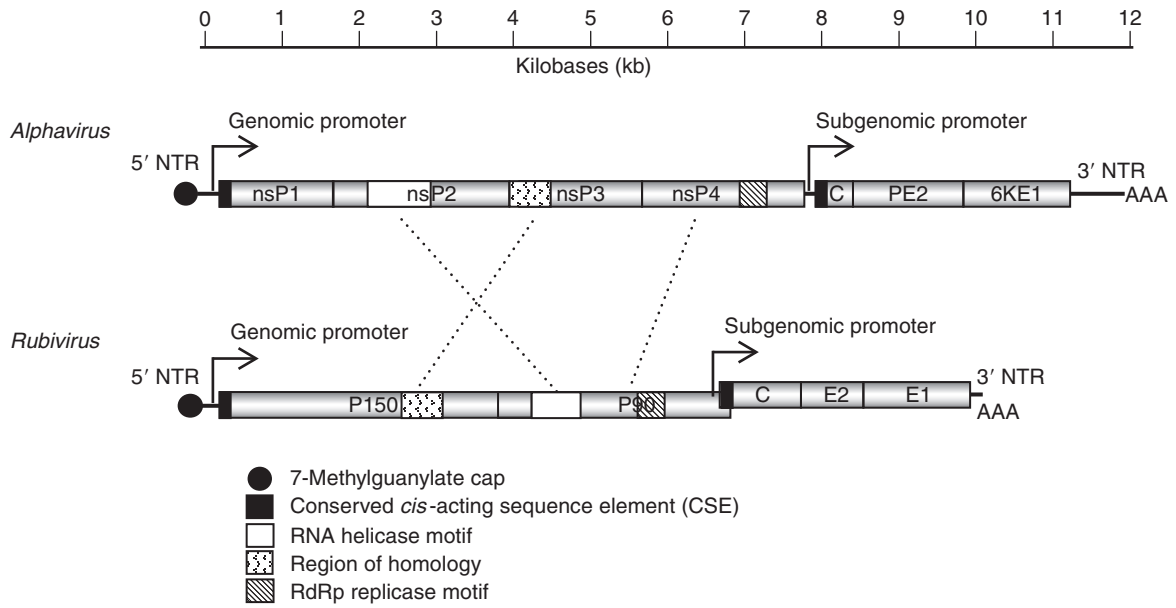

Figure 2 Comparison of *Alphavirus* (SINV) and *Rubivirus* (RUB) genome organization. Regions of nucleotide homology and regions encoding homologous amino acid sequence within the nonstructural protein ORF are shown. ORFs are denoted by boxes and nontranslated regions (NTRs) by lines. Note that for SINV the two ORFs are separated by a NTR region, whereas for RUB the two ORFs overlap in different translational frames. Reproduced from Dominguez G, Wang C-T, and Frey TK (1990) Sequence of the genome RNA of rubella virus: Evidence for genetic rearrangement during togavirus evolution. *Virology* 177: 225–238 with permission from Elsevier.

conformational changes (threshold of ~pH 6.2 with SFV) in the E2/E1 spike leading to formation of E1 homotrimers and exposure of a putative class II fusogenic domain in E1 that is thought to interact with the host cell membrane, promoting fusion of host and virion lipid bilayers. In mammalian cells, SFV membrane fusion is cholesterol-dependent and sphingolipid-dependent, and inhibitors of endosomal acidification block infection. Endosomal fusion leads to a poorly characterized entry of nucleocapsids into the cytoplasm and to their association with ribosomes, most likely directing final uncoating of the genomic RNA and translation initiation.

Genome Translation, Transcription, and Replication

Togavirus genome transcription and replication occur by a strictly positive-sense strategy and are entirely cytoplasmic (**Figure 3**). The alphavirus replicase complex comprises four nsPs encoded in the 5′-terminal ORF, all of which are essential for viral transcription and replication: (1) nsP1 is a guanine-7-methyltransferase and guanylyl-transferase; (2) nsP2 has NTPase, RNA helicase, and RNA triphosphatase activities in its amino-terminal domain, while the carboxy-terminus has highly specific thiol protease activity; (3) nsP3 is a phosphoprotein with unknown function; and (4) nsP4 is the catalytic RNA-dependent RNA polymerase (RdRp). In addition to the final products, some of the processing intermediates have distinct and indispensable functions during the replication process. The 5′-proximal ORF of the Rubella virus genome is also translated as a polyprotein (p200) and cleaved in *cis* by the Rubella virus protease (NS-pro) to form the replication complex comprising P150 and P90. However, the order of its conserved motifs differs from that of the alphavirus nsP polypeptide (**Figure 2**): P150 contains the putative methyltransferase (N-terminal) and protease sequences (C-terminal), while P90 contains the predicted helicase (N-terminal) and RNA polymerase (C-terminal).

Once the nsPs have been translated from the infecting, positive-sense RNA genome, full-length RNAs complementary to the genomic sequence (negative-sense) are synthesized, creating partially double-stranded (ds) RNA replicative intermediates. The RdRp complex then switches to preferential synthesis of positive-sense RNAs, which continues throughout the remainder of the infection replication cycle, while negative-sense RNA transcription ceases entirely. Two positive-sense, capped, and polyadenylated RNAs are synthesized on the negative-sense template: full-length progeny genomes that are packaged into virions and subgenomic (26S) RNAs that are collinear with the 3′ one-third of the genome and encode the structural protein ORF. The 26S RNA accumulates in the cells to 5–20-fold molar excess over genomic RNA and is efficiently translated into a polyprotein that is co-translationally processed to produce the structural proteins.

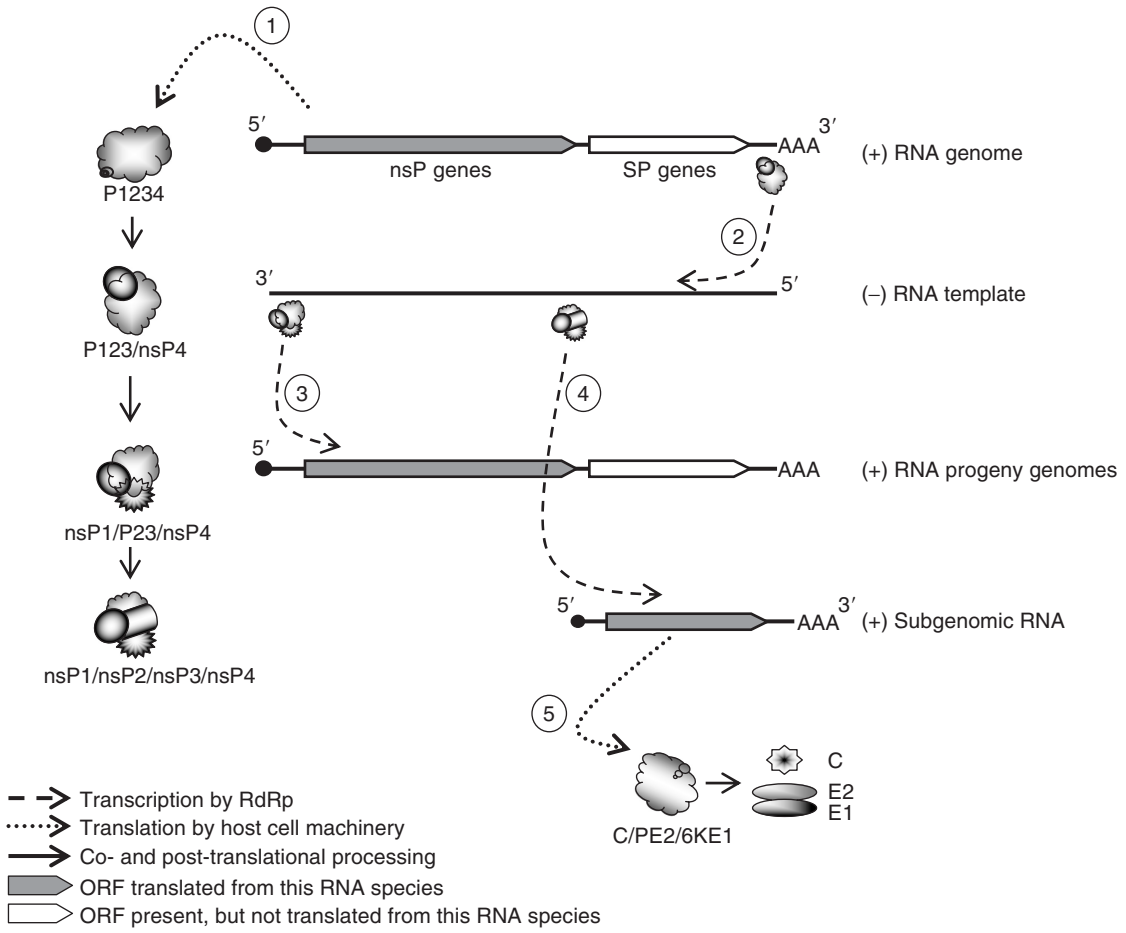

Figure 3 Diagrammatic representation of *Alphavirus* replication in a permissive cell. The replication cycle is depicted as a series of temporally regulated steps: ① Translation and processing of nonstructural polyprotein P1234 or P123; ② Synthesis of complementary, negative-sense RNA by P123/nsP4; ③ Synthesis of progeny genomes by nsP1/P23/nsP4; ④ Synthesis of subgenomic RNAs by nsP1/nsP2/nsP3/nsP4; ⑤Translation and processing of structural polyprotein C/PE2/6KE1. Progeny genomes are then packaged into nucleocapsids and bud at the plasma membrane to release progeny virions.

Alphavirus genome replication and transcription are tightly regulated temporally by sequential processing of the nsPs, which alters replicase composition and RdRp activity. For some alphaviruses (e.g., SFV), the nsPs are translated as P1234, while others (e.g., SINV) translate the nsPs as either P1234 or P123 polyproteins, depending upon read-through of an opal termination codon. The nascent P1234 polyprotein is partially processed by autocatalytic nsP2 protease-mediated cleavage at the 3/4 junction and assembled into the primary P123/nsP4 RdRp complex. This short-lived P123/nsP4 primarily synthesizes genomic, negative-sense RNA replicative intermediates. Membrane-bound P123 is cleaved relatively slowly in *cis* at the 1/2 junction, perhaps to enable formation of protein–protein interactions prior to proteolytic processing, and to form the nsP1–P23–nsP4 replicase that preferentially synthesizes positive-sense RNA. After the aminoterminus of nsP2 has been released, rapid autocatalytic cleavage of P23 produces a mature, stable RdRp complex (nsP1–nsP2–nsP3–nsP4), which transcribes only positive-sense RNA. Evidence suggests that nsP1–P23–nsP4 and the mature replicase may be biased, respectively, toward synthesis of genome-length or subgenomic mRNA, providing further temporal regulation of the replication cycle. Late in infection, when free nsP2 concentrations are high, cleavage at the 2/3 junctions is favored. P1234 polyproteins are rapidly processed into short-lived P12 and P34 precursors, thereby precluding assembly of new replication complexes and terminating negative-strand synthesis. *cis*-Cleavage of the P12 precursor gives rise to nsP1, which targets the plasma membrane, and nsP2. Interestingly, much of nsP2 is transported to the nucleus, suggesting a function beyond the replication and transcription of viral RNAs, as discussed below. P34 is cleaved in *trans* by free nsP2, yielding nsP3, which aggregates in the cytoplasm, and nsP4, which is rapidly degraded by the ubiquitin pathway.

Specificity of togavirus RNA replication by the RdRp replicase is achieved via differential recognition of *cis*-acting conserved sequence elements (CSEs) in the

termini of the viral genome and negative-sense genome template. These CSEs are conserved in all alphaviruses, as well as in Rubella virus. A 19-nucleotide (nt) CSE in the 3′ NTR immediately upstream of the poly(A) tail, is the core promoter for synthesis of genome-length, negative-sense RNA replicative intermediates, and probably interacts with the 5′ NTR via translation initiation factors to initiate replication and/or translation. The complement of the 5′ NTR in the minus-strand RNA serves as a promoter for the synthesis of positive-sense genomes. A third *cis*-acting element that is essential for replication, the 51-nt CSE, is also found near the 5′ end of the genomic RNA within the nsP1 gene. The primary sequence and two-stem–loop secondary structure of this CSE are highly conserved among alphaviruses and serve as replication and translation enhancers. Finally, a 24-nt CSE is found upstream of and including the start of the subgenomic RNA, the complement of which in the negative-strand forms the 26S subgenomic promoter and translation enhancer element.

Togavirus RNA replication occurs on cytoplasmic surfaces of endosome-derived vesicles or cytopathic vacuoles (CPVs). Expression of the nsP polyprotein (particularly nsP1) actively modifies intracellular membranes to create these compartments and to mediate membrane association of the replicase via membrane phosphatidylserine and other anionic phospholipids. The surfaces of CPVs have small invaginations or 'spherules', in which the nsPs and nascent RNA are sequestered, creating a microenvironment for RNA replication, synthesis of structural proteins, and assembly of nucleocapsids. The formation of CPVs in togavirus-infected cells may be linked to stress-induced autophagic mechanisms intended for the targeted degradation of cellular proteins and organelles, but exploited by the virus.

Structural Protein Maturation, Genome Packaging, and Egress of Virions

The subgenomic mRNAs of alphaviruses and of Rubella virus are translated as polyproteins; however, processing of the polyprotein differs between the two. With alphaviruses, the capsid protein is cleaved autoproteolytically from the E2 precursor (known as PE2 or P62) in the cytoplasm and the remaining polyprotein is translocated into the ER lumen, where N-linked oligosaccharide addition occurs. The 6K hydrophobic protein, which is primarily located in the ER membrane, is then cleaved from the polyprotein by the host signalase. With Rubella virus, the capsid-E2 and E2–E1 cleavages are all completed by signalase. Furthermore, Rubella virus lacks the 6K protein and mature E2 is produced in the ER. Alphavirus PE2 and E1 proteins form heterodimers in the ER that are anchored by their transmembrane domains and involve intra- and intermolecular disulfide linkages and associations with host chaperone proteins such as Bip and calnexin/calreticulin. The PE2/E1 heterodimers are routed to the cytoplasmic membrane and PE2 is cleaved into mature E2 by a host furin-like protease as a late event, in a structure between the *trans* Golgi network and cell surface. The cleaved E3 fragment is lost from some (e.g., SINV), but not all (e.g., SFV) virus particles. PE2-containing virions appear to bud normally from vertebrate cells, but are often defective in conformational rearrangements associated with cell fusion, supporting the hypothesis that the presence of PE2 stabilizes the glycoprotein heterodimer during low pH exposure in the secretory pathway.

Budding of particles occurs through an interaction between C and the cytoplasmic tail of E2; however, it is unclear at which point in the secretory pathway this interaction occurs and whether the interaction is between C monomers, oligomers, or RNA-containing preformed nucleocapsids. With alphaviruses, RNA packaging is directed by an RNA secondary structure in either the nsP1 or nsP2 genes, depending upon the virus, leading to selective packaging of the genome over the subgenome, which is in molar excess. In the accepted model, final budding occurs at the cytoplasmic membrane at sites enriched in E2/E1 heterodimers and is driven by E2 tail-C interactions that force an extrusion of the host lipid bilayer, envelopment of the particle, and release.

Infectious Clone Technology

Knowledge of the genome organization and replication cycle of the togaviruses have enabled the construction of full genome-length cDNA clones from which infectious RNA molecules can be transcribed *in vitro* and transfected into permissive cells to initiate productive virus replication. This procedure allows easy introduction of specific mutations into the virus genome followed by generations of genetically homogeneous virus populations encoding the mutation(s). Indeed, much of the work described in this article was performed using virus mutants generated from cDNA clones. In addition, 'double-subgenomic promoter viruses' (DP-virus) have been created in which the subgenomic promoter is reiterated immediately upstream of the authentic subgenomic promoter or at the 3′ end of the E1 coding region to drive expression of genes used as reporters of infection or vaccine vectors (e.g., GFP, luciferase, or immunogens from infectious microorganisms) or to test the effect of protein/RNA expression in the context of a togaviral infection (e.g., antiviral or apoptosis-inhibiting proteins, or interfering RNAs). Propagation-defective virus-like particles or 'replicon' systems have also been developed in which the structural protein genes are deleted and replaced with a heterologous protein gene. With alphaviruses, replicon genomes can be packaged to form replicon particles by expressing the structural proteins in *trans*. Typically, the replicon genome RNA is co-electroporated with two

'helper' RNAs, which are replicated and transcribed by the nsPs provided by the replicon genome and separately encode the capsid and PE2/6K/E1 proteins. Use of these bipartite helper systems minimizes the potential for generation of propagation-competent progeny. In contrast, Rubella virus exhibits a dependence of expression on the nsP ORF from the same nucleic acid as the structural proteins, limiting this approach. Replicon particles can infect a single cell and express the heterologous protein at high levels from the subgenomic promoter but, in the absence of structural protein expression, no progeny virions are produced. Therefore, these vectors allow detailed examination of the interaction of the virus with single cells and can also be used as vaccines with little possibility that adverse effects associated with propagating vial vectors will occur in vaccinated hosts. The results of numerous studies have indicated that togavirus DP-viruses and replicons will likely become important vector systems for the delivery of heterologous gene products to cells *in vitro* and *in vivo*.

Togavirus–Host Cell Interactions

The togavirus–cell interaction can be viewed as a conflict between the cell and the virus: the virus must replicate to propagate itself, generally leading to cytopathic effects (CPEs), while the host cell attempts to suppress virus replication in order to avoid CPE or to save the greater organism from death (in which case the individual cell may be sacrificed). In the following section, these interactions are addressed as a continuum from poorly restrained virus replication leading to rapid CPE on one extreme, to host-cell-circumscribed virus replication and prolonged cell survival on the other.

Cell Viability and CPE

Historically, alphaviruses (e.g., prototypic SINV) have been considered to be strongly cytopathic, causing rapid killing of cultured vertebrate cells that are highly permissive of their replication. In contrast, alphavirus replication in mosquito cells is most often associated with persistent infection and limited cell death. Rubella virus is also cytopathic for vertebrate cells at high infection multiplicities, but can develop persistent infection at low multiplicity and does not infect mosquito cells. Only recently has the complex interaction between the virus infection cycle and cell death begun to be unraveled. Infection of many vertebrate cell lines with alphaviruses or Rubella virus results in morphological changes (e.g., chromatin condensation, nuclear fragmentation, and formation of membrane-enclosed apoptotic bodies), as well as molecular changes (e.g., caspase activation and DNA fragmentation), associated with programmed cell death/apoptosis. Expression of SINV structural glycoproteins, particularly the transmembrane domains, can cause apoptosis in rat AT-3 prostatic adenocarcinoma cells. Furthermore, mutation from glutamine to histidine at position 55 of the SINV E2 glycoprotein has been associated with increased apoptosis in cultured cells and neurons in mice. However, although accumulation of viral structural proteins accelerates CPE development, apoptosis also occurs in replicon-infected cells in the absence of structural protein synthesis, linked to replication and nsP2 activities. Complicating this picture further is that interaction of high concentrations of UV-inactivated SINV particles with cell surfaces can initiate cell death pathways in cells of some lines, suggesting that viral replication/gene expression is not always required for killing. Finally, evidence also exists for alphavirus-induced necrotic cell death (i.e., not involving active cellular processes) in subpopulations of infected neurons *in vivo*. Therefore, the stimulus for CPE caused by togaviruses may depend upon the virus genotype, dose, the infected cell type, and/or the infection context. At the molecular level, multiple pathways, including mitochondrial cytochrome *c* release, TNF-α death receptor signaling, sphingomyelinase activation and production of ceramide, and redox-stress and inflammatory-stress pathway activation have been associated with togavirus-induced cell death, further supporting the idea that induction of particular mechanisms may be dependent upon multiple virus and host cell factors.

Host-Protein Synthesis Shut-Off

Togavirus replication in highly permissive vertebrate cells devastates cellular macromolecular synthesis, arresting both cellular transcription and translation by independent mechanisms. Transcriptional downregulation of cellular mRNAs and rRNAs can be directly mediated by the mature SINV nsP2 protein even in the absence of viral replication and is critically involved in the production of CPE. This activity is determined by integrity of the nsP2 carboxy-terminal domain, not by helicase or protease activity and can be greatly reduced by point mutations in this region. Moreover, the degree of nsP2-mediated pro-apoptotic stimulus appears to vary considerably between different togaviruses. Nonstructural protein-mediated inhibition of cellular transcription in highly permissive cells, such as fibroblast cell lines, dramatically suppresses the cell's ability to generate an antiviral stress response and is likely beneficial for togavirus replication and dissemination. However, infection with the noncytopathic nsP2 mutants described above restores the cell's response. In contrast, infection of dendritic cells and macrophages, which may be less permissive to infection than fibroblasts or may express a different ensemble of antiviral response mediators, produces a vigorous stress response after virus exposure and large quantities of new mRNAs are synthesized.

Translation of cellular mRNAs is also dramatically inhibited within hours of togavirus infection in highly permissive cells. This process of host-protein synthesis 'shut-off' occurs independent of transcriptional arrest. The degree to which translational shut-off occurs is inextricably linked with the extent of viral RNA replication, such that incomplete translation inhibition is associated with permissivity and mutations in viral replicase complex proteins, particularly nsP2. As a cellular response, translational inhibition is a stress-induced defense mechanism, able to recognize viral infection, amino acid starvation, iron deficiency, and accumulation of misfolded proteins in the endoplasmic reticulum (ER) via the activation of stress kinases. The activity of four distinct stress kinases converges to phosphorylate eukaryotic translation initiation factor (eIF) 2α, inhibiting GTP–eIF2–tRNAi-Met ternary complex formation and globally suppressing translation initiation. However, the expression of specific stress-inducible cellular proteins continues under conditions of phosphorylated eIF2α and generalized shut-off. If the stress response fails to clear the virus and restore homeostasis, the effects of prolonged shut-off become detrimental to the infected cell, leading to CPE and apoptotic cell death. Phosphorylation of eIF2α during togavirus infection is triggered by the presence of dsRNA primarily through activation of the dsRNA-dependent protein kinase (PKR). In some situations, eIF2α phosphorylation appears to be largely responsible for translation inhibition, since the overexpression of a nonphosphorylatable eIF2α mutant abrogates shut-off despite efficient viral replication. However, the arrest of host protein synthesis has also been shown to occur independently of PKR activity and in the apparent absence of eIF2α phosphorylation, by an unknown mechanism.

In response to this cellular defense mechanism, togaviruses have evolved degrees of tolerance to translational shut-off, enabling them to circumvent this block and redirect the cell's inoperative translational apparatus to the synthesis of viral proteins. Indeed, once shut-off has occurred, virtually the only proteins synthesized by the cell are virus-encoded structural proteins, expressed from the subgenomic mRNA. This implies that host protein synthesis shut-off confers an advantage to the virus, allowing usurpation of cellular translation machinery and potentially dampening the host cell's antiviral stress response. Translation enhancer elements located in the 5′ termini of SINV and SFV 26S (and, very likely, Rubella virus) mRNAs, particularly the highly stable RNA hairpin downstream of the AUG start codon, facilitate the continued expression of alphavirus structural proteins during the translation inhibition imposed by eIF2α phosphorylation. SFV infection has been shown to induce the transient formation of stress granules containing cellular TIA-1/R proteins, which sequester cellular mRNAs, but disassemble in proximity to the viral replicase. The temporal correlation between eIF2α phosphorylation, stress granule assembly and localized disassembly, and the transition from cellular to viral protein synthesis suggest that these may be important processes in generalized shut-off of protein synthesis and avoidance of the shut-off by the 26S mRNA. It is likely that the togaviruses also evade and/or antagonize PKR/phospho-eIF2α-independent translation arrest. Notably, the 26S mRNA also has a low requirement for the translation complex scaffolding protein, eIF4G, although integrity of eIF4G is not known to be affected by togavirus replication.

The Interferon-Mediated Antiviral Response

Antiviral activity of interferon-alpha/beta (IFN-α/β) is a critical determinant of the outcome of togavirus infection both *in vitro* and *in vivo*. In mice, the absence of this response results in greatly increased susceptibility to alphavirus infection and disease. In cell culture, IFN-α/β pretreatment profoundly blocks virus replication and protects cells from CPE induced by all togaviruses tested. However, some alphaviruses (e.g., VEEV) appear to be more resistant to the effects of exogenously added IFN-α/β than others (e.g., SINV). All togaviruses tested also stimulate the production of IFN-α/β from cultured cells to varying degrees. Presumably, IFN-α/β induction results from triggering of cellular pattern recognition receptors (PRRs), such as toll-like receptors (TLRs), PKR and/or cytoplasmic RNA helicases such as RIG-I or MDA-5 by 'pathogen-associated molecular patterns' (PAMPs). In addition to IFN-α/β induction, these receptors stimulate a general inflammatory response in infected cells by activating the NF-κB pathway (which is activated after SINV infection). Historically, cytoplasmic dsRNA, produced as a component of the togavirus replicative cycle has been considered the primary PAMP; however, UV-inactivated preparations of some alphaviruses (e.g., SFV) can elicit inflammatory responses in certain cultured cells suggesting multiple pathways of pathogen detection and response. Secreted IFN-α/β signals through its cognate receptor on infected and uninfected cells to upregulate expression of many IFN-stimulated genes (ISGs), producing antiviral proteins, some of which directly inhibit togavirus replicative processes. In less permissive vertebrate cells, induced IFN-α/β can act upon the infected cell to suppress togavirus replication, prevent overt CPE, and promote a persistent infection.

Several studies have evaluated the individual and combined contribution of the two best-characterized IFN-α/β-inducible antiviral pathways, the PKR pathway (described above), and the coupled 2–5A synthetase/RNase L pathway, to the control of alphavirus replication. The latter pathway is composed of the interferon-inducible 2′–5′ oligoadenylate synthetase (OAS) family of dsRNA-dependent enzymes and dormant, cytosolic RNase L. dsRNA-activated 2′–5′ OAS synthesizes 2′–5′-linked

oligoadenylates that specifically bind and activate RNase L which then cleaves diverse RNA substrates, thus inhibiting cellular and viral protein synthesis. As described above, constitutively expressed and IFN-α/β-inducible PKR is activated by dsRNA binding to phosphorylate eIF2α, causing a decline in cap-dependent translation of viral and cellular mRNAs. Infection of mice with targeted disruption of the PKR gene, the RNase L gene or both, revealed that PKR, but not RNase L, is involved in the early control of SINV replication *in vivo* and in primary cell cultures. Surprisingly, IFN-α/β-mediated antiviral responses against SINV are largely intact in the absence of PKR and/or RNase L, confirming the existence of 'alternative' IFN-α/β-induced pathway(s) capable of curtailing togavirus replication. Gene transcription and *de novo* protein synthesis are required for this activity. Although the proteins involved are yet to be characterized, one such pathway involves a novel inhibition of cap-dependent translation of infecting viral genomes in the absence of eIF2α phosphorylation. In addition, the interferon-inducible proteins MxA, ISG15, and the zinc-finger antiviral protein (Zap) have some inhibitory effects upon alphavirus replication. Considering the potent inhibitory effects of IFN-α/β toward numerous togaviruses, the expression of additional mechanisms to evade or antagonize the IFN-α/β response is likely critical for togavirus virulence, although convincing evidence of their existence is yet to be presented.

Conclusions and Perspectives

Research into the molecular biology of togaviruses has two primary goals: (1) to understand the relationship of virus interactions with single cells to replication and disease pathogenesis in natural hosts and, subsequently, to identify targets for therapeutic intervention; and (2) to manipulate virus–cell interactions to capitalize upon the potential for use of these viruses as tools for gene therapy and vaccination. In the examples described above, the dissection of virus attachment, entry, translation, replication, effects upon host cells, and host cell responses to infection all have identified vulnerabilities through which virus infection may be curtailed and many laboratories are currently developing antiviral and/or disease-ameliorating strategies. Furthermore, research into virus stimulation of CPE or stress responses has led to an improved understanding of how to, for example, maximize CPE (important for the development of tumor-destroying vectors) or minimize host antiviral activity (important for expression of immunogens by vaccine vectors). Some important issues that remain to be addressed include the full elucidation of the complex relationship of virus replication to development of CPE, the nature of antiviral stress response mediators capable of blocking virus replication, and the mechanisms through which togaviruses antagonize and/or evade these responses.

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Pseudorecombinants New strains of a virus that result from the reassortment of genome nucleic acids during the replication of viruses with divided genomes in mixed infections.

Recombinant A new strain/species of a virus that occurs as a result of the breakage and renewal of covalent links in a nucleic acid chain for rearrangement of nucleic acids in the chain.

Synergism The association of two or more viruses acting at the same time, which enhances symptom severity.

Introduction

Whitefly-transmitted geminiviruses cause epidemics in vegetable, staple, and fiber crops. The diseases are generally associated with local or regional whitefly (*Bemisia tabaci* Gennadius) infestations. They cause enormous economic losses in several crops in the Tropics, which provide ideal conditions for the perpetuation of viruses and the insect vector. Intensive agricultural practices necessitated by the ever-increasing demands of a rapidly growing population and the introduction of new genotypes, cropping pattern, and crops have further aggravated the situation. For example, the continuous cultivation of crops (such as cotton, tomato, pepper, beans, soybean, and melon which are susceptible to the viruses and are attractive hosts for the whiteflies) certainly account for some of the increase in the severity and the vast spread of diseases caused by geminiviruses.

Tomato leaf curl disease (ToLCD) is the most devastating disease of tomato, affecting a large area under cultivation; it can be on the scale of an epidemic. Incidence of this disease was first reported from northern India in 1948. During the 1950s, incidence was reported from central India, followed by occurrence of the disease in the main tomato-growing regions of southern India. Since then, this disease has emerged as a major threat to tomato cultivation, and incidence has increased after introduction of high-yielding tomato varieties during the late 1960s. The disease is ubiquitous with the crop and has been observed in all the tomato-producing areas of the country. Leaf curl disease of tomato is so serious that the ability of small farmers to cultivate tomato in several major production areas, especially during the peak of whitefly infestation season, has been eliminated.

Yield loss varied with the age of plants at the time of infection and varieties being tested. The virus affects all stages of the growth causing 17.6–99.7% loss in yield, depending on the stage of the crop at the time of infection. When plants get infected early, within 20 days after transplanting, they remain stunted and produce few or no fruits and the yield loss may reach up to 100%. However, if the plants are infected at 35 and 50 days after transplanting, the yield loss is reduced to 74.1% and 28.9%, respectively. This indicates that earlier the infection, higher is the yield loss.

Symptoms

Leaf curl disease of tomato is characterized by severe stunting of the plants with upward and downward rolling and crinkling of the leaves. Infected plants exhibit intervenal yellowing, vein clearing, and crinkling and puckering of the leaves, sometimes accompanied by inward rolling of the leaf margins. The disease induces severe stunting, bushy growth, and partial or complete sterility, depending on the stage at which infection has taken place (**Figure 1**).

Figure 1 (a–g) Variation of symptoms induced by begomoviruses infecting tomatoes in India.

Transmission

Under natural conditions, whiteflies transmit the tomato leaf curl viruses (ToLCVs) from infected to healthy plants. Even a single whitefly can transmit the virus. Minimum acquisition access period and inoculation access period of 30 min each is required for successful transmission to occur. Pre-acquisition and pre-inoculation starving of the vector results in higher levels of transmission. ToLCV can persist up to 10 days after acquisition in a single adult whitefly. Females are more efficient transmitters than the males. The virus is also transmitted by dodder (*Cuscuta reflexa* Roxb.). Under artificial conditions, grafting can transmit the disease. It is also known that some of the isolates of ToLCVs are also sap transmissible under laboratory conditions.

Epidemiology

Like other vector-borne diseases affecting crop species, the factors contributing to ToLCD buildup are: (1) availability of virus inoculum and the vector around the fields;

(2) the movement of viruliferous vectors into the freshly sown field; (3) the susceptibility of the variety that builds up vector population and allows establishment of the virus; (4) weather parameters favoring vector population buildup; and (5) vector biotype which can effectively transmit the disease. Interaction of these factors leads to epidemic outbreak. The most important factors responsible for the epidemic are source of inoculum and vector. In India, wherever tomato is grown continuously, there is increase in leaf curl disease incidence. Virus inoculum in the weeds and continuous cropping contribute to rapid disease buildup. Weather parameters, both at macro- and micro-level, affecting the developmental stages of the plant and the life cycle of the vector are important. Tomato is grown in different agroclimatic zones in India, which makes prediction of the outbreak of epidemics more difficult. However, there is definitely a correlation between vector population and disease incidence.

Maximum temperature and rainfall play an important role for spread of the disease in southern India, while minimum temperature and minimum relative humidity influence the whitefly population in the north. ToLCD incidence depends on weather conditions (humidity, rainfall, temperature). It was observed that the disease progresses from February to June, when the dry and hot season with low humidity prevail. The incidence may even reach up to 100% during these months. These types of weather conditions favor whitefly multiplication and disease spread. The whitefly population and ToLCV incidence remain comparatively less during winter and rainy seasons. The tropical climate in southern India allows year-round tomato cropping, which, together with the presence of perennial host plants for both ToLCVs and *B. tabaci*, enables an easy carry-over of ToLCD between growing seasons. Whitefly biotype B can effectively transmit the virus. Overall, factors like long persistence of the virus in the vector, efficient transmission by the biotype, cultivation of tomato throughout the year, and abundance of weed hosts are the contributing factors for the high incidence of the disease under natural conditions.

Host Range

ToLCV strains/species are easily transmitted by grafting and through vector to a wide range of weeds and cultivated crops. Molecular detection using ToLCV-specific primers has led to identification of a range of plant species that can harbor ToLCVs in India. ToLCVs can infect crops such as *Lycopersicon esculentum*, *L. peruvianum*, *L. hirsutum*, *L glandulosum*, *L. pimpinellifolium*, *Capsicum annuum*, *Nicotiana tabacum*, *Vigna unguiculata*, and *Luffa cylindrica*. The viruses perpetuate on many weed hosts, viz. *Acanthospermum hispidum*, *Ageratum conyzoides*, *Blainvella rhomboids*, *Euphorbia hirta*, *Fraveria hirta*, *Parthenium hysterophorus*, *Malvastrum coromandalinum*, and *Croton bonplandianum*.

Genome Organization

Full-length genome of isolates of ToLCVs have been cloned and sequenced. Three types of genomic DNA (DNA-A, DNA-B, and DNA-β) have been found to be associated with begomoviruses causing ToLCD in India.

Apparently, the isolates from southern India have a monopartite genome (DNA-A) associated with DNA-β while both monopartite (DNA-A with DNA-β) and bipartite (DNA-A and DNA-B) begomoviruses have been found to infect tomatoes in northern India. The genome organization of DNA-A (ranges between 2739 and 2759 bp) resembles other begomoviruses having two open reading frames (ORFs) on the viral strand (AV1 and AV2) and four on the complementary strand (AC1, AC2, AC3, and AC4). Genome organization of DNA-B (ranges between 2656 and 2686 bp) and DNA-β (genome size between 1344 and 1376 bp) also resembles other begomoviruses having two ORFs (one on the viral strand, BV1, and the other on the complementary strand, BC1) and one on the complementary strand (βC1), respectively.

Diversity of Tomato-Infecting Begomoviruses

ToLCD appears to be caused by a complex of several viruses based on symptom variations on different indicator hosts. During the 1980s, based on symptoms produced in a particular tomato cultivar, ToLCVs were divided into five groups: (1) severe leaf curl with thickening of veins, (2) severe symptom with enation, (3) screw pattern of leaf arrangement, (4) vein purpling and leaf curl, and (5) exclusively downward curling of leaves. Variability was subsequently also found in the epitope profiles of ToLCVs collected from Karnataka, with groupings suggesting that the tomato crop and some neighboring weed species were hosts to the same ToLCV strains/species. Species status for begomoviruses, however, cannot be conferred based on symptom type or epitope profile.

In accordance with the ICTV *Geminiviridae* study group guidelines, nucleotide sequence identity of DNA-A, and genome organization (see **Table 1**), the following five Indian ToLCV species are to be demarcated: *Tomato leaf curl Bangalore virus*, *Tomato leaf curl Gujarat virus*, *Tomato leaf curl Karnataka virus*, *Tomato leaf curl New Delhi virus*, and *Tomato leaf curl Pune virus*. Except for *Tomato leaf curl Pune virus*, four species have been characterized in detail based on their biological and molecular properties (**Figure 2**).

Tomato Leaf Curl New Delhi Virus

During the mid-1990s, two isolates of this virus were reported from New Delhi and Lucknow. In addition to the severe isolate, a mild isolate was also described from New Delhi. It has a bipartite genome with DNA-A and DNA-B. However, occurrence of DNA-β has also been observed. Infectivity of the cloned DNAs has been demonstrated.

Tomato Leaf Curl Gujarat Virus

Three isolates from Varanasi, Vadodara, and Mirzapur belong to this species. Among them, Varanasi strain has been characterized in detail. DNA-A alone is infectious but DNA-B increases symptom severity. Association of DNA-β has also been observed with this mono-bipartite species under natural conditions. Tomato leaf curl Gujarat virus (ToLCGV) is also sap transmissible to tomato, pepper, *N. benthamiana*, and *N. tabacum*. Unexpectedly, ToLCGV-Var DNA-A (AY190290) and DNA-B (AY190291) share a common region (CR) of 155 bp that is only 60% identical which were cognate pair of components that cause severe disease of tomato under field conditions.

Tomato Leaf Curl Bangalore Virus

This virus was reported for the first time from Bangalore, southern India. Several isolates referred to as tomato leaf curl virus Ban1, Ban3, Ban4, Ban5, and Kolar belong

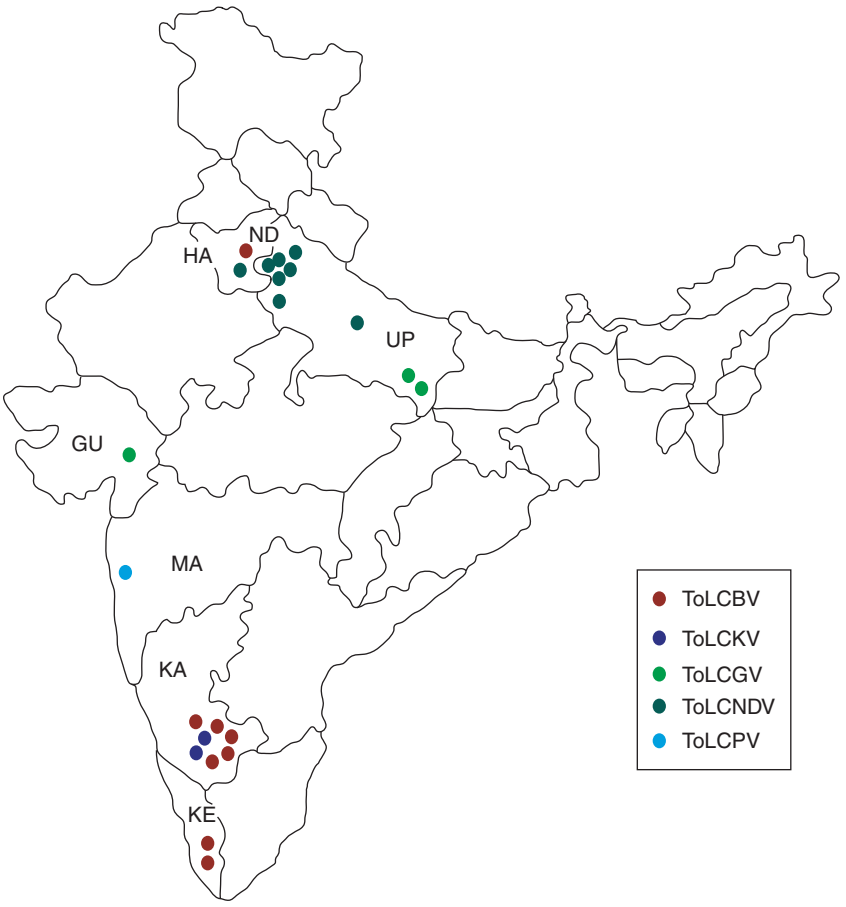

Figure 2 Distribution of five species of tomato-infecting begomoviruses in India. Presence of ToLCVs was located based on availability of full-length DNA-A sequences in GenBank.

to this species. It contains a monopartite DNA-A genome, and a satellite DNA-β molecule was observed to be present with tomato leaf curl Bangalore virus (ToLCBV) infection. Pathogenicity of cloned DNAs has not been demonstrated.

Tomato Leaf Curl Karnataka Virus

This sap-transmissible virus has been isolated from Bangalore. DNA-A alone is infectious and produces typical leaf curl symptoms on tomato. Association of DNA-β has also been observed.

Tomato Leaf Curl Pune Virus

This is the most recently reported new virus from India, whose only DNA sequences are available in GenBank. Tomato leaf curl Pune virus (ToLCPV) contains a DNA-β molecule, which is quite distinct from all other known ToLCVs.

In addition, viruses such as tomato leaf curl Bangladesh virus, tomato leaf curl Malayasia virus, and tomato leaf curl Joydebpur virus are also known to infect tomatoes in India.

Molecular Relationships among ToLCVs

Relationships among the type member of the five species (viz. ToLCBV, ToLCGV, tomato leaf curl Karnataka virus (ToLCKV), tomato leaf curl New Delhi virus (ToLCNDV), and ToLCPV) revealed that there is a great degree of diversity among the Indian tomato-infecting begomoviruses. To examine the diversity of the sequences, phylogenetic trees were generated of the 18 full-length DNA A sequences together with representative sequences present in GenBank (**Figure 3**). The trees constructed using either neighbor joining or most parsimonious methods for full-length sequences were all similar. Members of four different species are closely related and form a well-knitted cluster with the exception of ToLCMYV-[IN]

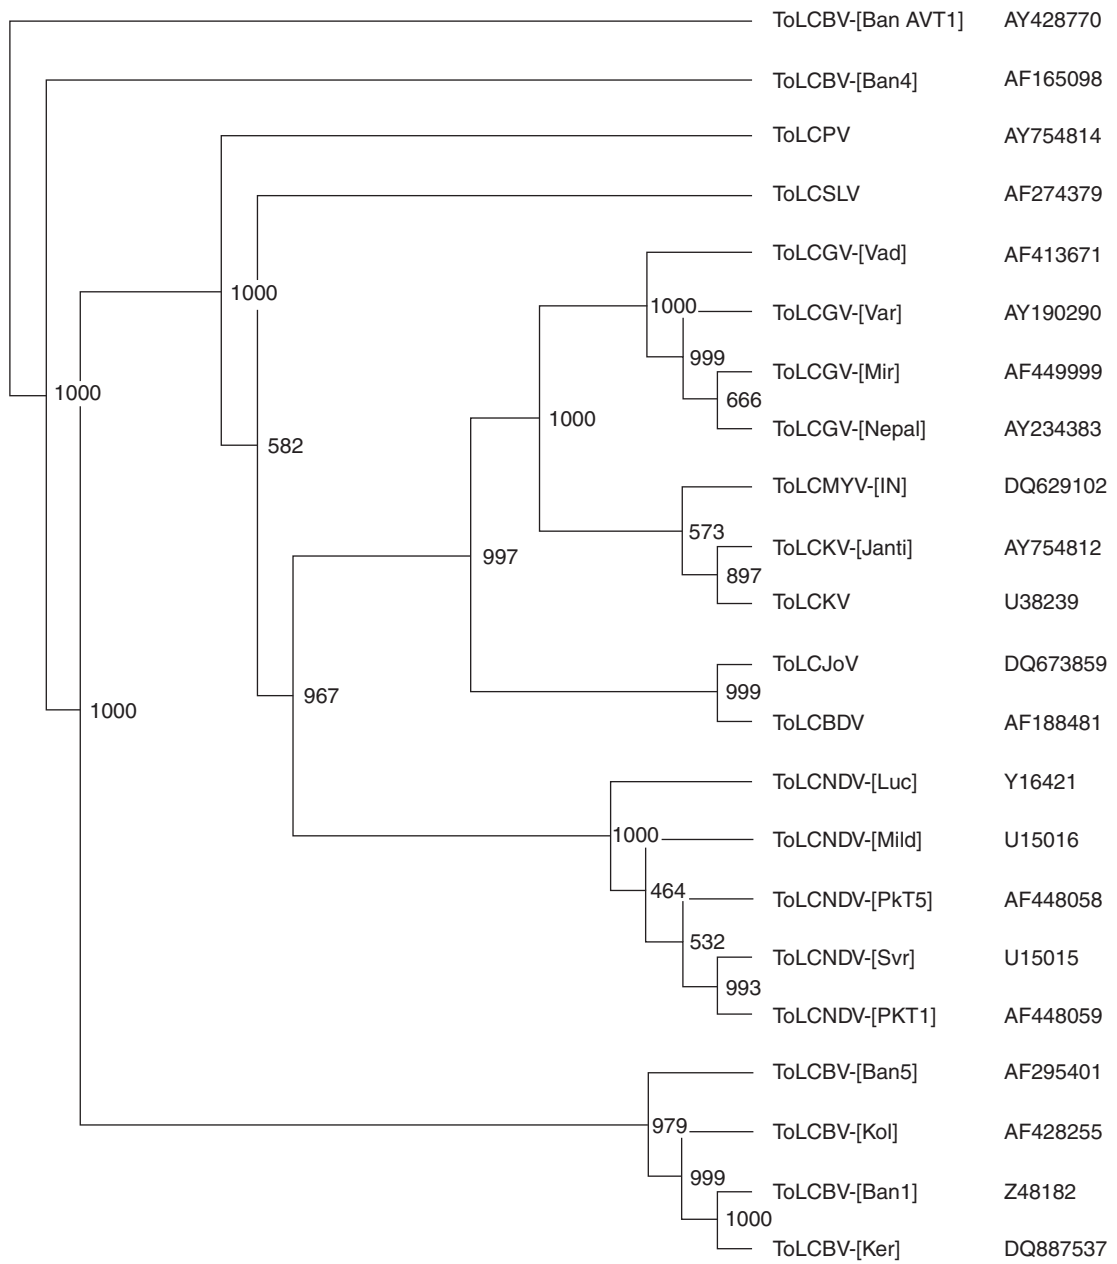

Figure 3 Phylogenetic analyses of begomoviruses causing ToLCD in India with other GenBank-published begomovirus sequences. Numbers at nodes indicate the bootstrap value out of 1000 replicates. The tree was generated with the PHYLIP programs using full-length DNA-A sequence data of Indian ToLCVs and other selected ToLCVs of the SE Asia. The full names of the viruses can be found in **Table 1**.

which was grouped with ToLCKV-Janti and ToLCKV. Full-length DNA-A sequences of Indian ToLCVs formed five different clusters, which generally had 72–82% nucleotide identity between clusters. However, one cluster formed by ToLCKV, belonging to a species known to have arisen through recombination, shared up to 88.3% with ToLCBVs.

Four out of the five sequences typed as ToLCBV shared 94.2–99.5% nucleotide identity with each other. ToLCPV also fell into the ToLCBV group, but had only 88% nucleotide identity to previously published ToLCBVs. ToLCBDVs originated from Bangladesh are distinct and form a different cluster while tomato leaf curl Sri Lanka virus (ToLCSLV) is close to ToLCPV and ToLCBV.

Comparison of DNA-A Sequence

Representatives of five species share varied degree of identity among each other (66–88%). Minimum nucleotide identity (66%) was observed with ToLCGV and

ToLCNDV while maximum identity of 88% was observed between ToLCBV and ToLCPV. Among the five species, ToLCKVs share more than 75% homology with all the species (**Table 2**(**a**)).

Comparison of DNA-B Sequence

GenBank database revealed the presence of four full-length DNA-B sequences associated with ToLCD in India. DNA-B of ToLCVs is highly conserved among each other in comparison to DNA-A. All the DNA-Bs are closely related (80–97%) (**Table 2**(**b**)). ToLCNDV, ToLCNDV-[Luc], and ToLCGV-[Var] have the same pairwise comparison profile all along their genomes.

Comparison of DNA-β Sequence

DNA-β molecules associated with ToLCVs share a less degree of homology as compared to DNA-A and DNA-B (**Table 2**(**c**)), indicating their uniqueness. So far nine full-length sequences have been reported with ToLCD in India and a wide range of 63–96% identity was observed among them. ToLCB-Varanasi share 96% with ToLCB-Aurangabad, followed by ToLCB-Jabalpur having 94% identity with ToLCB-Chinthapalli and by ToLCB-Coimbatore having 93% with ToLCBB. Two DNA-β sequences available from ToLCD-infected samples from Pune share 96% identity with each other.

Comparison of Common Regions

The replication of the B-component by the Rep protein of the A-component is possible because of the existence of the so-called CR, a short stretch of ±200 nt that usually is highly conserved between the two molecules. The CRs of the DNA-A (CRAs) of A-components of several isolates of a particular species are very closely related, with 89–99% identity. The CRAs of different species share 52–77% identity with each other. Sequence identities between the CRs of ToLCGV-[Var] DNA-B and genomic components of ToLCNDV are very high: it is 83% identical to ToLCNDV-[Svr] DNA-A CR and 86% identical to ToLCNDV DNA-B CR, indicating that these sequences could pertain to isolates of the same species. However, the CRs of DNA-A and DNA-B of ToLCGV-[Var] are only 61% identical. The lowest sequence identity (52%) was

observed between the CR of ToLCGV-[Var] DNA-A and the CR of ToLCNDV DNA-B. A multiple alignment of the CRs and inter-cistronic regions of the five species causing ToLCD in India revealed that all the isolates of ToLCNDV, ToLCGV, and ToLCKV have similar or very related iteron sequences (GGTGT-XX/X-GGAGT) while ToLCBV and ToLCPV have similar iteron sequences (GGTGG-XX/X-GGTGG) (**Table 3**). The exception is the ToLCNDV-Mld and ToLCNDV-Luffa isolates whose iteron sequence is GGCGT-CT-GGCGT. The major difference between the CRs of the DNA-A among these viruses is found in the spacer sequence between the two iterons that varies between 2 and 3 nt. It was also observed that a third identical iteron is present at the 5′ end of the CRs. The CRs of DNA-A of ToLCGV-[Var], compared with DNA-B of ToLCGV-[Var], DNA-B of ToLCNDV, and DNA-A of ToLCNDV-Svr, share more than 85% identity in the first 80 nt of their CRs, whereas the region between the TATA box and the hairpin loop is below 50%.

Recombination

Tomato-infecting begomoviruses from India appear to have a great capacity to recombine. The amount of material that viruses may exchange ranges from small fragments of a few nucleotides to very large fragments of 2000 nt or more. When DNA-A was compared, no recombination was observed among ToLCGV-[Var] with other two isolates of the same species, ToLCGV-[Vad] or ToLCGV-[Mir]. Remarkably, a short possible recombination (150 nt) was observed between ToLCGV-[Var] DNA-A and ToLCNDV at the 3′ end of AC1. With ToLCKV, ToLCGV share high nucleotide sequence identity for their IR (approximately the first 100 nt), the 5′ end of AV1 (200 nt), and a long stretch of 1350 nt from the 5′ end of AC3 to the 5′ end of the IR (**Figure 4**). This indicates that, at these sites, recombination events possibly took place between these two tomato-infecting viruses or with a third unknown virus. Putative recombination sites among isolates of ToLCBV have been identified as AV1, AV2, AC1, and IR of the viral that may account of variability in strains/species.

ToLCPV	GGTGG-AAC-GGTGG	

Pseudo-Recombination and Synergism

Under natural conditions, mixed virus infections in a single plant possess biological and epidemiological implications. For the first time, synergism between two distinct species of begomoviruses infecting tomatoes in India was observed that results in an increase in viral DNA and symptom severity. Also, the occurrence of a more virulent pseudo-recombination between two distinct species may explain the sudden breakdown of resistant tomato cultivars and the development of epidemics in tomato-growing areas in India. Recently, the association of both ToLCGV-[Var] and ToLCNDV-Svr components in a single severely infected tomato plant under natural conditions has been detected. Also, based on coat protein (CP) gene sequences, associations of ToLCGV and ToLCBV, ToLCBV and ToLCKV, and ToLCBV and ToLCNDV have been observed in a single plant. The synergistic role of ToLCGV DNA-A and ToLCNDV-Svr DNA-A, resulting in a much higher level of ToLCNDV-Svr DNA-A in turn, helped to a more efficient replication of the B-components, and particularly the ToLCGV

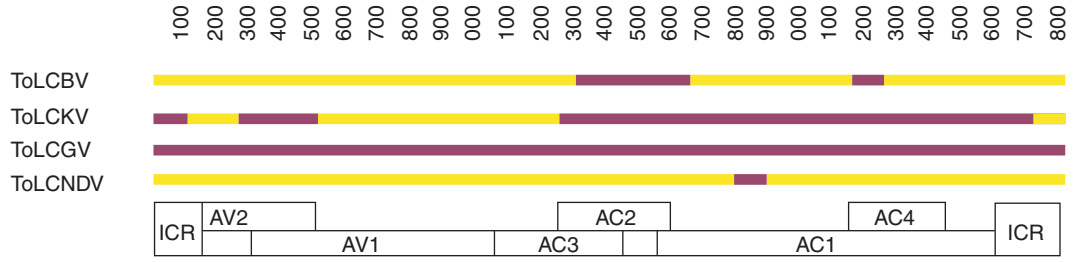

Figure 4 Diagrammatic representation of recombinant fragments between tomato leaf curl Gujarat virus-[Varanasi] and another three biologically characterized ToLCVs originating from India. Each line represents a linearized begomovirus genome (in the sense orientation starting from the origin of replication, in the CR) and each presence of red segments indicates homologous stretches of sequences to ToLCGV-[Var] at the strain level (>89%) within the genome of other Asian geminiviruses. Positions of the regions of the genome are represented at the top of the figure and a representation of a linearized geminivirus genome is represented at the bottom.

DNA-B component, resulting onto greater DNA accumulation in the systemically infected leaves, and consequently more severe symptoms. Since ToLCNDV-Svr and ToLCGV-[Var] belong to the same genus, infect the same hosts, and are transmitted by the same whitefly vector, they are therefore more likely to co-infect the same plants. The synergism between the two viruses will increase the amount of both the viruses in the systemically infected leaves and increase chances of transmission, if need be. As a consequence, doubly infected plants have a considerable potential as sources of inoculum for both viruses, and whiteflies feeding on such plants would, therefore, more easily acquire and transmit both viruses to virus-free plants. This information provides another source of geminivirus biodiversity.

Exchange of genomic components of the members of two distinct species of begomoviruses causing ToLCD in India can form infectious pseudo-recombinants. Transcomplementation between ToLCNDV-Svr DNA-A and ToLCGV DNA-B resulted in a more severe symptom phenotype as compared to wild type. ToLCGV DNA-B can also transcomplement ToLCNDV-Mld (mild isolate) and ToLCKV. The viable nature of these pseudo-recombinants was attributed to the highly conserved nature of AC1 and CR and also to identical iteron sequences. A highly specific interaction between the *Rep* protein of ToLCNDV (mild and severe strains) with their cognate iteron sequences also demonstrated the intimate relationship between these elements and the consequence in terms of DNA accumulation and symptoms. This led to the concept that matching N-Rep and iterons is required for efficient replication and consequently a severe symptomatology, and it also was supportive of the species concept where most of the time, with the exceptions of the recombinant in these regions, these two elements are different between species. Although the perfect match between the N-Rep sequence and the iteron sequences is probably vital in most of the cases, it may not be fatal in that particular one. This suggests that there must be other cooperative factors that are shared between the Rep of ToLCNDV-Mild and ToLCGV-[Var] B component CR, to the point that they compensate a nonmatching iteron interaction.

Replication and Pathogenesis

A highly specific interaction between the *Rep* protein of ToLCNDV (mild and severe strains) and their cognate iteron sequences also demonstrated the intimate relationship between these elements and the consequence in terms of DNA accumulation and symptoms. Two strains of ToLCNDV, viz. severe and mild, share 94% sequence identity on the basis of symptoms on tomato and tobacco. The studies demonstrated that the amino acid at position 10 in Rep protein coupled with a change in the binding site sequence may determine the replication of viral DNA. Change of Asp10 to Asn in Rep protein of the mild strain accompanied by exchange of the 13-mer binding site (making it identical to the severe strain) altered its replication, leading to increased accumulation of viral DNA. In addition, the modified mild strain could replicate heterologous strain DNA-B, indicating that the interaction of Rep protein with its binding site may be essential for replication of viral DNA.

Mutational analysis of ToLCNDV-Svr virion-sense ORFs has been carried out to assign the function. Plants inoculated with infectious DNA which contained deletions in AV2 developed very mild symptoms and accumulated only low levels of both single-stranded (ss-) and double-stranded (ds-) viral DNA, whereas inoculated protoplasts accumulated both ss- and dsDNA to wild-type levels, showing that AV2 is required for efficient viral movement. Mutations in the CP caused a marked decrease in ssDNA accumulation in plants and protoplasts while increasing dsDNA accumulation in protoplasts. The results demonstrated that multiple functions provided by AV2, BV1, and BC1 are essential for viral movement, and that changes in A-component virion-sense mRNA structure or translation affect viral replication.

The role of the movement protein (MP) and nuclear shuttle protein (NSP) in the pathogenicity of ToLCNDV, a bipartite begomovirus, has been elucidated using either potato virus X (PVX) expression vector or by stable transformation of gene constructs under the control of the 35S promoter in *N. tabacum*. No phenotypic changes were observed in any of the three species when the MP was expressed from the PVX vector or constitutively expressed in transgenic plants. Expression of the ToLCNDV NSP from the PVX vector in *N. benthamiana* resulted in leaf curling that is typical of the disease symptoms caused by ToLCNDV in this species. However, expression of NSP from PVX in *N. tabacum* and *L. esculentum* resulted in a hypersensitive response (HR), suggesting that the ToLCVDV NSP is a target of host defense responses in these hosts. The NSP, when expressed as a transgene under the control of the 35S promoter, resulted in necrotic lesions in expanded leaves that initiated from a point and then spread across the leaf. The necrotic response was systemic in all the transgenic plants. N-terminus of NSP is required for the HR. These findings demonstrate that the ToLCNDV NSP is a pathogenicity determinant as well as a target of host defense responses. The necrosis in transgenic tobacco plants is systemic, as it starts from a point on the fully emerged leaf and spreads over the lamina and to other leaves. Thus, ToLCNDV NSP is an avirulence determinant that interacts with the product of a resistance gene encoded by a host defense system, possibly an R gene product, triggering a host defense response involving an HR in *N. tabacum* and tomato.

Management

Until the late 1990s, the main control method employed against ToLCD was intensive use of insecticides targeted at viruliferous immigrant adult *B. tabaci* that spread ToLCVs into and within tomato crops. Identification of sources of resistance is difficult as the leaf curl disease syndrome is caused by different tomato begomoviruses. In the recent past, however, three high-yielding ToLCD-resistant tomato varieties have been developed that can be grown successfully with minimal insecticide use. Artificial screening through whiteflies has been carried out to identify resistant/tolerant varieties from different *Lycopersicon* spp., viz., *L. peruvianum*, *L. peruvianum* f. *glandulosum*, *L. peruvianum* f. *regulare*, *L. esculentum*, *L. chilense*, *L. hirsutum* f. *glabratum*, and *L. pimpinellifolium*. Gene governing resistance has also been mapped in tomato cultivar, H-24 (a derivative from *L. hirsutum* f. *glabratum*) on chromosome 11 against TYLCV and ToLCBV. In order to manage the deployment of this valuable resource, improve the efficacy with which further ToLCV-resistant material is screened, and investigate resistant-genotype/virus interactions, an improved understanding of the diversity and distribution of ToLCVs present will help in developing strategies for ecofriendly management of ToLCD. Agrobacterium-mediated inoculation of cloned DNAs will certainly provide better tool for identification of R genes in tomatoes in the future. Pathogen-derived resistance needs more attention in order to develop broad-spectrum resistance against Indian ToLCVs.

Tomato Spotted Wilt Virus

H R Pappu, Washington State University, Pullman, WA, USA

© 2008 Elsevier Ltd. All rights reserved.

Taxonomy

The species *Tomato spotted wilt virus* (TSWV) belongs to the genus *Tospovirus* in the family *Bunyaviridae*. Of the more than 300 species of primarily arthropod-borne viruses described in the family *Bunyaviridae*, a small proportion infects plants. Members of other genera in this family are important pathogens of humans and animals. TSWV is considered as the type member of the genus and hence its name formed the basis for coining the genus name. Discovery of a second tospovirus, *Impatiens necrotic spot virus* (INSV), was followed by description of more tospoviruses from several parts of the world. To date, there are more than 14 distinct tospoviruses described. Descriptors for classification of new viruses as tospoviruses include genome organization (**Figure 1**), thrips transmission, host range, and serological and molecular relationships of the nucleoprotein (N) gene. Excellent reviews on various aspects of tospoviruses have been published in the last few years. This review focuses on summarizing recent advances in our understanding of the tospovirus biology, molecular biology, epidemiology, and control.

Biology

TSWV was first described in 1915. The virus has a wide host range; it infects more than 900 plant species that include numerous crops and weeds. The virus is

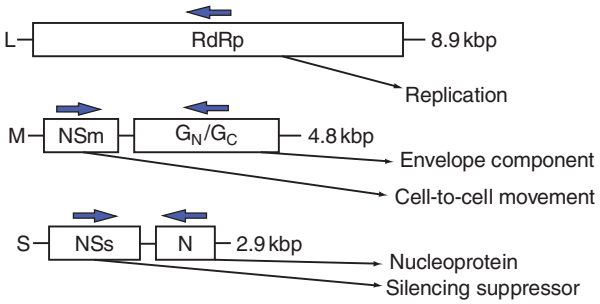

Figure 1 Genome organization of TSWV. Functions of each gene are noted on the right side.

Figure 2 Biological variability of TSWV isolates. Response of *Nicotiana tabacum* to a severe strain (top) and a mild strain (bottom).

mechanically transmissible and is not seed transmitted. In nature, TSWV is transmitted by several species of thrips. Crops that are affected by TSWV include bean, lettuce, peanut, pepper, potato, tobacco, and tomato. Biologically distinct isolates of TSWV exist in nature. Isolates that differ in thrips transmissibility, symptomatology, and symptom severity have been described (**Figure 2**). Variability in the N gene sequence of TSWV isolates suggested geographic delineation in natural virus populations which may be useful for attribution: that is, tracing the potential source or origin of a particular isolate. TSWV causes systemic infection in most of the crops it infects. Infection at early stages of the plant growth causes the most damage that may include severe stunting of the entire plant which often results in death. TSWV epidemics in peanut, pepper, tobacco, and tomato in southeastern United States caused major economic losses and forced shifts in production practices. Losses due to TSWV outbreaks in peanut were estimated at more than US $100 million in Georgia alone in the USA.

Molecular Biology

The morphology and genome structure and organization of tospoviruses share several features with members of other genera in the family *Bunyaviridae*. Particles are pleiomorphic, and 80–120 nm in diameter. The genome of tospoviruses includes three RNAs referred to as large (L), medium (M), and small (S). 5′ and 3′ terminal sequences of the RNAs are conserved. L RNA is in negative sense while M and S RNAs are ambisense in their genome organization. L RNA codes for the RNA-dependent RNA polymerase (RdRp). M RNA encodes precursors for two structural glycoproteins, G_N and G_C, and a nonstructural protein, NSm. The S RNA codes for the nucleocapsid protein (N) and another nonstructural protein, NSs. The three genomic RNAs are tightly linked with the N protein forming ribonucleoproteins (RNPs). These RNPs are encased within a lipid envelope consisting of two virus-encoded glycoproteins, and a host-derived membrane. The genome organization, gene products, and their roles are shown in **Figure 1**. Due to the negative strandedness of the genome, virions contain several molecules of the RdRp to initiate initial rounds of replication of the virion RNAs. Genome expression is facilitated through synthesis of subgenomic RNAs.

Considerable progress has been made in our understanding of the functional roles of various TSWV genes. The 331 kDa RdRp coded by the L RNA serves as a multifunctional, replication-associated protein and is believed to function cooperatively with host-encoded factors. Screening a cDNA library of *Frankliniella occidentalis* using fragments of TSWV RdRp, a putative transcription factor that binds to TSWV RdRp was isolated which was shown to bind to TSWV RNA and enhance TSWV replication. Mammalian cells expressing this putative transcription factor supported TSWV replication. Since TSWV is transmitted by several thrips species it remains to be seen if similar transcription factors exist in other thrips vectors.

Assignment of functions to various TSWV gene products was done using indirect approaches since a reverse genetics system based on an infectious cDNA clone is not yet possible for a negative-sense RNA virus such as TSWV. Using indirect approaches, the functions of the M RNA-encoded glycoproteins and NSm were recently deciphered. The absence of a gene similar to NSm in other genera of the family *Bunyaviridae* suggests that NSm serves a function that facilitates TSWV infection of plants. Virus movement in plants is mediated by a

virus-encoded movement protein and a similar function was suggested for NSm and subsequent experimental evidence supported this hypothesis. Recently, the role of NSm in TSWV life cycle was investigated *in vitro* and *in planta*. Virus-encoded movement proteins tend to bind to viral RNAs and facilitate virus movement through plasmodesmata. *In vitro*-expressed NSm interacted with N protein and bound ssRNA in a sequence-nonspecific manner. Members of DnaJ family were found to bind NSm in a yeast-two-hybrid system. Transgenic *Nicotiana tabacum* plants expressing NSm produced symptoms suggestive of TSWV infection. Biochemical analyses of this plant response showed the accumulation of callose, an indicator of the triggering of plant defense response. Constitutive expression of the NSm and its subsequent interference with the plasmodesmata's transport functions could have resulted in abnormal growth pattern seen in these transgenic plants. More direct evidence of the role of NSm in virus movement was obtained by heterologous complementation studies using an infectious cDNA clone of tobacco mosaic virus (TMV) and replacing TMV genes with the NSm gene of TSWV. The NSm gene complemented a movement-deficient mutant of TMV in tobacco plants and facilitated the long-distance movement of the TMV–TSWV NSm hybrid. The NSm protein, when expressed *in planta*, mediated tubule formation in infected protoplasts.

TSWV mutants lacking the envelope were not thrips transmissible, indicating that the determinants for thrips transmission are localized on the glycoprotein-containing envelope. Using two distinct isolates of TSWV that differ in thrips transmission, genetic reassortants (=pseudo-recombinants) were generated by coinoculating plants with both isolates. The resulting reassortants were evaluated for their ability to be thrips transmitted and the source of the genomic components of each of these reassortants was determined. Only those reassortants that had the M RNA derived from the thrips-transmissible isolate retained thrips transmissibility confirming the functional contribution of M RNA to thrips transmission (**Figure 3**). Sequence comparisons of the glycoprotein genes of these two isolates showed that a point mutation played a critical role in determining the thrips transmissibility. The roles of G_N and G_C in TSWV–thrips vector interaction are beginning to be elucidated and are discussed under 'Transmission and epidemiology'. Moreover, the M RNA was shown to carry determinants for host adaptation and overcoming host plant resistance as well as pathogen-derived resistance in tomato and tobacco. In the absence of a reverse genetics system, complementation studies

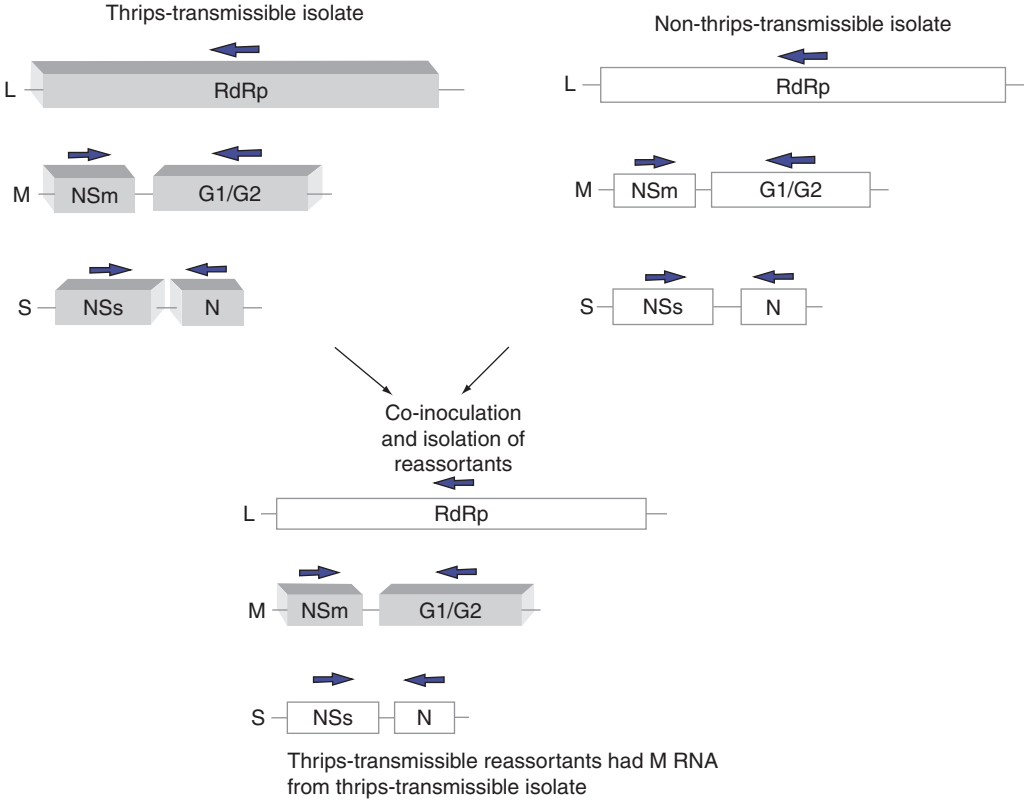

Figure 3 Genetic reassortment as a tool for the functional analysis of tospovirus genes. Localization of thrips transmission determinants on the M RNA of TSWV.

and genetic reassortment tudies such as those mentioned above offer alternate approaches for studying structure–function relationships of various TSWV genes.

The S RNA-encoded proteins, N and NSs, play important roles in the TSWV infection cycle. The N protein, as part of the RNP, serves as the structural protein and may also have some regulatory role in modulating the transcription and replication. Additionally, the involvement of the N protein in particle assembly was suggested based on its interaction with one of the two viral glycoproteins. When co-expressed with G_N and G_C in mammalian BHK21 cells, N protein displayed selective interaction with G_C and the subsequent localization of the N and glycoprotein complex in the Golgi apparatus. The nonstructural protein, NSs, encoded by the S RNA was shown to be a suppressor of RNA silencing.

Diagnosis

TSWV produces a wide range of foliar symptoms. Symptomatology varies depending on the strain, host species, and genotype, and is also influenced by environmental factors such as temperature. In most cases, accurate diagnosis is facilitated by serological or molecular techniques. Purified TSWV is a good immunogen and virus-specific antisera and enzyme-linked immunosorbent assay (ELISA) kits are commercially available. Molecular techniques based on reverse transcription-polymerase chain reaction (RT-PCR) have been developed that can detect the virus in plants and thrips vectors. Sensitive, rapid real-time PCR methods are also available. An NSs-specific monoclonal antibody was produced which was shown to be effective in identifying adults that are capable of transmitting the virus since detection of NSs in thrips is an indication that the virus had multiplied in the vector.

Transmission and Epidemiology

TSWV is transmitted by several species of thrips in a circulative and propagative manner. These include *F. occidentalis, Frankliniella schultzei, Frankliniella intonosa, Frankliniella bispinosa, Frankliniella fusca, Thrips setosus*, and *Thrips tabaci*. The virus is not known to be seed transmitted. Hence, susceptible crops with overlapping production seasons and prevalence of weed hosts and thrips vectors constitute the most important factors for TSWV epidemics. TSWV has to be introduced into a crop by viruliferous thrips and patterns of disease spread mostly suggests primary spread with little secondary spread within the crop. Considerable progress has been made in our understanding of thrips–TSWV interactions, especially in the case of TSWV–*F. occidentalis* association. For the adult thrips to become a transmitter, the larva has to acquire the virus by feeding on an infected plant. First and second instar larvae are capable of acquiring the virus though the former is more efficient. The virus starts replicating in the larva and survives through the developmental stages. The emerging adult transmits the virus and continues so for life. There is no evidence of transovarial transmission. Thus, the virus has to be acquired by each generation of thrips. Therefore, tospoviruses are capable of replicating in both their host plants and thrips vectors. This intimate biological association between tospoviruses and their thrips vectors had created possibilities for evolution and shifting preferences and specificities between individual tospoviruses and thrips species. New vector species of TSWV began to emerge in the past decade. For example, *F. bispinosa* was reported as a vector of TSWV. For TSWV epidemics to occur, thrips vectors should complete a life cycle on virus-infected host plants. Infected plants that do not support thrips lifecyle can be considered as a dead end in disease epidemiology. The economic impact of TSWV on a number of important crops combined with the fact that thrips-borne inoculum is the most important contributory factor to virus outbreaks resulted in extensive research efforts to understand the basis of TSWV–thrips interactions and the virus and insect factors that contribute to the specificity of virus–vector relations. Of more than 5000 thrips species described, only seven of them are known to transmit TSWV, suggesting complex interactions of recognition, acquisition, replication, and movement at the virus–vector association level. Much is now known about the interaction between TSWV and *F. occidentalis*.

The virus upon acquisition was shown to move through the midgut and subsequently reaches the salivary glands. It is hypothesized that the close proximity of midgut and salivary glands in the thrips larval stage facilitates the virus movement whereas the virus fails to do so as the thrips reaches adult stage. This may explain the inability of adult thrips to transmit the virus if the virus is acquired for the first time in its adult life. The specificity of TSWV and thrips vectors may be due to the presence of a receptor in the vector species which may be absent in nonvector species. A 50 kDa protein and a 94 kDa protein were identified as potential thrips proteins involved in interaction with TSWV. However, cloning the gene for the putative receptor remains to be accomplished. A soluble form of *in vitro*-expressed TSWV G_N protein was used to study its role in recognition by thrips vectors. When thrips were fed with the purified G_N, the protein could be detected in the midgut epithelial cells of the larvae which subsequently resulted in the prevention of TSWV acquisition, suggesting that G_N may be involved in virus recognition by the thrips vector. While G_N potentially mediates the specific recognition between TSWV and its thrips vector, sequence comparisons

and biochemical analysis of G_C protein indicated that it facilitates the fusion and subsequent uptake of the virion into vector cells.

Management

TSWV has been an economically important constraint for several crops over the past several decades in several parts of the world. Due to the nonpredictive nature of the outbreaks combined with the lack of forecasting, adoption of preventive measures has not always been practical. The disease cycle has proven to be extremely difficult to break because of the wide and often overlapping host range of both the virus and the thrips vectors.

However, multidisciplinary research in the past decade has led to identification of factors that contribute to TSWV epidemics and development of practical control recommendations which resulted in reduced impact of TSWV in several crops. An integrated management approach must be taken as no single control tactic was found to be effective by itself. The crucial element in the management program is growing virus-resistant or virus-tolerant cultivars. TSWV-resistant cultivars with desirable agronomic traits are now available for peanut, pepper, and tomato. Resistance-breaking strains of TSWV continue to pose a threat, potentially limiting the durability of resistant cultivars. Resistance governed by multigenes should be used where available to make the resistance more durable. Production practices such as growing on plastic mulch or reflective mulch significantly reduced the disease incidence in certain crops. Novel strategies utilizing chemicals such as acibenzolar-*S*-methyl that induce systemic acquired resistance are found to be effective in reducing the incidence of TSWV (**Figure 4**). Thrips management based on selective use of insecticides during the early part of the cropping season combined with resistant cultivars resulted in reduced incidence and increased yield in tomato. Ability to forecast the epidemics by making use of information such as the seasonal dynamics of TSWV transmitters in the vector populations will help growers make appropriate management decisions. Pathogen-mediated resistance due to post-transcriptional gene silencing was shown to be effective in several crops. Expression of single-chain antibodies, TSWV N gene, or various modifications of the N gene were found to be effective in conferring resistance. Genetic engineering can be very useful in situations where natural sources of host plant resistance are not available or difficult to transfer to existing agronomically desirable cultivars. Consumer acceptance and other market-related issues have hampered the efforts to commercialize this technology.

Glossary

Agroinoculation An alternative route for viral infection; the viral genome is cloned, usually as a head-to-tail dimer, in the T-DNA of *Agrobacterium tumefaciens* and is delivered to plants by inoculation.
Introgression Incorporation of chromosomal segments of wild tomato species in the domesticated tomato by crosses and selection; introgression lines are used to localize genes to the tomato chromosomes.
Rolling circle Mechanism of replication followed by many viral DNA and by begomoviruses in particular.
Viruliferous whitefly Insect that has acquired virus from an infected plant and is ready to infect other host plants.
Whitefly Insect that belongs to the order *Homoptera*; they cause damage to plants by feeding and by vectoring plant viruses.

Introduction

In the late 1950s the tomato cultures in the Jordan valley of Israel were unexpectedly affected by a disease of unknown etiology. The disease was accompanied by large populations of whiteflies. The suspicion that the whiteflies were the vector of a viral disease was confirmed following controlled transmission experiments in the laboratory. The virus was named tomato yellow leaf curl virus (TYLCV). The virus was isolated and its genome sequenced in the late 1980s.

TYLCV is a member of the genus *Begomovirus* of the family *Geminiviridae*, which includes viruses transmitted by the whitefly *Bemisia tabaci*. Begomoviruses have a genome either split between two circular single-stranded (ss) DNA - molecules of approximately 2700 nt each named DNA A and DNA B (bipartite) or with a single genomic DNA A-like molecule (monopartite). TYLCV is monopartite. The relationships between the virus, the vector, and the host tomato plant have been the object of many studies.

From the early 1960s tomato cultures have been under the constant threat of TYLCV-like begomoviruses worldwide. TYLCV has quickly spread to the Middle East, Central Asia, North and West Africa, Southeast Europe, the Caribbean islands, Southeast USA, and Mexico. TYLCV-related begomoviruses have been identified in Italy, the Maghreb and Western Africa, and the Arabian Peninsula. Breeding programs for resistance have started in the mid-1970s and several commercial varieties with adequate resistance have been released. Several loci tightly linked to TYLCV resistance have been assigned to the small arm of tomato chromosome 6. A variety of strategies have been devised based on the pathogen-derived resistance concept, which involves the expression of functional as well as dysfunctional viral genes. RNA-mediated virus resistance based on antisense RNA and post-translational gene silencing was efficient but was highly sequence dependent.

Virus Structure

Like all geminiviruses, TYLCV has a characteristic particle of twinned morphology of approximately 20×30 nm in size (**Figure 1(a)**). The virus capsid (total m.w. 3330 kDa) consists of two joined, incomplete icosahedra, with a $T = 1$ surface lattice containing a total of 22 capsomeres each containing five units of a 260-amino-acid coat protein (30.3 kDa). TYLCV has a single 2787 nt (total m.w. 980 kDa) covalently closed-genomic circular ssDNA.

Figure 1 Virions, host tomato plants and whitefly vector. (a) Viral particles with twinned morphology of approximately 20 × 30 nm in size. (b) Left – infected tomato plant with typical symptoms; right – noninfected tomato plant. (c) Adult *B. tabaci* whiteflies, approximately 2 mm in size.

Host Range

The domesticated tomato *Solanum esculentum* (formerly *Lycopersicon esculentum*) is the primary host of TYLCV. Most of the wild tomato species such as *S. chilense*, *S. habrochaites* (formerly *L. hirsutum*), *S. peruvianum*, and *S. pimpinellifolium* include accessions that are symptomless carriers and are used as genitors in breeding programs for TYLCV resistance. Several cultivated plants (bean (*Phaseolus vulgaris*), petunia (*Petunia hybrida*), and lisianthus (*Eustoma grandiflorum*)) are hosts of TYLCV and present severe symptoms upon whitefly mediated inoculation. Weeds, such as *Datura stramonium* and *Cynanchum acutum*, present distinct symptoms, whereas others, such as *Malva parviflora*, are symptomless carriers. Plants used to rear whiteflies, such as cotton (*Gossypium hirsutum*) and eggplant (*Solanum melongena*), are immune to the virus. Experimental hosts of the virus include jimsonweed (*Datura stramonium*). Some plants recalcitrant to whitefly mediated inoculation, such as *Nicotiana benthamiana* and *N. tabacum*, may be infected by TYLCV DNA clones using agroinoculation.

Transmission to Tomato

In nature TYLCV is transmitted exclusively by the whitefly *B. tabaci* in a persistent manner (**Figure 1**). Symptoms included growth arrest leaflets cupped inward with yellow margins, and barely produced fruits (**Figure 1**). *B. tabaci* thrives in commercial fields of cotton, tomato, eggplant, and pepper, in tropical and subtropical countries. It also infests the greenhouses in these regions as well as those in temperate countries. Whiteflies may cause dramatic damages due to feeding and the transmission of begomoviruses. *B. tabaci* comprises many types (or biotypes) that can be distinguished by their plant host range, fertility, as well as with molecular markers (especially from the mitochondrial genome). Among the many biotypes, B and Q are extremely efficient vectors of TYLCV.

Transmission of TYLCV to tomato by *B. tabaci* B biotype has been studied thoroughly. The virus is transmitted to tomato plants after vector-feeding on infected tomato plants or alternative hosts. The incidence of the disease is directly correlated with the pressure of the whitefly population. One to three viruliferous insects are able to infect a tomato plant. The efficient acquisition access period (AAP) is 15–30 min, the latent period is 8–24 h, and the efficient inoculation access period (IAP) is at least 15 min. Female *B. tabaci* are more efficient vectors than males. The ability of the whiteflies to transmit TYLCV to tomato test plants steadily decreases with age, from 100% to 10–20% during their adult life time.

Symptoms develop on inoculated seedlings 2–3 weeks after insect first inoculation feeding. In the field inoculation can occur immediately after transplantation. Infected seedlings remain stunted and do not yield fruits. Infection at a later stage affects vegetative growth and fruit setting. Disease incidence increases rapidly and in severely affected regions results in yield reduction of up to 100%.

The viral DNA replicates in the nuclei of infected cells and is mostly phloem limited. Apart from whiteflies, TYLCV can be transmitted by grafting and agroinoculation. It is not mechanically transmitted and it is not propagated by seeds.d

Genome Organization and Expression

A schematic drawing of the TYLCV genome is shown in **Figure 2**. It replicates according to a rolling circle mechanism. The viral genome encodes two large open reading frames (ORFs) on the viral strand (V1 and V2), and four on the complementary strand (C1–C4). A 313 nt long intergenic region (IR) contains a 29 nt long stem–loop structure with the conserved nanonucleotide TAATATTAC which is the origin of replication (Ori) of the virus. The IR also contains the promoters of the V1, V2, C1, and C4 genes.

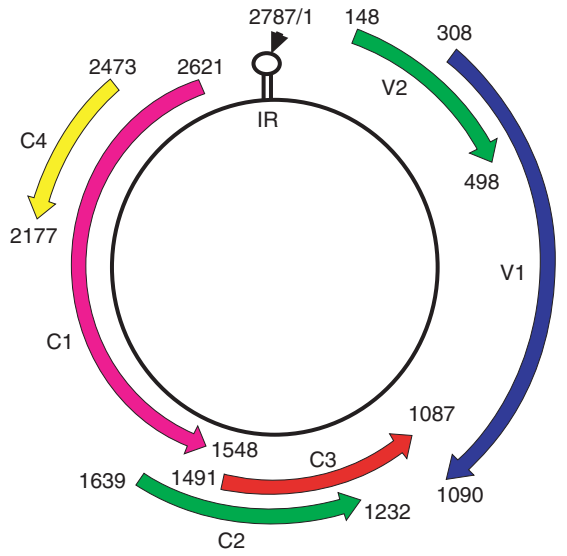

Figure 2 Genome organization of tomato yellow leaf curl virus. The single-stranded virion DNA comprises 2787 nt. Open reading frames (ORFs) of virion-sense and complementary-sense strand polarity are designated (V) and (C), respectively. ORFs are represented by an arrow; numbers indicate first and last nucleotide of each ORF. V1 encodes the capsid protein (CP), V2 a movement protein, C1 the replication initiator protein (Rep), C2 a transcriptional activator protein (TrAP), C3 a replication enhancer protein (REn), and C4 a symptom and movement determinant. IR: intergenic region. The conserved inverted repeat flanking the conserved nanonucleotide sequence TAATATTAC is symbolized by a stem–loop; an arrow head indicates the cleaving position of Rep in the TAATATT/AC loop; A at the cutting site (/) is nucleotide number one, by definition.

- V1. The V1 ORF encodes the capsid protein (CP). The CP is a multifunctional protein: The N- and C-termini of CP monomers interact to form the capsid (one viral genomic molecule is encapsidated in each geminate particle). The CP has a nuclear localization signal (NLS) and it is able to shuttle the viral genomic DNA in and out of the nucleus. It is essential for infectivity, and it is the only viral protein recognized by the insect vector.
- V2. The V2 ORF has properties analogous to those of a movement protein and in some cases mutants affect symptom expression.
- C1. The C1 ORF encodes the replication initiator protein (Rep). It is the only viral protein necessary for replication. The functional protein is an oligomer. The Rep protein recognizes the Ori located in the IR and specifically cleaves the nanonucleotide TAATATTAC between nucleotides 7 and 8. Together with plant host polymerase(s) it initiates viral DNA replication according to the rolling-circle model. Short inverted repeats located in the IR upstream the stem–loop structure are recognized by the Rep protein and also involved in the replication process. Rep also interacts with another viral protein, the viral replication enhancer protein (REn), encoded by ORF C3 and with a variety of cellular proteins such as a retinoblastoma-like protein, an interaction that may enhance plant cell replication and thereby viral multiplication.
- C2. The ORF C2 encodes a transcriptional activator protein (TrAp). Both ORFs C2 and C3 are transcribed from a promoter located in the 3′ end of the C1 ORF. TrAp enhances transcription of the viral strand promoter. It is able to bind to viral genomic DNA and possesses an NLS. In addition, the C2 gene product acts as silencing suppressors.
- C3. The ORF C3 encodes the replication enhancer protein (REn). This protein interacts with itself to form oligomers. REn interacts with Rep and with cell-cycle associated host proteins to increase the amount viral DNA (genomic and double-stranded) in the infected plant.
- C4. The ORF C4 encodes a protein not essential for infectivity but contributes to the spread of the virus in the plant and induction of symptoms. The protein may also act as a silencing suppressor, but this has not been definitively proved.

Geographical Distribution

The name TYLCV was coined in the early 1960s to describe a virus transmitted by the whitefly *B. tabaci* that affected tomato cultures in Israel. Early diagnosis of TYLCV was essentially based on symptom observation, although symptoms vary greatly as function of soil, growth conditions, and climate. Serology has been of limited use because whitefly transmitted geminiviruses share many epitopes. The analysis of DNA sequences has become the tool of choice, allowing one to accurately identify the virus and to evaluate its relationship with other TYLCV isolates. TYLCV has been reported in the mid- and late 1970s in Cyprus, Jordan, and Lebanon. It has been identified in Egypt and Turkey in the early 1980s. The virus has spread to Turkey, Iran and the Asian republics of the former USSR, and to Saudi Arabia and Yemen during the mid–late 1990s. Two TYLCV isolates closely related to the Middle Eastern virus have been described in Japan in the late 1990s. In China, TYLCV isolate TYLCVs has been identified in the southwest province of Guangxi. In the early 1990s two virus isolates belonging to a new species related to the Middle Eastern TYLCV, named tomato yellow leaf curl Sardinia virus, have been identified in Sardinia (TYLCSV-Sar) and in Sicily (TYLCSV-Sic), Italy. The Sardinian isolate TYLCSV-Sar has been discovered in Spain in the early 1990s. By he mid-1990s the Middle Eastern TYLCV was found in Portugal and in Spain; in the latter country, it tended to displace the previously established Italian virus.

Recombinants between the two viruses have been found. TYLCV has invaded North Africa, possibly from Spain and Italy. In Morocco, both the Italian and the Middle Eastern strain were discovered in the early 2000s. In Tunisia the Italian virus was identified in the early 2000s. TYLCV appeared in Southern France in 1999. In 2000, the Middle Eastern strain of TYLCV was identified in Crete, Attiki, and Southern Peloponnesus in Greece. In East Africa, TYLCV was present in Sudan as early as the late 1970s. In Tanzania a virus distinct from the Mediterranean isolates has been sequenced. In the Réunion Island the virus was detected in the late 1990s. The Middle Eastern strain of TYLCV has appeared in the Western Hemisphere in the mid-1990s in the Caribbean Islands, first in the Dominican Republic, then Cuba, Jamaica, Puerto Rico, and the Bahamas. From there, the virus has reached the USA, identified first in Virginia in the late 1990s, then in Florida, Georgia, Louisiana, North Carolina, and Mississippi. It seems that TYLCV is now found in several regions of Mexico.

Hence during the last decade TYLCV has spread extremely fast and constitutes a major limiting factor to tomato cultivation, worldwide. In many regions, the invading Mediterranean strain of TYLCV coexists with local TYLCV strains, but in several cases it has almost replaced them, as in Southern Spain. The Sardinian isolate of TYLCSV has been recently detected in Jordan and in Israel, indicating that the expansion of TYLCSV is not unidirectional, from the Eastern Mediterranean region to other parts of the world as thought not long ago.

Taxonomy and Classification

TYLCV is the name of the virus originally isolated in Israel. Sequence comparisons of TYLCV-like viruses analyzed worldwide have revealed that the name TYLCV was used mistakenly to name a complex of closely as well as distantly related begomoviruses affecting tomato. Viruses with nucleotide sequence homology of more than 89% have been considered to be strains of the same species while viruses with homologies of less than 89% have been considered as belonging to different virus species. Accordingly, the begomoviruses affecting tomato have been classified into several species: all the TYLCV isolates known today have a monopartite genome.

The members of the TYLCV species, as well as members of species closely related to TYLCV updated as of December 2006, are listed in **Table 1**; the acronym and the GenBank accession number of the DNA sequence are provided.

This classification is rendered even more complicated by the recent discovery that recombination between members of different species of geminiviruses happens relatively frequently. For example, a naturally occurring recombination has been recently found in the Almeria region, Spain, between TYLCV and TYLCSV. The recombinant virus, coined tomato yellow leaf curl Malaga virus (TYLCMalV-[ES], AF271234), probably occurred because the two virus species have coexisted in the tomato plants grown in the greenhouse.

Additional begomoviruses that infect tomato cultures have not been assigned to the TYLCV and are discussed elsewhere in this encyclopedia. These viruses clearly differ from the various TYLCV isolates in the symptoms they induce on tomato, in their host range, and in their nucleotide sequence.

Virus–Vector Relationship

Path of the Virus in the Insect

Like all begomoviruses TYLCV follows a definite path in its *B. tabaci* vector. Whiteflies feed when their stylets reach the virus-rich phloem of infected leaves. TYLCV can be detected in the insect head approximately 10 min after feeding started. From the esophagus the virus reaches the midgut where it can be detected approximately 30 min after it was first found in the head. At this point, some of the viruses might be excreted through the hindgut. The crossing of TYLCV from the midgut to the hemolymph is surprisingly fast. The virus reaches the hemolymph 30 min after it was first detected in the midgut, 90 min after the beginning of the AAP. The crossing of the gut is likely to be an active process involving specialized unknown receptors. To avoid degradation in the hemolymph, geminiviruses interact with a GroEL-like chaperonin produced by the insect endosymbiotic bacteria and excreted in the hemolymph. TYLCV can be detected in the salivary glands approximately 5.5 h after it was first detected in the haemolymph, 7 h after the beginning of the AAP, approximately 1 h before the insects are able to infect tomato plants. Once the virus reaches the salivary gland, crossing several cell walls that may constitute selective receptor-mediated barriers, it is almost immediately excreted into the salivary pump and from there into the plant together with the saliva. The capsid (and the coat protein) is the only begomoviral structure recognized by the would-be receptors and by the endosymbiotic chaperonin.

Retention of TYLCV in the Insect Vector

The virus can be detected in every stage of vector development. Following a 48 h AAP on TYLCV-infected tomato, viral DNA remains associated with *B. tabaci* for the entire adult life of the insect while infectivity decreases with time, but not entirely. Various TYLCV isolates present sometimes different parameters of interactions with their whitefly host. For example, the maximum retention period

[a]Australian accession.
Species names are in italic fonts and strain and isolate names are in roman fonts.

of isolates of TYLCSV (TYLCSV-[IT:Sar]) was 8 days from the end of the AAP compared to 5 weeks for TYLCV.

Both TYLCV and TYLCSV can be detected in the eggs and in adult progeny of viruliferous whiteflies in low incidence. However while the TYLCV progeny was able to transmit the virus to tomato plants, the TYLCSV progeny did not. Although the question of the possible replication of TYLCV in its insect vector remains controversial, transcripts of viral genes V1, V2, and C3 accumulated in *B. tabaci* long after transfer of viruliferous whiteflies on nonhost cotton plants. In contrast to TYLCV, transcripts of the bipartite begomovirus ToMoV did not accumulate in the whiteflies.

Deleterious Effects of TYLCV on Life Expectancy and Fertility of the Whitefly Vector

Three-day-old insects raised on eggplants (a TYLCV nonhost) following a 48 h AAP on TYLCV-infected tomato plants showed a reduction of 17–23% in their life expectancy compared to insects that have not acquired the virus, and to a 40–50% decrease in the mean number of eggs laid. These deleterious effects, in addition to the invasion of the reproductive system, suggest that TYLCV has some features reminiscent of an insect pathogen.

Sexual Transmission

TYLCV can be transmitted among whiteflies in a sex-dependent manner, in the absence of any other source of virus. TYLCV was transmitted from viruliferous males to females and from viruliferous females to males, but not among insects of the same sex. The recipient insects were able to efficiently inoculate tomato test plants. In the recipient insects TYLCV was first detected in the hemolymph, but not in the head as in the case of acquisition from infected plants. Therefore the virus follows, at least in part, the circulative pathway associated with acquisition from infected plants. Insect to insect virus transmission was instrumental in increasing the number of whiteflies capable of infecting tomato test plants in a whitefly population. Accordingly, a plant virus can be sexually transmitted among its insect vector.

Breeding Tomato for Resistance to TYLCV

Incorporation of Resistance Trait from Wild Tomato Species

The domesticated tomato *S. esculentum* is extremely susceptible to TYLCV. Breeding tomato for resistance started in the early 1960s and is going on since then. It has been initially observed that some accessions of wild tomato species exhibited resistance to the virus and could be crossed with the domesticated tomato. The first successful breeding program was initiated with *S. peruvianum.* Although this type of resistance was controlled by three to five recessive genes, a first hybrid with acceptable resistance was released in 1988. Advanced breeding lines and commercial varieties containing this type of resistance were released subsequently. Resistance genes from several different accessions of the wild tomato species *S. chilense* have been incorporated into breeding programs in the early 1990s. For each *S. chilense* accession, resistance is determined by a different semidominant gene and several minor genes. The wild tomato species *S. habrochaites* has been used in the late 1990s to produce breeding lines in which resistance is under the control of a major dominant locus.

After more than 25 years of effort, the best resistant cultivars and breeding lines give far higher yields upon

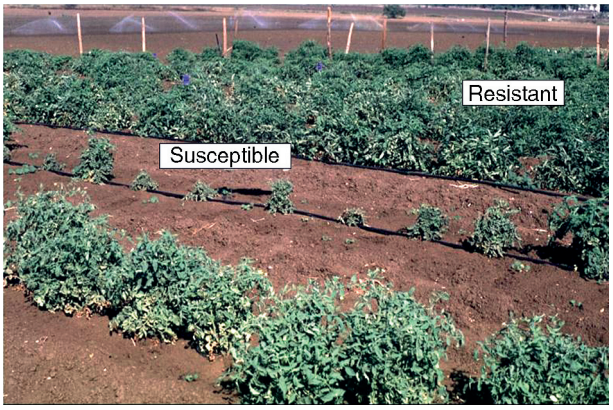

Figure 3 TYLCV-infected tomato fields planted with susceptible and resistant tomato genotypes. Note that the susceptible plants are stunted, and they will not produce fruits; for comparison, the resistant plants will remain symptomless, or have mild symptoms, and will yield.

infection than those of susceptible cultivars; disease symptoms are absent or mild but all of them contain various amounts of virus (**Figure 3**). It is interesting to note that in many cases (especially when the resistance originates from certain accessions of *S. chilense* and of *S. habrochaites*), the tomato lines are resistant to TYLCV and also to a number of begomoviruses in very different parts of the world, some of them monopartite and others bipartite. For example, line Lh902 that originated from *S. habrochaites* is resistant to TYLCV in the Mediterranean region as well as to a wide range of bipartite geminiviruses in Central America.

Genetically Engineered Tomato for Resistance

A variety of strategies have been devised based on the expression of functional as well as dysfunctional viral genes such as coat protein and Rep protein. A tomato interspecific hybrid expressing the TYLCV coat protein gene under the control of the 35S CaMV promoter responded upon whitefly mediated TYLCV inoculation showed expression of delayed disease symptoms and recovery from disease. Tomato inbred lines have been transformed with a 3′ truncated Rep gene (two-fifths of the gene) and the virus intergenic region from the Florida isolate of TYLCV (TYLCV-[US:Flo]). Resistance was achieved upon whitefly mediated inoculation in field conditions. However, these plants were susceptible to the bipartite begomovirus ToMoV from Florida. Similarly, tomato plants transformed with the Rep gene of TYLCSV (TYLCSV-[IT-Sar]) truncated in its 3′ end (leaving 210 amino acids out of 257) exhibited resistance to TYLCSV-[IT:Sar] but were susceptible to the related strain from Spain TYLCSV-ES[ES]. The viral Rep gene altered in the NTP-binding site crucial for virus replication has been used as *trans*-dominant proteins to block virus replication.

RNA-mediated virus resistance was highly sequence dependent. Expression of antisense sequence of the TYLCV-[IT-Sar] Rep gene in transgenic *N. benthamiana* resulted in repression of nearly all virus replication. The incorporation of a ribozyme structure into the antisense construct did not increase the efficiency of the system. Resistant tomato plants have been developed which exploit the mechanism of post-transcriptional gene silencing via double-stranded RNA sequences. Noncoding conserved regions from the genomes of TYLCV, TYLCV-mild (TYLCV-Mld[IL]), and from the TYLCV strains from Egypt (TYLCV-[EG:Ism]), and TYLCSV from Sardinia (TYLCSV-[IT:Sar]) and Spain (-TYLCSV-ES[ES]) were used to design a construct that can trigger broad resistance against the different TYLCVs. A high level of resistance was obtained when plants were inoculated with TYLCV-[EG:Ism], TYLCV-Mld[IL], and TYLCSV-ES[ES]. A positive correlation between resistance and the accumulation of virus-specific siRNAs was observed in silenced plants.

Localization of Loci Linked to Resistance to TYLCV in Tomato for Possible Use in Marker-Assisted Breeding

Mapping genes in tomato has been facilitated by the development of saturated maps based on DNA polymorphism (RFLP, AFLP, SSR, SCAR, etc.). A TYLCV-resistance gene originating from *S. chilense* accession LA 1969, *Ty-1*, has been mapped to tomato chromosome 6 using RFLP markers. Three additional loci linked to resistance against TYLCV have been mapped to chromosome 6 using resistant tomato inbreds derived from *S. chilense* accessions LA1932, LA2779, and LA1938. Another resistant gene originating from *S. pimpinellifolium* has been mapped, using RAPD markers, also to chromosome 6 but to a locus different from *Ty-1*. It can be noted that a locus conferring resistance to a nonrelated TYLCV isolate belonging to the species tomato leaf curl Taiwan virus from Taiwan, originating from *L. hirsutum* LA1777, has been located in chromosome 11 using RFLP markers.

Glossary

Modular evolution Evolution of viral genomes involving the combination of common genes/gene families.
Movement protein A plant viral protein that potentiates viral cell-to-cell movement through plasmodesmata.
Origin of assembly Unique RNA sequence and structure that specifically binds CP to initiate capsid assembly.
Polycistronic The characteristic of a given RNA containing more than one gene (open reading frame).
Quasiequivalence Capsid protein subunits arranged so that they are in somewhat equivalent environments with respect to their adjacent subunits.
(Silencing) suppressor Virally encoded product that inhibits a stage in the host RNA silencing pathway.
Subgenomic RNAs Less-than-full-length RNAs that are produced during replication, usually to express internal open reading frames.

Introduction

The *Tombusviridae* is a relatively large and diverse family of single-stranded, positive-sense, RNA plant viruses with common morphological, structural, molecular, and genetic features. Due to their small size and extremely high virus titer in experimental hosts, viruses in the family are particularly well characterized in terms of virion structure, replication, gene expression strategies, local and systemic movement, suppression of host gene silencing and associated satellite viruses, and defective interfering RNAs.

The family is constituted based on a unifying phylogenetic and biological feature. The RNA-dependent RNA polymerase of tombusviruses is highly conserved in terms of sequence identity, genomic structure, and gene expression and function. Biologically, tombusviruses share the property of being primarily soil transmitted, often without a biological vector, and accumulate to high levels in the roots of infected plants. Beyond these constants the family is remarkably diverse in biology, pathology, host range, and genome organization.

Many of the viruses now comprising the family *Tombusviridae* have been studied for a number of decades. Viruses like tomato bushy stunt virus (TBSV), carnation ringspot virus (CRSV), carnation mottle virus (CarMV), and cymbidium ringspot virus (CymRSV) were first described and virions purified and characterized in the 1940s. The taxonomic and phylogenetic relatedness of many of the viruses now comprising this family was not resolved until the mid-1980s, when genomes of these viruses were first cloned and sequenced.

Taxonomy, Phylogeny, and Evolution

The family *Tombusviridae* of plant viruses is composed of the genera *Aureusvirus*, *Avenavirus*, *Carmovirus*, *Dianthovirus*, *Machlomovirus*, *Necrovirus*, *Panicovirus, and Tombusvirus*, with more than 43 species and 15 tentative species recognized. Several genera are represented by many species whereas three genera are monotypic. The type species of the genus *Aureusvirus* is *Pothos latent virus*. This genus is quite similar to the genus *Tombusvirus* but is distinguished by having significantly different sized movement and silencing suppressor proteins. The type species of the monotypic genus *Avenavirus* is *Oat chlorotic stunt virus*. This species constitutes a separate genus because the genome organization is intermediate between those of the genera *Carmovirus* and *Tombusvirus*. Furthermore its capsid protein (CP) is significantly larger than those found in other genera whose CPs have a protruding (P) domain. *Carnation mottle virus* is the type species of the genus *Carmovirus*. This genus is distinguished by having two small proteins associated with virus movement and a CP with a P domain. The genus *Dianthovirus*, of which

Carnation ringspot virus is the type species, has the most dramatic taxonomic distinction: its genome is split into two segments. *Maize chlorotic mottle virus* is the type and monotypic species of the genus *Machlomovirus*. This genus is structurally quite similar to the genus *Panicovirus* but contains an additional open reading frame (ORF) at the 5′ end of its genome which nearly completely overlaps the polymerase. The genus *Necrovirus* is represented by *Tobacco necrosis virus A*. The genome organization and expression strategy are quite similar to those in the carmoviruses, but the necroviruses have the phylogenetically distinct CPs lacking a P domain. The genus *Panicovirus* is also represented by a single species, *Panicum mosaic virus*. This virus is distinguished by having carmovirus-like movement proteins (MPs), a CP without a P domain, as well as several accessory genes (**Figure 1**).

This family serves as an excellent example supporting the concept of modular evolution of viruses. The polymerase is the sole shared module binding the family. Within the limitations of the viral polymerase the family has taken great liberties with the arrangement and expression of the various genes on its polycistronic RNA. While it is true that all members of the family have a $T = 3$ icosahedral virion, different genera achieve this structure using two phylogenetically distinct CP modules. At this time, it appears that this family has acquired at least three phylogenetically different cell-to-cell movement modules. The sources of the virus suppressor of host gene silencing appear to be equally diverse. In addition, various species within a particular genus have acquired additional unique accessory modules, possibly for transmission by fungal vectors.

The minimal viral polymerases of the *Tombusviridae* lack any identifiable helicase motif, and do not have a nucleotide triphosphate binding motif. They do, however, have the canonical glycine–aspartate–aspartate (GDD) motif found in most RNA polymerases. All *Tombusviridae* polymerases are similarly expressed from an interrupted ORF by one of two translational regulatory mechanisms: terminator readthrough or −1 ribosomal frameshifting (**Figure 1**). The *Tombusviridae* polymerase is also phylogenetically related to that in the genus *Luteovirus* and, to a lesser extent, *Enamovirus* but not with the genus *Polerovirus* in the family *Luteoviridae*. Polymerases of tombusviruses belong to the Sindbis-like superfamily of RNA polymerases, but they are often categorized in a separate subgroup because of their reduced size and missing motifs.

The virions of tombusviruses are morphologically similar. They all form icosahedral $T = 3$ symmetry particles approximately 30–38 nm in diameter. Virions are formed from 180 copies of a single CP subunit ranging from 25 to 48 kDa in size. Virions parse into two morphological subclasses the first of which have rough or granular surfaces and the second smooth surfaces. The smooth particles, such as those found in the genera *Machlomovirus*, *Necrovirus*, and *Panicovirus*, have smaller CPs and lack the P domain found in the larger CPs (**Figure 2**).

There are also common elements in the viral genome structures of tombusviruses. They are all small, single-stranded, positive-sense RNA viruses, encoding four to six ORFs on a single RNA molecule, with the exception of the dianthoviruses, which have a split or bipartite genome. In addition, members of the *Tombusviridae* all rely on the generation of one or more subgenomic RNAs (sgRNAs) to express genes from the polycistronic viral genome.

Virion Structure

Although the underlying size and structure of the virions are similar, the members can be broadly subdivided into two groups based on the presence or absence of a P domain at the c-terminus of the CP. Genera containing P domains (*Aureusvirus*, *Avenavirus*, *Carmovirus*, *Dianthovirus*, and *Tombusvirus*) produce virions that are 32–38 nm in diameter and display a granular surface. These CP subunits range in size from 37 to 48 kDa. The X-ray crystal structures of TBSV and turnip crinkle virus (TCV; *Carmovirus*) revealed the discrete organization of each CP subunit. Generally, the CP subunit can be divided into four domains: the RNA-binding (R) domain is located at the N-terminus followed by the arm (a), shell (S), and P domains (66, 35, 67, and 110 amino acids, respectively, in TBSV). The R domain contains many basic residues and is found in the interior of the virion. Cryoelectron microscopy reconstructions have further revealed the presence of internal ordered cages of RNA intertwined with CP residues from the R domains beneath the virion surface. This internal scaffold may play a role in directing specific packaging of viral RNA and formation of the icosahedral virions. The virion structure is primarily formed by the globular S domains (stabilized by a pair of Ca^{2+} per subunit) which are composed of two sets of four-stranded antiparallel β-sheets. The S domain is also the most highly conserved region of the CP subunit. There is a flexible hinge of five residues between the S and P domains that allows the CP subunit to adopt different configurations by varying the angle between the domains. This feature of the CP subunit overcomes the structural constraints imposed by the icosahedral morphology. P domains (containing antiparallel β-sheet structures in a jellyroll conformation, with one six-stranded β-sheet and one four-stranded β-sheet) of adjacent CP subunits dimerize to produce 90 projections leading to the granular surface texture. Genera lacking the P domain (*Machlomovirus*, *Necrovirus*, and *Panicovirus*) produce virions that are 30–32 nm in diameter with a smooth surface similar to viruses in the genus *Sobemovirus*. These shorter CP subunits range from 25 to 29 kDa in size.

Figure 1 Genomic organization of the type species for each genus in the family *Tombusviridae*. The genomes are aligned vertically at the site of the polymerase readthrough event. Boxes represent known and predicted ORFs with the sizes of the respective proteins (or readthrough products) indicated, for example, p27 for 27 kDa protein. Similarly, colored boxes represent proteins with extensive sequence conservation and function. RT, translational readthrough of termination codon; –1 FS, -1 ribosomal frameshifting event; CP, capsid protein; CRSV, carnation ringspot virus (genus *Dianthovirus*); TBSV, tomato bushy stunt virus (genus *Tombusvirus*); PoLV, pothos latent virus (genus *Aureusvirus*); OCSV, oat chlorotic stunt virus (genus *Avenavirus*); CarMV, carnation mottle virus (genus *Carmovirus*); TNV-A, tobacco necrosis virus A (genus *Necrovirus*); PMV, panicum mosaic virus (genus *Panicavirus*); MCMV, maize chlorotic mottle virus (genus *Machlomovirus*).

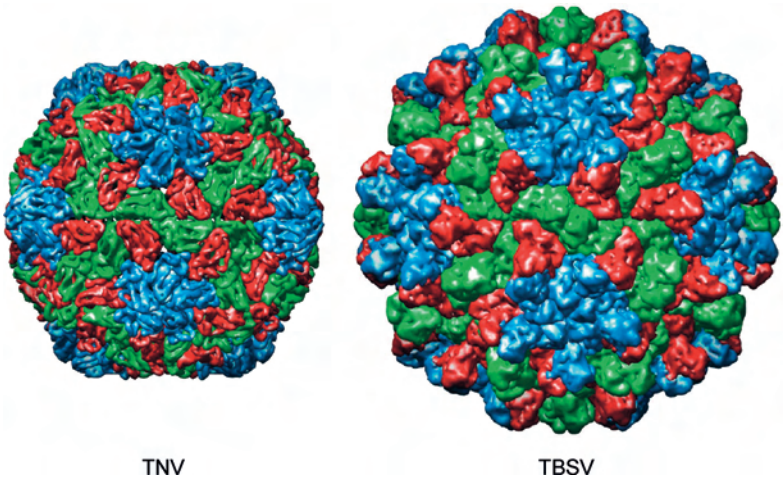

Figure 2 Virion images of tombusviruses based on X-ray crystal structures. Left image is tobacco necrosis virus (TNV) at 2.25 Å. The capsid protein of this virus does not contain a protruding domain and is representative of species in the genera *Machlomovirus*, *Panicovirus*, and *Necrovirus*. Right image is TBSV at 2.9 Å. The capsid protein of this virus contains a protruding domain and is representative of species in the genera *Avenavirus*, *Aureusvirus*, *Carmovirus*, *Dianthovirus*, and *Tombusvirus*. For both images, the individual subunits are colored according to their various conformations: A (blue), B (red), and C (green). From Shepherd CM, Borelli IA, Lander G, *et al.* (2006) VIPERdb: A relational database for structural virology. *Nucleic Acids Research* 34 (Database Issue): D386–D389, VIPERdb.

Due to the quasi-equivalent nature of the CP subunits when arranged in an icosahedron, each subunit can take on one of three distinct conformations, termed A, B, and C (respectively, blue, red, and green in **Figure 2**). The A and B conformations differ in the angle between the S and P domains and their arrangement on the virion surface (A: fivefold axes, B: threefold axes). The C conformation differs from A and B in that their R/a domains intertwine to form an ordered internal structure around threefold axes of symmetry termed the β-annulus. The three different CP subunit conformations pack together as either AB or CC dimers in the virion particle. For TCV, virion assembly initiates with three CP dimers and viral RNA followed by formation of the virion shell according to structural constraints imposed by CP/RNA interactions. In TCV, the origin of assembly RNA sequence (which specifically initiates the interaction with CP subunits) is contained within a 186 nt region at the 3′ end of the CP ORF. Assembly studies with TCV also showed that only RNAs equal to or smaller than 4.35 kbp in size could be packaged, suggesting very strict size limitations for icosahedral virions.

Virions of tombusviruses have an M_r of ~8.2–8.9×10^6 and produce a single, well-defined band upon centrifugation with sedimentation coefficients ranging from 118 to 140$S_{20,w}$. Virion densities range from 1.34 to 1.36 g cm^{-3} in CsCl gradients. Virions are stable at acidic pH, but expand above pH 7 and in the presence of ethylenediaminetetraacetic acid (EDTA). Virions are resistant to elevated temperatures although thermal inactivation usually occurs above 80 °C. Due to the lack of a lipid membrane, virions are insensitive to organic solvents and nonionic detergents.

Most genera produce virions containing a single molecule of positive-sense, linear single-stranded RNA (ssRNA) ranging in size from 3.7 to 4.8 kb depending on the genus. The genomic RNA constitutes about 17% of the particle weight. The exception is the genus *Dianthovirus* where virions contain two genomic RNAs: a large RNA-1 of ~3.9 kb and a smaller RNA-2 of 1.5 kb. The genomic RNAs lack a 5′ cap structure and the 3′ ends are not polyadenylated nor do they form tRNA-like structures. Satellite RNAs (satRNAs) of nonviral origin are associated with several genera. Satellite viruses (which code for their own CP) are also associated with several genera but these are readily distinguishable due to their significantly smaller dimensions. Both small RNAs modify the symptoms of their respective helper viruses.

Genome Organization and Replication Strategy

The dimensions of the icosahedral virions constrain the genome sizes of the various members of the family *Tombusviridae*. This forces the members to adopt several strategies for expression of their genetically compact, polycistronic genomes. Their unifying genomic feature is the presence of an interrupted ORF for the virally encoded RNA-dependent RNA polymerase at the 5′ end of the genome. The interruption is manifested as either an amber termination codon which may be read through (most members) or a −1 ribosomal frameshifting signal (genus *Dianthovirus* only). In either case, this leads to the direct translation of two ORFs with identical amino

termini from the genomic RNA (**Figure 1**). These polymerase subunits share a high degree of sequence similarity within the family. Notably, they do not contain a helicase-type motif and the genomes do not encode a helicase-like ORF. ORFs downstream of the polymerase are expressed via 3′ co-terminal sgRNAs with the resident ORFs produced with an assortment of translational strategies such as ribosomal scanning and frameshifting. Aside from the single CP ORF mentioned previously, the genomes of *Tombusviridae* also encode one or more MPs that are involved in cell-to-cell spread of the virus. These range in size from the 34–35 kDa version found in the genus *Dianthovirus* to the 22 kDa product found in the genus *Tombusvirus* and down to the 6–9 kDa pair found in the genus *Carmovirus*. In most cases, the MPs can potentiate the local movement of unencapsidated viral RNA but systemic infection generally requires encapsidation. The exception is for members of the genus *Tombusvirus* which can infect systemically without CP albeit at a reduced rate. The other prominent protein product with a clearly defined function is the genus *Tombusvirus* p19 protein which is a potent suppressor of post-transcriptional gene silencing (PTGS). p19 binds double-stranded short interfering RNAs (siRNAs) that are generated by a Dicer-like RNase as part of the host RNA-silencing response to viral infection. This binding prevents incorporation of the siRNAs into the RNA-induced silencing complex (RISC) to prevent further cleavage of viral RNAs. Although other members of the family may not encode a unique suppressor protein, it is known that other proteins can have suppressor activity aside from their primary functions. This is the case for TCV where the CP is the viral suppressor of PTGS. Various additional ORFs are also encoded with undefined functions. One other method utilized by members of the family *Tombusviridae* for gene expression is genome segmentation which is only employed by the genus *Dianthovirus* where RNA-2 is monocistronic and encodes the MP.

Since the genomic RNAs are positive sense, they are directly infectious as unencapsidated RNAs. However, the lack of a 5′ cap structure and a 3′ poly(A) tail precludes the normal circularization procedure employed by mRNAs for translation. Instead, a cap-independent mechanism involving a long-distance RNA–RNA interaction between sequence elements in the 5′ and 3′ noncoding regions has been demonstrated in TBSV and tobacco necrosis virus-A (TNV-A) and proposed in the case of red clover necrotic mosaic virus (RCNMV; genus *Dianthovirus*) RNA-1. The direct translation readthrough strategy ensures that the longer ORF (containing the catalytic site of the polymerase) is present in only 5–10% of the translation products since readthrough is inefficient. Translation of the virally encoded polymerase subunits is followed by localization to and proliferation of cellular membranes. The location of viral replication varies dependent on the particular virus and is specified by the pre-readthrough portion of the polymerase. In all cases studied to date, the polymerase anchors on membranes, causing proliferations. The advent of yeast-based replication systems for TBSV, cucumber necrosis virus (CNV; genus *Tombusvirus*), and CymRSV has provided valuable insights into the host components utilized by the viral replication complex.

Once the polymerase has been assembled, it binds to the 3′ terminus to initiate minus-strand synthesis. If full-length copies are generated, these serve as templates for synthesis of progeny genomic RNAs. This synthesis is highly asymmetric with positive-stranded RNA accumulating at much higher levels than negative-stranded RNA. Occasionally, positive-strand synthesis will be terminated prematurely which leads to the formation of templates for plus-strand sgRNA synthesis. This premature termination is controlled by long-distance RNA–RNA interactions which occur in *cis* (for instance, in TBSV) or in *trans* (for instance, RCNMV). Generally, sgRNAs are produced later in the infection cycle and behave as monocistronic mRNAs. However, the sgRNAs also demonstrate various translational strategies such as ribosomal scanning in the case of p19 expression which is nested within the p22 ORF in TBSV. In this case, the p22 start codon is suboptimal and occasionally read through by ribosomes before translation at the optimal p19 start codon.

During replication, defective interfering (DI) RNAs (which are not packaged into virions) arise in viruses belonging to some genera. These DI RNAs are derived from the viral genome and are replicated to very high titers which lead to their interfering with viral genomic replication levels. DI RNAs have been used extensively to delimit critical sequence elements required for RNA replication.

Transmission, Host Range, and Epidemiology

The natural host range of a given species is relatively narrow; however, the experimental host range tends to be broad. Members can infect either monocotyledonous or dicotyledonous plants, but no species can infect both. Natural infections can be limited to or are often concentrated in the root system. Many species induce a necrosis symptom in the foliar parts of the plant. All species are readily transmitted by mechanical inoculation and by host vegetative propagation and some may be transmitted by contact and through seeds. A number of species are readily detected in the soil, surface waters, rivers, lakes, and even the ocean. Transmission by the chytrid fungi in the genus *Olpidium* and beetles have also been reported for members of several genera. Most, if not all, members can be transmitted through the soil either dependent on, or

independent of, a biological vector. This rather unusual soil and water mode of transmission is unique to this plant virus family and is based on the unusually robust constitution of the virion.

Geographical distribution of particular species varies from wide to restricted. Most species occur in temperate regions although legume-infecting carmoviruses and a tentative member of the genus *Dianthovirus* have been recorded from tropical areas.

In nature, viruses in the family *Tombusviridae* can be spread in a variety of ways, including seed and pollen transmission, mechanical transmission, vegetative propagation and grafting, growth in infected soil, and by vectors such as fungi, thrips, and beetles. As mentioned above, one hallmark of members of the family *Tombusviridae* is the amount of virus present in the roots of infected plant tissue, and the ease of transmission through the soil, whether that transmission is dependent on a biological vector or not. For viruses that can be transmitted by fungi, there is a considerable amount of specificity required between the virus and the fungal vector. For example, CNV (*Tombusvirus*), melon necrotic spot virus (*Carmovirus*), and cucumber leaf spot virus (*Aureusvirus*) are transmitted by the root-inhabiting chytrid fungus *Olpidium bornovanus*, whereas TNV (*Necrovirus*) is transmitted exclusively by *Olpidium brassicae*.

Pathogenesis

For the species in which it has been studied, the virus titers and pathogenic effects are at least as high, if not higher, in the root system of the host as in the other parts of the plant. This is consistent with the robust nature of the virions and that viruses in the family are transmitted through the soil.

Many tombusviruses generate DI RNAs that can affect pathogenesis. DI RNAs are essentially deletion mutants of the viral genome which are generated by errors in replication such as rearrangement or recombination. Several species such as TBSV and TCV produce DI RNAs during viral infection. For TBSV the presence of DI RNAs results in attenuation of symptoms, whereas for TCV the presence of DI RNAs intensifies symptoms. Many species, including both TBSV and TCV, are also known to harbor satRNAs. These small RNAs are generally not derived from viral sequences, but they depend on the helper virus for replication and packaging. As with DI RNAs, they can attenuate TBSV or intensify symptoms (TCV).

The origin of nonhomologous satRNAs is unclear at present, but like DI RNAs, satRNAs can be generated from recombination events with other satRNAs, the viral genome, DI RNAs, or host sequences. Both DI RNAs and satRNAs have been useful molecular tools for studying viral replication and recombination. Since both satRNAs and DI RNAs are dependent on the host or parent virus for replication, they must have retained any sequence or structural signals required for recognition by the viral polymerase, and therefore can help determine exactly what those signals are.

Recombination can facilitate viral evolution as well as repair of viral genomes, and so it is an important factor in the virus life cycle and it can have profound effects on pathogenesis. In the family *Tombusviridae*, recombination in the genera *Carmovirus* and *Tombusvirus* has been shown to repair damaged or deleted 3′ ends of virus-associated RNAs, as well as generate new satRNAs or DI RNAs. Recombination can occur between both homologous and nonhomologous sequences, probably by a copy-choice mechanism in which the viral replicase jumps from one template to another during the replication process.

Plants infected with tombusviruses display a distinctive cytopathology, observed by electron microscopy as dense-staining features. These features are known as multivesicular bodies, and are believed to be sites of viral replication as well as accumulation of exceedingly high concentrations of progeny virions. To date, cell biology studies have shown that species can replicate on, remodel, and proliferate membranes of peroxisomes, mitochondria, and the cortical ER. There appears to be no correlation between a specific organelle membrane used for replication and taxa.

Glossary

Colostrum-deprived (CD) calves Conventional calves that did not receive antibody-rich first milk or colostrum during the first 6–12 h of life, therefore lacking of passive immunity from the mother (calves are hypogammaglobulinemic individuals when they born).
Gnotobiotic (Gn) calves Animals that are obtained and maintained in germ-free environments, in which the composition of any associated microbial flora, if present, is fully defined.

History

Equine torovirus (EToV), originally referred to as Berne virus, was accidentally isolated in equine kidney cells in 1972 from a rectal swab taken from a horse with diarrhea. EToV is the only torovirus that has been propagated in cell culture, in lines of equine dermis or embryonic mule skin cells, where it causes a cytopathic effect that results in cell lysis. While Berne virus was not neutralized by antisera against known equine viruses, serologic cross-reactions were observed in neutralization tests and enzyme-linked immunosorbent assay (ELISA) using sera from calves that had been experimentally infected with morphologically similar particles, then named 'Breda' viruses.

The first Breda virus, now called bovine torovirus (BToV), was discovered in 1979 during an investigation in a dairy herd in Breda (Iowa), in which severe neonatal calf diarrhea had been a problem for three consecutive years. After this initial report, other strains of BToV were identified in beef calves from Ohio, and in a colostrum-deprived (CD) calf from Iowa. Despite repeated attempts, BToV cannot be adapted to grow in cell or tissue cultures and must be passaged in gnotobiotic (Gn) calves, which has hampered its biochemical, biophysical, and molecular characterization. Most of the studies on the pathogenesis and pathology of torovirus infections have been done in BToV-infected Gn and CD calves, as well as in limited field studies; in contrast, most of the biochemistry and morphogenesis data on toroviruses are based on EToV studies.

In 1984, torovirus-like (TVL) particles were detected in the feces from human patients with gastroenteritis by using electron microscopy (EM). Since then, reports of human toroviruses (HToVs) in children and adults with acute diarrhea have appeared in several countries. TVL particles have also been detected in fecal samples from pigs, and named porcine torovirus (PToV). Proof that the observed structures were not artifacts was obtained when toroviral RNA sequences were found in the feces of piglets and in stools from humans with diarrhea. In recent years, TVL particles have also been detected in turkeys and have been associated with a 'stunting syndrome'.

Taxonomy and Classification

Toroviruses are single-stranded, positive-polarity RNA viruses with a peplomer-bearing envelope. The term *torus* (Latin) refers to the circular convex molding in the form of a doughnut that some columns or pilaster have at their bases; indeed, it was the unique biconcave disk and C-shape of the virion in the extracellular environment that suggested this naming. Since 1992, the genus *Torovirus* has been included with the genus *Coronavirus* and the newly recognized genus *Bafinivirus* in the family *Coronaviridae*, based on similarities in genomic organization and replication strategies. Toro- and coronaviruses are also

ancestrally related: their polymerase and envelope genes diverged from those of a common predecessor. Because of their inclusion in the family *Coronaviridae,* the nomenclature for coronavirus genes, mRNAs, and structural proteins have also been applied to toroviruses. However, the lack of sequence homology in the structural genes and the absence of antigenic relatedness with coronaviruses justify their taxonomic position as a separate genus. The International Committee on Taxonomy of Viruses (ICTV) presently recognizes four species in the genus *Torovirus*: *Equine torovirus*, *Bovine torovirus*, *Porcine torovirus*, and *Human torovirus.*

The families *Coronaviridae* and *Arteriviridae*, as well as the new family *Roniviridae*, are the constituents of the order *Nidovirales*, the second order in animal virology (after the order *Mononegavirales*). This assignment is based on their similar basic genomic organization and common replication strategy: the synthesis of a 3′ co-terminal nested set of subgenomic mRNAs, and the possession of two open reading frames (ORFs) connected by a frameshift site to express a replicase directly from the genomic RNA. This nested set of mRNAs was the foundation for the name of the order *Nidovirales* (from Latin *nidus*, 'the nest').

Virion Properties

Torovirus particles possess a nucleocapsid with helical symmetry coiled into a hollow tube (diameter 23 nm, average length 104 nm, periodicity 4.5 nm). Extracellular, negatively stained torovirus virions are generally observed as kidney- or C-shaped particles (105–140 nm × 12–40 nm). They can also be seen as spherical or oval particles (89 ± 7 nm × 75 ± 9 nm) or rod-shaped virions (35 nm × 170 nm), depending on the different orientations of the virions with respect to the electron beam. A graphic representation of a torovirion is shown in **Figure 1**. A tightly fitting envelope, 11 nm thick, surrounds the virion structure bearing prominent drumstick-shaped peplomers (17–24 nm), and a fringe of shorter spikes (8–10 nm), which represent the spike and the hemagglutinin-esterase (HE) proteins, respectively. Intracellularly, toroviruses are observed as elongated tubules with rounded ends (rod-shaped virions, 35–42 nm × 80–105 nm), located in the cytoplasm of infected intestinal cells.

Genome

The torovirus genome consists of a single-stranded, polyadenylated RNA of positive (messenger) polarity, which is about 28.5 kbp in length. Recently, the BToV genome has been completely sequenced, and it has been shown to comprise 28 475 nt and contain six ORFs (see **Figure 1**), each of which encodes a known protein. ORF1a and ORF1b are the most 5′ proximal reading frames and constitute the replicase (RNA-dependent RNA polymerase) gene, which is expressed as a large precursor protein directly from the genomic RNA by a ribosomal frameshift mechanism, similar to other nidoviruses. The large product of these ORFs is apparently involved in the synthesis of a negative-strand RNA and the onset of genomic and subgenomic RNA synthesis. The other four ORFs correspond to structural protein genes and are expressed by the production of a 3′

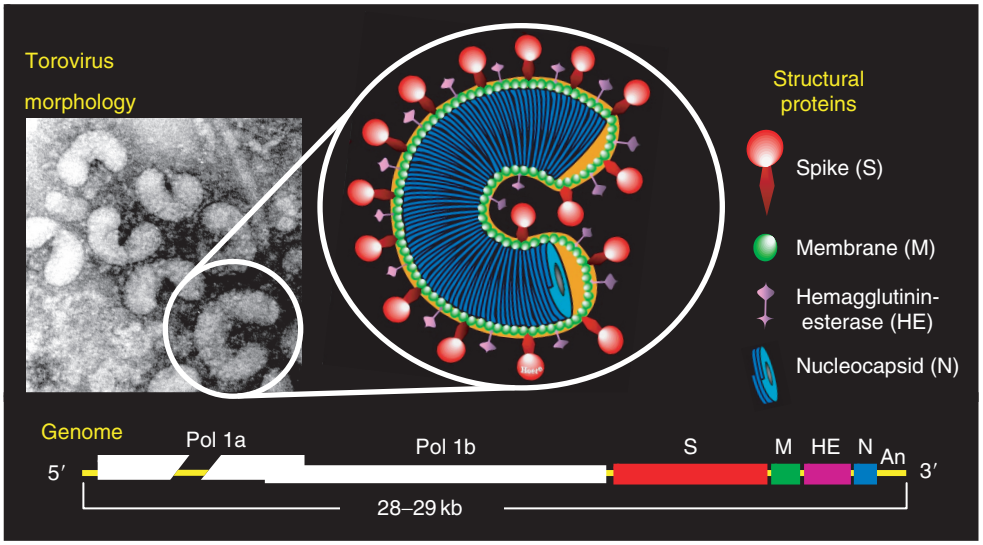

Figure 1 Typical extracellular morphology of a torovirus as visualized by immune electron microscopy (IEM), with a graphic representation of torovirus virion and its structural proteins and genome. Modified with permission from Hoet AE (in press) Torovirus pathogenesis and immune responses. In: Perlman S, Snijder EJ, and Gallagher TM (eds.) *The Nidoviruses*, copyright 2008 by the ASM Press.

co-terminal nested set of four mRNAs. The BToV ORF2 (4752 nt), ORF3 (702 nt), ORF4 (1248–1251 nt), and ORF5 (504 nt) encode the spike (S), membrane (M), HE, and nucleocapsid (N) proteins, respectively.

Proteins

Proteins with molecular weights of 20, 22, 37, and 80–100 kDa have been identified in EToV virions. Detergent treatment of virions releases the 22, 37, and 80–100 kDa proteins, which indicates their association with the envelope. Similar polypeptides of 20, 37, 85, and 105 kDa have been identified in purified BToV by means of surface radioiodination. The nucleocapsid (N) protein (167 aa) is the most abundant polypeptide found in the virion (80–84%) with a predicted molecular weight of 18.3–19.2 kDa. Blotting experiments performed with EToV have identified this internal protein as the only RNA-binding polypeptide in the virion. The M glycoprotein (233 aa, 26.5 kDa) is the second most abundant protein (~13%) and is probably associated with the envelope. Computer analysis has revealed characteristics of a class III membrane protein lacking a cleaved signal sequence, but containing three successive transmembrane α-helices in the N-terminal half. The M protein accumulates in intracellular membranes, predominantly those of the endoplasmic reticulum and is believed to play a role in assembly, maturation, and nucleocapsid recognition during the budding process.

The heterogeneous, N-glycosylated, 80–100 kDa protein is recognized by both neutralizing and hemagglutination-inhibiting monoclonal antibodies and is therefore identified as the spike (S) protein projecting from the virion surface. The spike (S) gene encodes an apoprotein (1581 aa) with a molecular weight of about 178 kDa. The deduced amino acid sequence contains domains typical of type I membrane glycoproteins: an N-terminal signal sequence, a putative C-terminal transmembrane anchor, and a cytoplasmic tail. The HE is a class I membrane N-glycosylated protein (416–417 aa) of 65 kDa that is also located in the BToV envelope. It has an N-terminal signal sequence, a C-terminal transmembrane domain, several N-glycosylation sites, and a putative 'FGDS' motif which displays acetylesterase activity specific for *N*-acetyl-9-*O*-acetylneuraminic acid. The HE protein could be an additional receptor-binding protein (next to the spike protein) but without a function in viral entry. EToV virions lack an HE protein, only possessing a partial sequence in ORF4.

Physical Properties

Buoyant densities of 1.16, 1.17, 1.18, and 1.14 g ml^{-1} have been reported for the virions of EToV, BToV serotype 1, BToV serotype 2, and HToV, respectively. EToV is remarkably stable in the environment, and relatively resistant to phospholipase C, trypsin, chymotrypsin, and even deoxycholate; however, Triton X-100 and organic solvents destroy its infectivity. EToV is stable within a wide range of pH, being inactivated only below pH 2.5 or above pH 10.3. BToV1 appears to be less stable than both EToV and BToV2 as changes in its sedimentation behavior and density have been observed after prolonged storage at −70 °C. The infectivity of a fecal preparation containing BToV1 has been reported to be lost completely after 3 weeks at 4 °C, whereas EToV in cell-free supernatant remained stable for 92 days. Storage of toroviruses at −20 to −70 °C helps to preserve infectivity. However, even at these temperatures the viruses will deteriorate, though at a slower rate. Repeated cycles of freezing and thawing of purified BToV2 results in loss of peplomers and disintegration of virions.

Replication and Morphogenesis

Because it can be grown in cell culture, the morphogenesis of EToV has been most extensively studied. Ultrastructural and immunofluorescence (IF) studies on intestinal cells from BToV-infected calves have shown similarities with EToV morphogenesis.

Attachment, Entry, and Uncoating

Attachment to the apical surface of enterocytes is apparently mediated through the spike proteins, but the HE proteins may be involved as well. Entry or penetration of BToV into enterocytes is apparently by receptor-mediated endocytosis. Lysosomal degradation in vesicles containing the virus is probably responsible for uncoating and subsequent release of the BToV RNA. The site at which this occurs has not yet been determined.

EToV replication occurs in the cytoplasm. Preformed tubular capsids bud through membranes of the Golgi stack and of the endoplasmic reticulum. A host cell nuclear function seems to be required since ultraviolet (UV) preirradiation of cells, actinomycin D, and α-amanitin have been reported to reduce virus yields. The replication cycle takes around 10–12 h to complete.

Transcription

In EToV-infected cells, five virus-specific, polyadenylated mRNAs are found with sizes of >20.0, 7.5, 2.1, 1.4, and 0.8 kbp. Northern (RNA) blot hybridizations with restriction fragments from cDNA clones have shown that the five EToV mRNAs form a 3′ co-terminal nested set. Sequence analysis has revealed the presence of four complete ORFs with initiation codons coinciding with the

5′ ends of EToV RNAs 2–5, respectively; RNA 5 is contiguous on the consensus sequence. EToV RNAs 1–3 are transcribed independently, as has been shown by UV transcription mapping. The genes for M, HE, and N are preceded by short noncoding 'intergenic' regions, containing a transcription-regulating element (TRE) conforming to the consensus sequence 5′ (C)ACN$_{3–4}$CUUUAGA 3′. A copy of this sequence is also present at the extreme 5′ terminus of the genome. In contrast, the S gene overlaps with the replicase gene and the N-terminal 28 residues of S are in fact encoded by an internal (–1) reading frame within ORF1b; moreover, there is no TRE. The production of this 3′ co-terminal nested set of mRNAs characterizes the toroviruses and justifies their inclusion into the order *Nidovirales*.

Translation

No RNA-dependent RNA polymerase is found in torovirus virions. The torovirus replicase is probably translated as soon as the RNA is liberated. Translation yields two large polyproteins, from which by proteolytic cleavage the various subunits of the viral replicase/transcriptase are derived, as well as accessory proteins of as yet unknown function. Downstream of ORF1b, there are the genes for the structural proteins S, M, HE, and N (as ordered from 5′ to 3′); these are translated from four subgenomic mRNAs, numbered 2–5 (with the genomic RNA as RNA1).

Post-Translational Processing

The N-glycosylated S protein is derived from the processing of a 200 kDa precursor present in infected cells, but not in virions. Eighteen potential N-glycosylation sites, two heptad repeat domains, and a possible 'trypsin-like' cleavage site exist in the spike protein amino acid sequence. The mature S protein consists of two subunits and their electrophoretic mobility upon endoglycosidase F treatment suggests that the predicted cleavage site is functional *in vivo*. The heptad repeat domains are probably involved in the generation of an intrachain coiled-coil secondary structure; similar interchain interactions can play a role in the formation of the observed S protein dimers. The intra- and interchain coiled-coil interactions may stabilize the stalk of the torovirus peplomers.

Assembly, Budding, Egress, and Maturation

About 10 h after infection, EToV particles are observed within parts of the unaltered Golgi apparatus, and extracellularly. At that time, tubular structures of variable length, diameter, and electron density appear in the cytoplasm, and also in the nucleus of infected cells, probably representing preformed nucleocapsids. It is unknown whether the accumulation of nucleocapsids in the nucleus reflects a nuclear phase in the replication of EToV or some sort of defective assembly. Viruses predominantly bud into the lumen of Golgi cisternae. The preformed nucleocapsid tubules approach the Golgi membrane with one of the rounded ends oriented toward the membrane and attach to it laterally. During budding, the nucleocapsid is apparently stabilized, leading to a higher electron density and a constant diameter (23 nm). Release into the intestinal lumen is probably through reverse pinocytosis. Virus maturation apparently occurs intracellularly during the egress process, where the virus nucleocapsid appearance changes from a straight rod (intracellular) into a torus shape (extracellular). The characteristic torus morphology of BToV is only observed in extracellular viral particles or in vacuoles near the cell surface, and never in the cytoplasm.

Geographic Distribution

In cattle, toroviruses have been detected by ELISA, reverse-transcriptase polymerase chain reaction (RT-PCR), and/or immune electron microscopy (IEM) in Austria, Belgium, Canada, Costa Rica, France, Germany, Great Britain, Hungary, Japan, Netherlands, New Zealand, South Africa, and the USA. BToV-seropositive cattle have also been reported in Belgium, France, Germany, India, Switzerland, United Kingdom, and the USA, with seroprevalence ranging between 55% and 94.6%. Most adult horses tested in Switzerland possess neutralizing antibodies to EToV. HToV appears to occur in Canada, Brazil, France, Great Britain, India, the Netherlands, and the USA.

Host Range

Neutralizing antibodies to EToV have been found in sera from horses, cattle, goats, sheep, pigs, rabbits, and feral mice, but not in humans or in carnivores. The host range of BToV appears to be restricted to cattle; however, seropositive reactions to BToV have also been detected in several ungulate species.

TVL particles have been observed in the feces of children and adults with diarrhea. Interestingly, these can be aggregated after the addition of anti-BToV calf sera, can be detected by using a BToV antigen capture ELISA, and the hemagglutination of rat erythrocytes by TVL particles can be inhibited by BToV antisera. These observations indicate antigenic cross-reactivity between HToV and BToV, and may point to a zoonotic connection. TLVs have also been seen in fecal samples of cats and dogs but neither serologic nor molecular identification has been obtained.

Genetic Relationships

There is limited information available on genetic variation amongst toroviruses. The complete genome sequence has been reported only for BToV. However, partial genome sequences have been obtained and used to chart the genetic diversity. In general, there is little divergence (20–40%) among known genotypes of EToV, BToV, PToV, and HToV in the (S, M, HE, and N) genes. Phylogenetic analyses have shown that all BToV strains are closely related, whether they are of European or American origin. Also, all PToV variants form a distinct genetic cluster. However, BToV and PToV sequences are sufficiently different to be assigned as different genotypes. HToVs show a high degree of similarity to New World BToVs (83%), and less with European strains of BToV (73%) and PToV (56%).

Antigenic Properties

In addition to the typical torovirus morphology, BToV, EToV, HToV, PToV, and Lyon-4 virus (Breda-like BToV detected in France) share common antigens. Currently, only one strain of EToV has been isolated, and all attempts to obtain a second equine isolate have been fruitless. Two strains of BToV have been reported in addition to the original isolate described by Gerald Woode and colleagues. One of the strains was detected in feces from a 5-month-old diarrheal calf in Ohio; the second (Iowa strain) was recovered from a 2-day-old experimental animal. On the basis of their cross-reactivity in ELISA, IEM, and hemagglutination/hemagglutination inhibition (HA/HI) assays using rat or mouse erythrocytes, the three isolates were assigned to two serotypes: BToV1, represented by the Iowa 1 isolate, and BToV2, comprising the Ohio and the second Iowa isolate.

Antigenic cross-reactivity has been demonstrated by ELISA, IEM, HI, and immunoblotting between BToV and HToV, indicating a close relationship. Several authors reported that HToV particles detected in humans with persistent diarrhea, and morphologically similar to BToV, could be agglutinated by BToV antiserum; stronger reactions are observed when BToV-2 antisera are used. Hyperimmune sera to BToV have also been used to detect toroviruses in humans by ELISA and IEM.

Epidemiology

Several epidemiological studies have demonstrated a high seroprevalence of BToV antibodies in several different groups of cattle, indicating that the virus may circulate with high frequency in these populations. BToV have also been detected by ELISA and/or RT-PCR in cases of gastroenteritis in cattle. Up to 44% of the BToV-positive samples from these cases did not contain other major enteric pathogens. Calves up to 4 months of age are highly susceptible to diarrhea induced by BToV, especially those below 3 weeks of age. The virus has also been recognized in 5–6-month-old beef calves arriving from sales barns. Intermittent BToV shedding can occur in young calves during the first 10 months of life. Older calves and adult animals can also shed BToV at different ages, perhaps by intermittent subclinical infections or by contracting new BToV infections. Levels of maternal BToV-specific antibodies circulating in the calf influence the clinical outcome of the infection; a seronegative neonatal calf is about seven times more likely to develop diarrhea than a seropositive calf.

Transmission and Tissue Tropism

It has been suggested that the transmission of BToV is via the oral/nasal route by direct contact with contaminated feces or nasopharyngeal secretions. Oral inoculation of calves with BToV has been shown to induce diarrhea with virus shed in feces under experimental conditions. The nasal route is another possible pathway for entry as BToV antigen and viral RNA have been detected in the nasal secretions of feedlot calves. Additionally, diarrhea has been induced after intranasal inoculation in Gn and CD calves. For bovine coronavirus (BCoV), respiratory tract infections have been reported to occur prior to enteric infections, indicating the possible importance of this route of transmission in the spread and pathogenesis of this distantly related group of enteric nidoviruses. It is possible that BToV, like BCoV, could initially replicate in nasal epithelial cells, and thereby amplify before being swallowed and infecting the intestinal tract. This hypothesis for BToV pathogenesis should be further studied.

BToV has a tissue tropism for enterocytes located from the lower half of the villi extending into the crypts, affecting the caudal portion of the small intestine (midjejunum through ileum) and the large intestine. Infection of other types of cells and organs by BToV has not been reported.

Pathogenesis and Clinical Features of Infection

All BToV strains are pathogenic, causing mild to profuse diarrhea in experimentally and naturally infected young calves. Twenty-four to seventy-two hours post exposure, the first clinical signs are observed (mild fever, depression, weakness, and anorexia), followed by a greenish-yellow to bright yellow watery diarrhea that lasts for 3–5 days. Calves may develop severe dehydration and die. Fecal virus shedding begins 24–72 h post infection, coinciding with the onset of diarrhea, and lasts for 2–6 days. Shedding

peaks around 3–4 days post infection. Mixed infections with other enteric viruses, such as rotaviruses or astroviruses, result in a more severe watery diarrhea than is induced by either virus alone. In CD calves with a normal intestinal flora, diarrhea is generally more severe than in Gn calves. Sporadic and recurrent shedding of BToV can last for up to 4 months. BToV has also been detected in nasal samples. Further studies are needed to analyze BToV replication and shedding in the respiratory tract as well as its role in respiratory pathologies.

EToV seroconversion occurs in horses between 10 and 12 months of age, without the appearance of symptoms. Experimentally infected animals (intravenous route) have been reported to seroconvert without clinical signs. Oral infection experiments in horses have not been reported to date.

Several studies have shown an association of HToV infection with diarrhea in children. In one study, 35% of children with enteritis shed HToVs in their feces, but only 14.5% of the asymptomatic controls shed the virus (statistically significant difference – odds ratio 3.1). Affected children showed watery diarrhea, vomiting three to four times daily, and dehydration as a consequence; neither fever, nor the presence of other enteric pathogens, was recorded. Recently, fecal excretion of HToV has been associated with nosocomial infections in infants with necrotizing enterocolitis (NEC). Immunocompromised children appear to be highly susceptible to disease following HToV infection.

Pathology and Histopathology

The target organs of BToV in calves are the lower half or two-thirds of the small intestine and the entire large intestine, particularly the spiral colon. There is little macroscopic evidence of the infection. Histological examination shows villous atrophy and epithelial desquamation in randomly scattered areas from the mid-jejunum to the lower small intestine, as well as areas of necrosis in the large intestine. As shown by IF, both crypt and villus epithelial cells contain antigen. The watery diarrhea is probably a result of the loss of reabsorptive capacity of the colonic mucosa, combined with malabsorption in the small intestine. The germinal centers of Peyer's patches are depleted of lymphocytes and may occasionally show fresh hemorrhage. The dome epithelial cells, including the M-cells, display the same cytopathic changes as seen in the absorptive cells of the villi. Virions are found in cells of both the small and large intestine, and between enterocytes at the basal and lateral plasma membranes. In macrophages of the lamina propria, virions in various stages of degradation are found.

Antigen is detected as early as 48 h after infection in epithelial cells of the lower half of the villi and crypts of the affected areas, as well as in dome epithelium. Fluorescence is cytoplasmic (although a few nuclei may be faintly stained) and generally most pronounced in the intestines with the least tissue damage. The mid-jejunum is infected first and the infection eventually reaches the large intestine. Diagnosis by IF should be performed preferentially on sections of the large intestine from calves killed after the onset of diarrhea (i.e., several days after infection of the epithelium).

Immune Response

Up to the age of 4 months, all calves in a sentinel experiment regularly excreted BToV in their feces. They showed early serum IgM responses despite the presence of IgG1 isotype maternal antibodies, but no IgA seroconversion. Antibody titers then decreased below detection; persistent IgG1 titers developed in only a few animals. After introduction into the dairy herd at 10 months of age, all calves developed diarrhea and shed virus. Seroconversion for all antibody isotypes was observed at this stage, indicating lack of mucosal memory. In contrast, coronavirus infection in the presence of maternal antibodies leads to isotype switch and a memory response.

Prevention and Control

There are no specific preventive measures for this virus; however, general hygiene, biosecurity practices, and the intake of adequate, protective amounts of colostrum can be used to prevent BToV infections. There are no reports on the effects of disinfection or heat sterilization on toroviruses.

Acknowledgments

The authors would like to thank R. de Groot, Utrecht, The Netherlands, for the use of unpublished information from his torovirus review article in press.

Glossary

Ambisense genome Viral RNA genome with open reading frames in both the viral- and viral complementary (vc) sense on the same genome segment.
Envelope Membrane-like structure that packages genome segments.
IGR The intergenic region is the untranslated, A-U rich region found between the two open reading frames on the S and M RNA segments.
Negative sense genome Viral RNA genome that codes for proteins in the vc sense. Transcription of vc mRNA is required for translation of viral proteins.
Nucleocapsid Viral RNA encapsidated in the nucleoprotein.
Protoplast Plant cell lacking its cell wall.
RNP Ribonucleoprotein complex consisting of the viral RNA genome segment, nucleoprotein, and a small number of polymerase molecules.
Virion Quasispherical structure containing the viral genome and bounded by a membrane-like envelope.

History

Diseases now known to be caused by tomato spotted wilt virus (TSWV) were first reported in 1915 and were shown to be of viral etiology by 1930. This taxon of plant viruses was categorized as a monotypic virus group consisting of a single virus (TSWV) until the report of impatiens necrotic spot virus (INSV) in 1991. Thus, most of the characteristics which define the genus *Tospovirus* were obtained through investigation of TSWV even after the discovery of additional viruses in the genus (**Table 1**). Biological investigations beginning in the 1940s revealed a virus that had an unusually large host range and occurred in nature as a complex mixture of phenotypic isolates. However, it was one of the least stable viruses and most difficult plant viruses to mechanically transmit. Although the enveloped virions were observed in the 1960s, molecular characterization and elucidation of the genome organization were not completed until the early 1990s. The virus was shown to be vectored by thrips in the 1930s and later transmitted in a persistent manner. Thrips were demonstrated to be a host for replication of the virus and that replication was required for transmission in the early 1990s. Later it was recognized that limited, localized replication may occur in thrips that does not result in the thrips becoming viruliferous. Advances in gene function and cellular biology have been limited due to the absence of a robust *in vitro* plant or thrips cell culture system, and lack of an efficient reverse genetics system. However, limited progress has been made utilizing gene expression systems and classical viral genetics.

Taxonomy and Classification

Tospoviruses constitute the only genus of plant-infecting viruses in the family *Bunyaviridae*, however, these viruses share many molecular characteristics typical of other members of this virus family. They have an enveloped virion containing the viral genome which is distributed among three RNA segments that replicate in a manner consistent with that of other negative strand viruses. All three segments have highly conserved, complementary

Table 1 List of *Tospovirus* species[a, b, c]

Tospovirus species	*Abbreviation*
Groundnut bud necrosis virus (Peanut bud necrosis virus)	GBNV
Groundnut ringspot virus	GRSV
Groundnut yellow spot virus (Peanut yellow spot virus)	GYSV
Impatiens necrotic spot virus	INSV
Tomato chlorotic spot virus	TCSV
Tomato spotted wilt virus	TSWV
Watermelon silver mottle virus	WSMoV
Zucchini lethal chlorosis virus	ZLCV
Tentative *Tospovirus* species	
Capsicum chlorosis virus (Gloxinia tospovirus) (Thailand tomato tospovirus)	CACV
Chrysanthemum stem necrosis virus	CSNV
Iris yellow spot virus	IYSV
Groundnut chlorotic fan-spot virus	GCFSV
Physalis severe mottle virus	PhySMV
Watermelon bud necrosis virus	WBNV

[c]Synonyms are indicated inside parentheses.

termini resulting in a pan-handle structure and genes with functions similar to those of viruses in other genera are located in similar locations on the genome. However, the genome organization is distinct from the other genera. The small (S) and middle (M) segments each encode two genes in opposite or ambisense polarity.

Classification of a *Tospovirus* population as a distinct species (virus) is based upon the similarity of sequence between the nucleocapsid genes of the respective viruses. This is in contrast to the system used to differentiate viruses in other genera which traditionally relied on serological neutralization of infectivity or other biological properties (hemagluttination) mediated by the glycoproteins. Tospovirus isolates with greater than 90% nucleotide similarity in the nucleocapsid gene are classified as isolates of the same species (virus). Serologically related isolates with 80–90% sequence identity are subjectively classified as strains or as distinct species depending on other criteria. Isolates with less than 80% identity are classified as distinct species.

Geographic Distribution

TSWV, the type member of the tospoviruses is found worldwide in temperate regions in association with its thrips vector. The wide host-range of TSWV and its thrips vector is consistent with the geographic distribution. Other tospoviruses have more well-defined distribution. For example, GBNV, WBNV, and WSMoV, that are transmitted by *Thrips palmi*, a thrips species found only in the subtropics are only known to occur in Southeast Asia. Another anomaly is INSV. While INSV is reported to occur around the world, it is almost entirely limited to greenhouse-grown floral crops.

Host-Range and Virus Propagation

TSWV has one of the most diverse host-ranges of any plant-infecting virus. The virus infects over 925 plant species belonging to 70 botanical families, both monocots and dicots. In addition, TSWV infects approximately ten thrips species. Important economic plants susceptible to TSWV include tomato, potato, tobacco, peanut, pepper, lettuce, papaya, and chrysanthemum. Other tospoviruses (e.g., IYSV) have much narrower host-ranges and thus the broad host-range of TSWV is not characteristic of the genus. These viruses can be transmitted mechanically or by their thrips vector, but are not transmitted transovarially, by plant seeds or pollen. Purified RNA preparations are not infectious. There are no robust plant or insect culture systems for tospoviruses. However, plant and insect protoplasts have been successfully inoculated.

Virion Properties

Tospovirus virions are quasispherical, enveloped particles 80–120 nm in diameter (**Figure 1**). Two viral coded glycoproteins, G_N and G_C, are embedded in the viral envelope and form surface projections 5–10 nm long. Ribonucleoprotein (RNP) particles consisting of the viral RNA encapsidated in the nucleoprotein (nucleocapsid), and a small number of polymerase molecules are contained within the envelope. Nucleocapsids are pseudocircular due to noncovalent bonding of the complementary RNA termini. Intact virions as well as carefully prepared RNPs retrieved from sucrose or $CsSO_4$ gradients are infectious. There are several reports that TSWV and INSV isolates, while infectious, are defective for virion formation.

Genome Properties

Tospoviruses have a single-stranded, tripartite RNA genome with segments designated as L, M, and S in order of decreasing size (**Figure 2**). The termini of each of the RNA segments consist of an eight nucleotide sequence (5′ AGAGCAAU 3′) that is strictly conserved among all tospoviruses. The remaining untranslated region at the termini also has a high degree of complementarity. Base pairing at the termini between the inverted complementary sequences supports a pan-handle structure that most likely serves as a promoter for replication.

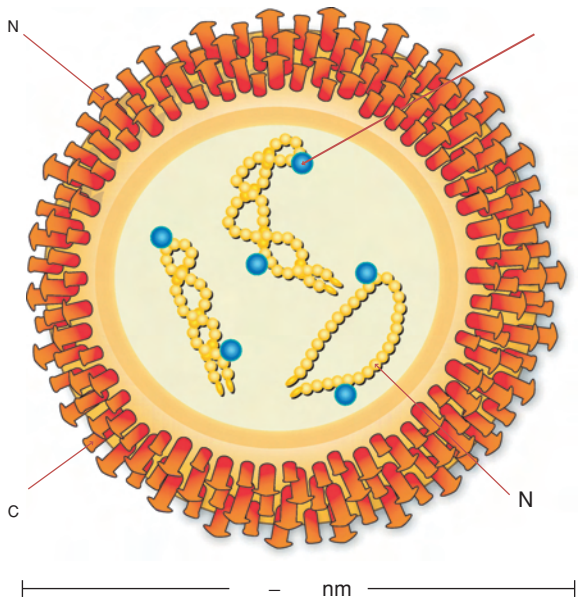

Figure 1 Tospovirus quasispherical virion particles. The S, M, and L RNA genomic segments are encapsidated by the nucleoprotein, are in association with L protein molecules, and form pan-handle structures due to the complementarity of their 5′ and 3′ ends. The glycoproteins G_N and G_C are embedded within the viral envelope.

The L RNA is 8.9 kbp and codes for the L or RdRp protein in the viral complementary (vc) sense (**Figure 2**). The M and S RNAs are in ambisense orientation. The M RNA is 4.8 kbp and codes in the viral sense for the nonstructural protein NSm and for the G_N/G_C precursor glycoprotein in the vc sense. The S RNA is 2.9 kbp and codes in the viral sense for the nonstructural protein NSs and the nucleocapsid protein in the vc sense (**Figure 2**).

TSWV M and S RNA IGRs have variable lengths, are A–U rich, and are the most hypervariable regions of the genome. The 5′ and 3′ ends of the IGRs are conserved, separated by variable sequences, deletions, and insertions. In addition, highly conserved sequences are embedded within the S RNA IGR. A 33 nucleotide (nt) duplication occurring in the S RNA IGR of some isolates has been correlated with loss of competitiveness in mixed infections of isolates with and without the duplication. A 31nt conserved sequence, with significantly higher GC-content compared to the remaining S RNA IGR, has also been found in some TSWV isolates. The IGRs of the M and S segments have high inclination for base pairing thought to be involved in initiation and termination of transcription. There is speculation that the termination of transcription is dictated by a conserved nucleotide sequence (CAACUUUGG) in the center of the S and M RNA IGR or that it is due to a secondary structure highly stabilized in the 31nt region referred to above.

Full length molecules of the M and S RNAs are found in infected tissue and purified virions in both the viral and vc sense (approximate ratio of 10:1), consistent with ambisense segments from other viruses. Defective interfering RNAs (DIs) associated with attenuated symptom expression and increased replication rate are also frequently observed. DIs from the L ORF in TSWV infected tissue are the result of and associated with attenuated infectivity. Deletions, frameshift, and nonsense mutations in the G_N/G_C ORF have been shown to interfere with thrips transmissibility and virion assembly. Recently, frameshift and nonsense mutations with unknown effect have also been identified in the N ORF. The formation of DIs is favored by repeated mechanical passage in certain plant hosts, high inoculum concentration, and low temperatures. Available evidence supports the hypothesis that secondary structure rather than sequence is the primary determinant of the site of deletion. There is also a high frequency of DIs that maintain the original reading frame resulting in translation of truncated proteins whose existence was confirmed in nucleocapsid preparations.

Protein Properties

The 331.5 kDa L protein encoded by the L RNA has been identified as the putative RdRp, through sequence homology with other members of the *Bunyaviridae* and identification of sequence motifs characteristic of polymerases. RdRp activity has been associated with detergent-disrupted TSWV virion preparations. The 33.6 kDa NSm protein encoded by the M RNA has been shown to induce tubule structures in plant protoplasts and insect (*Spodoptera* and *Trichoplusia*) cells. Induction of tubules in plants, ability to change the size exclusion limit of plasmodesmata, an early expression profile and complementation of cell-to-cell and systemic movement in a movement-defective tobacco mosaic virus vector is evidence that NSm is the TSWV movement protein and that it supports long-distance movement of viral RNAs. In thrips, NSm does not aggregate into tubules, indicating that this protein might not have any function in the vector's life cycle. It is also known that NSm specifically interacts with the N protein, the At-4/1 intra- and intercellular trafficking plant protein and binds single-stranded RNA in a sequence-nonspecific manner. An NSm homolog is absent in the animal infecting *Bunyaviridae*. The 127.4 kDa G_N/G_C precursor glycoprotein also coded by the M RNA contains a signal sequence that allows its translation on the endoplasmic reticulum. Proteolytic cleavage of the polyprotein does not require other viral proteins. The M_rs of G_N and G_C is 78 kDa and 54 kDa respectively. Evidence for the involvement of the glycoproteins in thrips transmission is provided by: (1) their interaction with proteins of the thrips vector, (2) their association with the insect midgut during acquisition, (3) the loss of thrips transmissibility of envelope-deficient mutants, (4) the presence of a

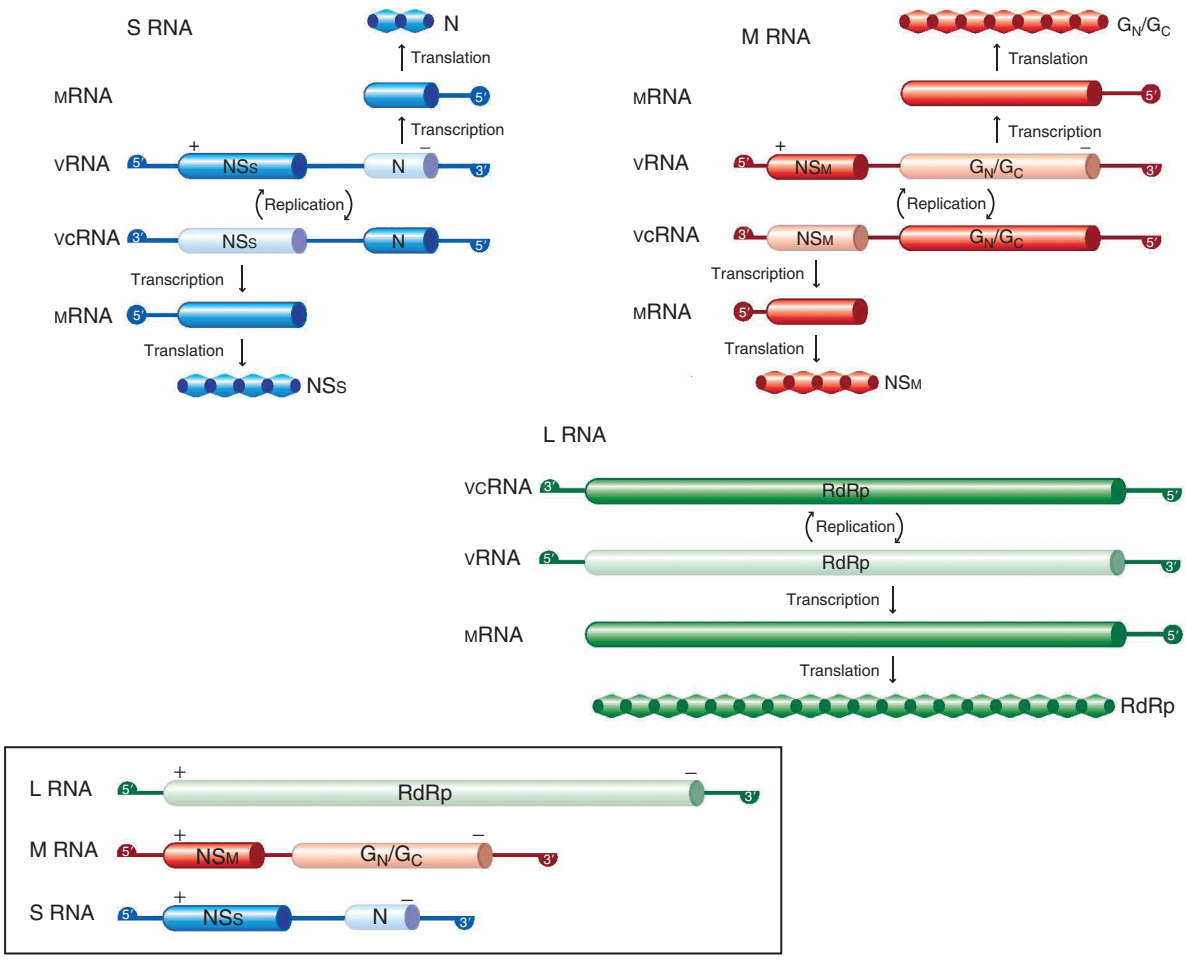

Figure 2 Tospovirus ambisense genome organization (inset in figure) and expression strategy. Positive (+) and negative (–) sense ORFs are dark and light shaded tubes respectively. Proteins from the S and M segments are translated from subgenomic mRNAs which are capped with 10–20 nt of non-viral orgain at the 5′ end.

glycoprotein sequence motif that is characteristic for cellular attachment domains and (5) the observation that only reassortants with the M RNA of a thrips-transmissible isolate rescue thrips transmissibility. Specifically, G_N is involved in virus binding and/or entry in thrips midgut cells, whereas G_C is a possible fusion protein playing a significant role in pH-dependent virus entry. It is also believed that these proteins are implicated in virion assembly. The NSs protein encoded on the S RNA is 52.4 kDa and accumulates to high levels as loose aggregates or paracrystalline arrays of filaments. NSs has RNA silencing suppressor activity, affects symptom expression in TSWV-infected plants, and is not present in the mature virus particle. The N protein, also encoded by the S RNA, ranges in size from 29 to 3 kDa depending on the virus. This protein encapsidates the viral RNA segments, is highly abundant, and is the predominant protein detected in serological assays. A 'head-to-tail' interaction of the nucleoprotein N terminus (aa 1–39) with the C terminus (aa 233–248) results in multimerization.

Replication

Replication of viral RNA and assembly of virions occurs in the cytoplasm of both plant and insect cells. Tospovirus replication, however, has mainly been described based on plant infection. Upon entry into the plant cell, the virus loses its membrane and releases infectious nucleocapsids into the cytoplasm. In thrips cells, infection by tospoviruses is accommodated by binding of the viral surface glycoproteins to a host cell receptor(s) (possibly a 50 kDa and/or a 94 kDa protein). This is followed by release of infectious nucleocapsids into the cytoplasm, through fusion between the viral and thrips membranes possibly initiated by low pH. Depending on the concentration of N protein, the viral RNA is either transcribed or replicated. At low N concentrations, the polymerase transcribes mRNAs that are translated into the virus proteins. Translation of proteins from the S and M ambisense RNAs occurs from subgenomic mRNAs (**Figure 2**). The S and M subgenomic mRNAs are capped

at the 5′ terminus with 10–20 nucleotides of nonviral origin indicating that tospoviruses utilize a cap-snatching mechanism to regulate transcription. Leader sequences of alfalfa mosaic virus have also been detected as caps of TSWV mRNA in mixed infections of the two viruses. The TSWV transcriptase has a reported preference for caps with multiple base complementarity with the viral template. Upon increase of N protein concentration, the polymerase switches its mode to replication with the viral RNA serving as the template. Replicated viral RNAs form RNPs that can presumably associate with the NSm protein for movement through plasmodesmata to adjacent plant cells through tubular structures. Alternatively, RNPs form new virions by associating with the glycoproteins and budding through the Golgi membranes. Virions are initially double-membraned, but soon coalesce and form groups of virions with a single membrane surrounded by another membrane.

Pathogenicity and Cytopathology

Tospoviruses are noted for the severity of the diseases they cause in plants. Symptoms are highly variable, depending on the virus, the virus isolate, the host plant, time of the year, and environment, and are thus of little diagnostic value. Chlorosis, necrosis, ring or line patterns, mottling, silvering, and stunting often appear on inoculated and systemically infected leaves. Systemic invasion of plants is frequently nonuniform. Stems and petioles may exhibit necrotic lesions. Observed symptoms often mimic disease and injury caused by other biotic and abiotic stresses. Infection of younger plants results in severe stunting and high mortality rates. TSWV has been shown to affect more severely *Datura*, *Nicotiana,* and *Physalis* plants under a specific temperature regime (daytime, $29 + 2\,^{\circ}C$, nighttime, $24 + 3\,^{\circ}C$). The effect of tospovirus infection on thrips has been controversial, due to the confounded effects of plant host, virus, and environment on the insect vector and the genetic variability of thrips and virus populations. TSWV infection of *F. occidentalis* provided evidence that thrips exhibit an immune response to the virus. Recent work with TSWV-infected *F. fusca* reared on infected foliage indicated a direct effect of the virus on thrips resulting in reduced fitness. The same study showed that the plant infection status and the TSWV isolate have also an effect on the insect, explaining the variable results obtained from independent studies of virus pathogenicity on the insect vector.

Tospoviruses induce characteristic cytopathic structures that are host and virus-isolate dependent. In addition to virions, inclusions of viroplasms consisting of the NSs or N protein may be abundant in the cytoplasm. NSs may aggregate in loose bundles (e.g., TSWV) or in highly ordered paracrystalline arrays (e.g., INSV). Excess N protein occurs in granular electron dense masses. NSs and nucleocapsid protein inclusions have been observed in infected plant and insect cells. NSm protein induces tubule structures in plant protoplasts and insect cells.

Transmission and Epidemiology

Tospoviruses are transmitted from plant to plant by at least ten thrips species in the genera *Frankliniella*, *Scirtothrips*, and *Thrips*. Among the more common vectors are *Frankliniella occidentalis*, *F. fusca*, *F. schultzei*, *F. intonsa*, *F. bispinosa*, *Thrips palmi*, *T. setosus*, and *T. tabaci*. Thrips feed on the cytoplasm of plant cells. The contents of infected cells are ingested and the virus is transported along the lumen of the digestive tract to the midgut, the primary binding and entry site into the insect cells. The brush border of the midgut lumen is the first membrane barrier that the virus encounters. The virus replicates in the midgut and crosses the basement membrane into the visceral muscle cells. The virus subsequently enters the primary salivary glands. It has been hypothesized that the virus moves from the midgut to the salivary glands through infection of ligament-like structures, or when there is direct contact between membranes of the visceral muscles and the primary salivary glands during the larval stages of development. A less plausible hypothesis is that the virus infects the salivary glands after entry and circulation in the hemocoel. Viral inoculum is introduced into plants in the insect saliva coincident with feeding on the plant by adult thrips.

The process of successful acquisition occurs only by larvae and acquisition rates decrease as larvae develop, affecting adult vector competency. Vector competency is also determined by the thrips' feeding preference on a particular host, the uniformity of distribution of virus in plant cells, the rate of virus replication in the midgut, and the extent of virus migration from the midgut to the visceral muscle cells and the salivary glands. In some instances the virus can be acquired by adult thrips and infects midgut cells, but is unable to spread further possibly due to the formation of an age-dependent midgut barrier (e.g., basal lamina). Research has shown the existence of thrips transmitters with detectable levels of virus, nontransmitters with detectable virus, and nontransmitters with no detectable virus, supporting multiple sites for vector specificity between tospoviruses and thrips. Evidence for replication of the virus in the insect vector is based on the accumulation of NSs and the visualization of viral inclusions in midgut epithelial cells, muscle cells, and the salivary glands. Although the virus is maintained transtadially throughout the life of the insect, there is no evidence for transovarial transmission. Thus, each generation of thrips must acquire the virus during the larval stages.

The primary dispersal of tospoviruses is by adult thrips and dissemination of infected somatic tissue in vegetatively propagated crops. These viruses are thought to move long distances in thrips carried by wind currents. They may also survive in commercial agricultural systems in weeds that serve as a bridge between crops. Infected summer weeds (e.g., in NC *I. purpurea*, *I. hederacea*, *M. verticillata*, *A. palmeri*, *C. obtusifolia*, *R. scabra*, *Ambrosia artemisiifolia* L., *Polygonum pensylvanicum* L., *and Chenopodium album* L.) are the principal source for spread of TSWV to winter annual weeds, from which the virus is spread to susceptible crops in spring. Secondary spread within a crop can only occur in crops that concomittantly support virus infection and reproduction of the vector as only the larval stage can acquire the virus for transmission. Transmission through plant seed and pollen has not been conclusively demonstrated. The emergence of these viruses as serious pathogens in crops has been attributed to the increased prevalence of *F. occidentalis* as an agricultural pest on a worldwide basis.

Genetics and Evolution

The knowledge base for genetics and evolution of tospoviruses has been derived almost exclusively from TSWV. TSWV has a characteristic ability to adapt to new or resistant hosts and to lose phenotypic characters following repeated passage in experimental hosts, especially *Nicotiana benthamiana*. The virus occurs in plants as a heterogeneous mutant population with one or two predominant haplotypes and 9–21 rare haplotypes. Recent research shows that natural TSWV variants evolve in nature through recombination, random genetic drift, and mutation. Intergenomic recombination is important for the genesis and evolution of ancestral TSWV lineages. Genetic drift during thrips transmission and mutation concurrent with virus population growth, shape the genetic architecture of the most recently evolved lineages. The existence of single viral strains as mutant populations and recombination in ancestral viral lineages arm TSWV with a unique genetic reservoir for causing disease and spreading in epidemic proportions in nature. Additional research at the species level supports a distinct TSWV geographical structure and the occurrence of species-wide population expansions. TSWV is also known to use reassortment of genome segments to adapt to resistant hosts under specific laboratory conditions. The determinants of adaptation to resistance in tomato and pepper have been mapped to the M and S RNAs respectively. Little is known about the thrips–tospovirus coevolution and the genetic diversity of the thrips vector itself. The altered status of *Thrips tabaci* as a TSWV vector is one of the very few likely examples of coevolution between tospoviruses and their insect vector.

Detection and Diagnosis

Tospoviruses have certain unique biological properties that are useful for diagnosis. These viruses can be mechanically transmitted by gently rubbing inoculum on plants dusted with carborundum. *Nicotiana glutinosa* L., *Chenopodium quinoa* Wild., and garden petunia give characteristic lesions that progress as spots or concentric zones, and sometimes as lethal necrosis. Tospoviruses can also be identified by electron microscopy of leaf-dip preparations on thin sections of infected plants. Additional techniques for identification are based on the enzyme-linked immunosorbent assay (ELISA) using polyclonal and monoclonal antibodies, and detection of viral-specific nucleic acids using ribo- and cDNA-probes. The reverse transcription-polymerase chain reaction (RT-PCR) is the most powerful and commonly used technique for detecting small amounts of tospovirus RNA. Real time RT-PCR has been successfully used to detect and quantify TSWV in leaf soak and total RNA extracts from infected plants and thrips. RT-PCR with degenerate primers can detect five distinct tospovirus species. Tissue selection and sampling strategy are critical factors in TSWV diagnosis and detection regardless of the technique. Because, TSWV titer varies throughout the plant and does not spread uniformly throughout plants that are 'systemic' hosts, sampling strategies should be validated in each situation.

Prevention and Control

Tospoviruses cause significant economic losses annually, due to suppressed growth, yield, and reduced quality. These viruses can be partially managed in well-defined cropping systems such as glasshouses by obtaining uninfected plant propagules, implementing a preventative thrips control program in high risk areas, together with constant monitoring of production areas for thrips and infected plants. However, these strategies are costly and require intensive management. Control in field crops is problematic due to the array of external sources of inoculum. Vector control is generally ineffective against the introduction of virus from external sources, due to thrips' high fecundity, ability to develop insecticide resistance, and to infest many TSWV-susceptible crops. Some measure of control can be achieved using thrips-proof mesh tunnels in the field and reflective mulches. Cultural practices such as utilization of virus-tested planting stock, careful selection of planting dates, removal of cull piles and weeds, rotation with nonsusceptible crops, prevention of planting TSWV-susceptible crops adjacent to each other, reduced in-field cultivation to avoid movement of thrips from infected sources, can reduce the spread of tospoviruses. In peanuts, higher plant density, planting from early until late May and application of selected

insecticides have reduced the incidence of TSWV. In flue-cured tobacco, early-season treatment with activators of plant defenses and insecticides have also significantly reduced TSWV incidence.

Deployment of resistant cultivars has provided benefits in only three of the crops infected by TSWV. Although little is known about the benefits of host resistance against most of the tospoviruses, TSWV defeated nearly every resistance gene deployed against it in many crops. Single-gene resistance is available for TSWV in a limited number of tomato (*Sw-5*) and pepper (*tsw*) cultivars. Naturally occurring, resistance-breaking isolates of TSWV have been recovered from pepper and tomato cultivars containing their respective resistance genes. A co-dominant cleaved amplified polymorphic sequence (CAPS) marker has been developed for TSWV marker-assisted selection in pepper. 'Field' resistance has been reported for some peanut varieties. Progress has been made in understanding the genetic basis of the ability of TSWV to overcome single gene resistance by mapping determinants to specific segments of the TSWV genome and characterizing the selection process. Pathogen-derived resistance utilizing the N and NSm genes has been effective in some greenhouse and field tests; however, isolates have been obtained that overcome nucleocapsid mediated resistance. Best suppression of TSWV epidemics has been achieved with the integrated use of moderately resistant cultivars, chemical, and cultural practices. The impact of these viruses on agricultural production is in large part due to the absence of durable forms of resistance in the affected crops or other highly effective control measures.

Future Perspectives

The last decade has been characterized by exciting developments in our understanding of tospovirus molecular biology, evolution, and virus–host relationships. Further progress in understanding replication and gene function requires the development of efficient reverse genetics, plant and insect culture systems for tospoviruses. In addition, effective management of these viruses will depend on a deeper understanding of thrips' genetic diversity, virus–thrips coevolution and the changes in viral and thrips population dynamics upon exertion of specific selective forces. Such understanding can be acquired only through integrated research at the interface of virology, entomology, and ecology.

Glossary

Mycoviruses Viruses that infect and multiply in fungi.

Pseudoknot A secondary structure in viral mRNA that slows movement of the ribosome and may cause a frameshift that allows entry to an alternative reading frame during translation.

Ribosomal frameshifting Ribosomes switching reading frame on an mRNA, in response to the presence of a slippery site and/or a pseudoknot, to synthesize a protein or a polyprotein from two overlapping reading frames.

Introduction

The discovery of the killer phenomenon in the 1960s in yeast (*Saccharomyces cerevisiae*) and in the smut fungus (*Ustilago maydis*) eventually led to the discovery of the isometric double-stranded (ds) RNA mycoviruses with nonsegmented genomes, currently classified in the genus *Totivirus* (family *Totiviridae*). Killer strains of yeast or smut secrete a protein toxin to which they are immune, but which is lethal to sensitive cells. The precursor to the killer toxin is encoded by a satellite dsRNA, which is dependent on a helper virus with nonsegmented dsRNA genome (totivirus) for encapsidation and replication. Unlike the helper totiviruses associated with the yeast and smut killer systems, other members of the family *Totiviridae*, including the viruses that infect filamentous fungi (members of the newly proposed genus *Victorivirus*) and those that infect parasitic protozoa (members of the genera *Giardiavirus* and *Leishmaniavirus*), are not known to be associated with killer phenotypes. Purified preparations of some of these viruses, however, can contain dsRNA species suspected of being satellite or defective dsRNAs.

The isometric dsRNA totiviruses that infect fungi and protozoa are unique among dsRNA viruses in that their genomes are undivided, whereas the genomes of all other dsRNA viruses are segmented. The yeast and smut totiviruses and associated killer systems, as well as the totiviruses infecting parasitic protozoa, are discussed elsewhere in this encyclopedia. In addition to examining the similarities and differences among members of the family *Totiviridae*, this article will focus on the totiviruses that infect filamentous fungi, a group of viruses that are phylogenetically more closely related to each other than to other totiviruses and utilize a different strategy to express their genomes.

Taxonomy and Classification

The family *Totiviridae* encompasses a broad range of viruses characterized by isometric particles, ~40 nm in diameter, that contain a monosegmented dsRNA genome coding for a capsid protein (CP) and an RNA-dependent RNA polymerase (RdRp). At present, three genera are recognized: *Totivirus*, *Giardiavirus*, and *Leishmaniavirus*. Viruses currently placed in the genus *Totivirus* infect yeast, smut fungi, or filamentous fungi, whereas those in the latter two genera infect parasitic protozoa. Two distinct RdRp expression strategies have been reported for species in the family *Totiviridae*: those that express RdRp as a fusion protein (CP–RdRp) by ribosomal frameshifting, such as saccharomyces cerevisiae virus L-A and the viruses that infect parasitic protozoa; and those that synthesize RdRp as a separate nonfused protein by an internal initiation mechanism, as shown for Hv190SV and proposed for all of the other totiviruses that infect filamentous fungi. Although *Helminthosporium victoriae 190S virus* (Hv190SV) is the only species recognized by the International Committee on Taxonomy of Viruses (ICTV) as a member of the genus *Totivirus*, the complete nucleotide sequences of several tentative totiviruses that infect filamentous fungi have recently been reported (**Table 1**). Sequence and phylogenetic analyses have demonstrated that these viruses have many properties in common with Hv190SV and that they are more closely related to each other than to the viruses infecting the yeast and smut fungi. A new genus (genus *Victorivirus*) was recently proposed to accommodate Hv190SV and the related viruses infecting filamentous fungi, with Hv190SV as the type species. The name 'Victorivirus' is derived from the specific epithet of *H. victoriae*, the host of the proposed type species.

In addition to fungal and protozoal hosts, totiviruses may also have crustacean hosts. A nonsegmented dsRNA virus with isometric particles, designated penaeid shrimp infectious myonecrosis virus (IMNV), was recently isolated from diseased penaeid shrimp and tentatively assigned to the family *Totiviridae*. IMNV is the causal agent of the shrimp myonecrosis disease characterized by necrosis of skeletal muscle, particularly in the distal abdominal segments and tail fan. Phylogenetic analysis based on the RdRp region of viruses in the totivirus family suggests that giardia lamblia virus (GLV; genus *Giardiavirus*) is the closest relative to IMNV. Interestingly, both IMNV and GLV, unlike all other members of the family *Totiviridae*, are infectious as purified virions. IMNV is presently unclassified and it has yet to be determined whether it is a member of a novel genus in the family *Totiviridae* or whether IMNV is a member of a novel family of dsRNA viruses that infect invertebrate hosts. The complete nucleotide sequences of several members and tentative members of the family *Totiviridae* have been published and the GenBank accession numbers are listed in **Table 1**.

Virion Properties

The buoyant densities in CsCl of virions of members of the totivirus family range from 1.36 to 1.43 g cm^{-3}, and the sedimentation coefficients of these virions range from

[b]RdRp is expressed or proposed to be expressed as a CP–RdRp fusion protein.

160S to 190S (S_{20w}, in Svedberg units). Particles lacking nucleic acid sediment with apparent sedimentation coefficients of 90–105S. Isolates of ScV-L-A and UmV-H1 may have additional components, containing satellite or defective dsRNAs, with different sedimentation coefficients and buoyant densities. Virion-associated RdRp activity can be detected in all totiviruses examined to date. Protein kinase activity is associated with Hv190SV virions; capsids contain phosphorylated forms of CP.

Virion Structure and Composition

The totiviruses have isometric particles, approximately 40 nm in diameter, with icosahedral symmetry (**Figure 1**). The capsids are single-shelled and encompass a single major polypeptide. The capsids consist of 120 CP subunits of molecular mass in the range of 76–98 kDa. The capsid structures of three members of the family *Totiviridae* have been determined, at least one (the yeast L-A virus) at near atomic resolution using X-ray crystallography, and the other two (UmV-H1 and Hv190SV) at moderate resolutions (~1.4 nm) using cryo-transmission electron microscopy combined with three-dimensional image reconstruction. In all cases, the capsids of the fungal totiviruses are made up of 60 asymmetric CP dimers arranged in a '$T = 2$' layer. Compared to the yeast L-A capsid, the Hv190SV capsid shows relatively smoother outer surfaces. The quaternary organization of the Hv190SV particle, however, is remarkably similar to the yeast L-A and the cores of the larger dsRNA viruses of plants and animals: the A-subunits cluster around the fivefold axis and B-subunits around the threefold axis.

The ScV-L-A CP removes the 5′ cap structure of host mRNA and covalently attaches it to the histidine residue at position 154. The decapping activity is required for efficient translation of viral RNA. The published yeast L-A capsid structure reveals a trench at the active site of decapping. The decapping activity has yet to be demonstrated for any other totivirus CPs.

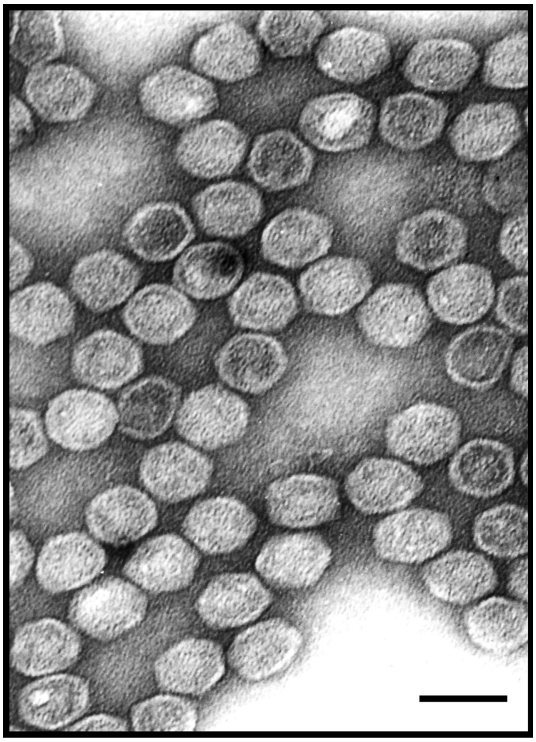

Figure 1 Negative contrast electron micrograph of particles of an isolate of *Helminthosporium victioriae 190SV*, the type species of the newly proposed genus *Victorivirus*. Scale = 50 nm.

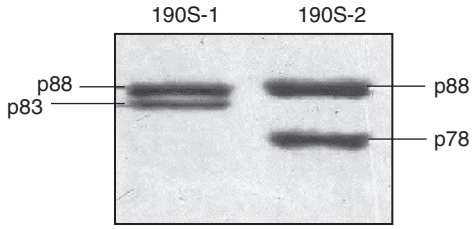

Figure 2 Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) analysis of Hv190SV sedimenting components 190S-1 and 190S-2. Purified preparations of Hv190SV contain two types of particles, 190S-1 and 190S-2, which differ slightly in sedimentation rates. The 190S-1 capsids contain p88 and p83, occurring in approximately equimolar amounts, and the 190S-2 capsids comprise similar amounts of p88 and p78. The capsid proteins p88 and p83 are phosphorylated, whereas p78 is nonphosphorylated.

Although a single gene encodes the capsid of Hv190SV, like other totiviruses, the Hv190SV capsid comprises two closely related major CPs, either p88 and p83 or p88 and p78. The capsids of all other totiviruses so far characterized appear to contain only a single major CP. Interestingly, HmTV-1-17, a totivirus infecting a filamentous fungus, has similar capsid heterogeneity to that of Hv190SV. It would be of interest to determine whether capsid heterogeneity and post-translational modification (phosphorylation and proteolytic processing) of the primary CP is a common feature of totiviruses infecting filamentous fungi (members of the tentative genus *Victorivirus*). Purified Hv190S virion preparations contain two types of particles, 190S-1 and 190S-2, which differ slightly in sedimentation rates (190S-1 is resolved as a shoulder on the slightly faster sedimenting component 190S-2) and capsid composition. The 190S-1 and 190S-2 virions are believed to represent different stages in the virus life cycle. The 190S-1 capsids contain p88 and p83, occurring in approximately equimolar amounts, and the 190S-2 capsids comprise similar amounts of p88 and p78. p88 and p83 are phosphoproteins, whereas p78 is nonphosphorylated (**Figure 2**). Totivirus virions encapsidate a single molecule of dsRNA, 4.6–6.3 kbp in size. Some totiviruses may additionally contain satellite dsRNAs or defective dsRNAs, which are encapsidated separately in capsids encoded by the totivirus genome.

Genome Organization and Expression

In general, the genome organization of the totiviruses infecting fungi and protozoa are similar: each virus genome contains two large open reading frames (ORFs); the 5′ proximal ORF encodes a CP and the 3′ ORF encodes an RdRp (see the genome organization of Hv190SV as an example; **Figure 3**). Except for LRV2-1 and UmV-H1, the RdRp ORF overlaps the CP ORF and is in the −1 frame (ScV-L-A, ScV-L-BC, Hv190SV, TVV-2, and GLV) or in the +1 frame (LRV1-1 and LRV1-4) with respect to the CP ORF. The RdRp ORF of LRV2-1 does not overlap the CP ORF, and is separated from it by a stop codon. The Umv-H1 genome contains only a single ORF that encodes a polyprotein that is predicted to be autocatalytically processed by a viral papain-like protease to generate the CP and RdRp proteins.

The totiviruses express their RdRps either as CP–RdRp (gag-pol-like) fusion proteins or as separate nonfused proteins. Expression of RdRp as a CP–RdRp fusion protein via −1 ribosomal frameshifting has been well documented for ScV-L-A. Virion-associated CP–RdRp has been detected as a minor protein in the capsids of ScV-L-A, ScV-L-BC, TVV, and GLV. Although CP–RdRp fusion proteins were neither detected *in vivo* nor associated with virions of LRV1-1, LRV1-4, or LRV2-1, expression of RdRp as a fusion protein by +1 ribosomal frameshifting or ribosomal hopping (LRV2-1) has been proposed.

The overlap region between ORF1 and ORF2 of ScV-L-A (130 nt), LRV1-1 and LRV1-4 (71 nt), and GLV (122 nt) contains the structures necessary for ribosomal frameshifting including a slippery site and a pseudoknot structure to promote fusion of ORF1 and ORF2 *in vivo*. Although the overlap region in TVV is short (14 nt), it contains a potential ribosomal slippage heptamer.

The overlap regions in the dsRNA genomes of Hv190SV and Hv190S-like viruses (members of the

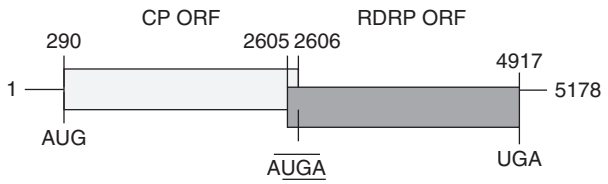

Figure 3 Genome organization of *Helminthosporium victoriae 190S virus*, the type species of the newly proposed genus *Victorivirus*. The dsRNA genome encompasses two large overlapping open reading frames (ORFs) with the 5′ ORF encoding a capsid protein (CP) and the 3′ ORF encoding an RNA-dependent RNA polymerase (RdRp). Note that the termination codon of the CP ORF overlaps the initiation codon of the RdRp ORF in the tetranucleotide sequence AUGA. Adapted from Ghabrial SA and Patterson JL (1999) *Encyclopedia of Virology*, 2nd edn., pp. 1808–1812. New York: Academic Press, with permission from Elsevier.

newly proposed genus *Victorivirus*), on the other hand, are of the AUGA type where the initiation codon of the RdRp ORF overlaps the termination codon of the CP ORF (**Figure 3**), suggesting that expression of RdRp occurs by a mechanism different from translational frameshifting. For Hv190SV, the stop codon of the CP ORF (nucleotide position 2606-UGA-2608) overlaps with the start codon (nucleotide position 2605-AUG-2607) for the RdRp ORF in the sequence AUGA (**Figure 3**). The complete nucleotide sequences of Hv190SV and eight other putative members of the family *Totiviridae* infecting filamentous fungi (members of the genus *Victorivirus*) have been reported and the sequences deposited in the GenBank, with Hv190SV being biochemically and molecularly best characterized of these (**Table 1**).

The 5′ end of the plus strand of all totiviruses dsRNAs examined to date is uncapped and the 3′ end is not polyadenylated. The 5′ end of Hv190SV dsRNA is uncapped and highly structured and contains a relatively long (289 nucleotides) 5′ leader with two minicistrons. These structural features of the 5′ untranslated region (UTR) of Hv190SV dsRNA suggest that the CP-encoding ORF1 (with its AUG present in suboptimal context according to the Kozak criteria) is translated via a cap-independent mechanism. The 5′-UTR of the leishmaniavirus LRV-1-1 functions as an internal ribosome entry site (IRES). Translation of the uncapped giardiavirus GLV mRNA in *Giardia lamblia* is initiated on a unique IRES element that contains sequences from a part of the 5′-UTR and a portion of the capsid coding region.

The UGA codon at position 2606–2608 of the Hv190SV genomic plus strand was verified by site-directed mutagenesis to be the authentic stop codon for ORF1 (**Figure 3**). The RdRp-encoding downstream ORF2 of Hv190SV is in a −1 frame with respect to ORF1 (**Figure 3**) and is expressed via an internal initiation mechanism (a coupled termination–initiation mechanism is proposed). The Hv190SV RdRp is detectable as a separate, virion-associated component, consistent with its independent translation from ORF2. The tetranucleotide AUGA overlap region, or a very similar structure, is characteristic of the overlap region of all putative members of the totivirus family that infect filamentous fungi (victoriviruses).

The initial report on the molecular characterization of IMNV, a monosegmented dsRNA virus infecting penaeid shrimp and tentatively assigned to the family *Totiviridae*, concluded that the viral genome encompasses two non-overlapping ORFs with ORF1 encoding a polyprotein comprised of a putative RNA-binding protein and a CP. The coding region of the RNA-binding protein was located in the first half of ORF1 and contained a dsRNA-binding motif in the first 60 amino acids. The second half of ORF1 encoded a CP, as determined by amino acid sequencing, with a molecular mass of 99 kDa. ORF2 encoded a putative RdRp with the eight conserved motifs characteristic of totiviruses. Phylogenetic analysis based on the RdRp clustered IMNV with GLV, the type species of the genus *Giardiavirus* in the family *Totiviridae*. Important novel features of the genome organization of IMNV, however, were most recently uncovered that has significant bearing on how the viral proteins are expressed. These features include two encoded '2A-like' motifs, which are likely involved in ORF1 polyprotein 'cleavage', a 199 nt overlap between ORF1 and ORF2, and the presence a 'slippery heptamer' motif and predicted RNA pseudoknot in the region of ORF1–ORF2 overlap. The latter features probably allow ORF2 to be translated as a fusion with ORF1 by '−1' ribosomal frameshifting. Although the generation of CP as a polyprotein and the potential involvement of encoded '2A-like' peptides (GDVESNPGP and GDVEENPGP) in processing of the polyprotein to release the major CP represent novel features not shared by totiviruses, the potential expression of RdRp as a CP–RdRp fusion protein via ribosomal frameshifting is a common strategy utilized by totiviruses for expressing their RdRps. Experimental evidence for the presence of the putative CP–RdRp fusion protein in purified virions or in infected tissues, however, is lacking.

Virus Replication Cycle

Limited information is available on the replication cycle of totiviruses and has mainly been derived from *in vitro* studies of virion-associated RNA polymerase activity and the isolation of particles representing various stages in the replication cycle. In *in vitro* reactions, the RNA polymerase activity associated with virions of the fungal totiviruses ScV-L-A, UmV-H1, and Hv190SV,

isolated from lag-phase cultures, catalyzes end-to-end transcription of dsRNA, by a conservative mechanism, to produce mRNA for CP, which is released from the particles. Purified ScV-L-A virions, isolated from log-phase cells, contain a less-dense class of particles, which package only plus-strand RNA. In *in vitro* reactions, these particles exhibit a replicase activity that catalyzes the synthesis of minus-strand RNA to form dsRNA. The resultant mature particles, which attain the same density as that of the dsRNA-containing virions isolated from the cells, are capable of synthesizing and releasing plus-strand RNA.

A proposed life cycle of Hv190SV is depicted in **Figure 4**. Host-encoded protein kinase and protease have been shown to be involved in post-translational modification of CP. Phosphorylation and proteolytic processing are proposed to play a role in the virus life cycle; phosphorylation of CP may be necessary for its interaction with viral nucleic acid and/or phosphorylation may regulate dsRNA transcription/replication. Proteolytic processing

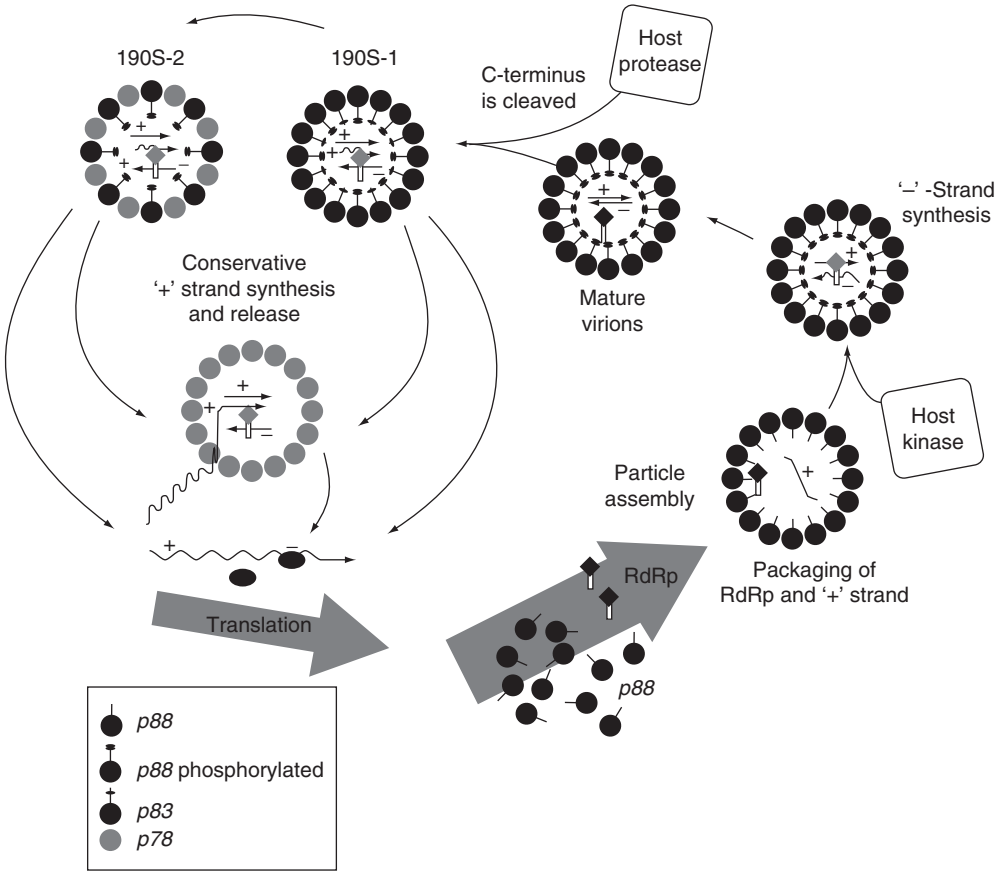

Figure 4 Life cycle of Hv190SV. Mature virions contain a single dsRNA molecule and their capsids are composed entirely or primarily of the capsid protein (CP) p88. Virions representing different stages of the virus life cycle can be purified from the infected fungal host *Helminthosporium victoriae* including the well-characterized 190S-1 and 190S-2 virions. These two types of virions differ in sedimentation rate, phosphorylation state, and CP composition; 190S-1 capsids contain p88 and p83, whereas the 190S-2 capsids contain p88 and p78 (p88 is the primary translation product of the CP gene; p83 and p78 represent post-translational proteolytic processing products of p88 at its C-terminus). p88 and p83 are phosphorylated, whereas p78 is nonphosphorylated. The virions with phosphorylated CPs (p88+p83) have significantly higher transcriptase activity *in vitro* than those containing the nonphosphorylated p78. Transcription occurs conservatively and the newly synthesized plus-strand RNA is released from the virions. Phosphorylation of CP is catalyzed by a host kinase, and is proposed to play a regulatory role in transcription/replication. A host-encoded protease catalyzes the proteolytic processing of phosphorylated p88; this occurs in two steps, leading first to p83 (the generation of the 190S-1 virions) and then to p78 (190S-2 virions). The conversion of p88-p83-p78 is proposed to play a role in the release of the plus-strand RNA transcripts from virions. The released plus-strand RNA is the RNA that is translated into CP and RNA-dependent RNA polymerase (RdRp) and packaged in capsids assembled from the primary translation product p88. It is not known whether p88 is phosphorylated before or after assembly. Synthesis of minus-strand RNA occurs on the plus-strand RNA template inside the virion; phosphorylation may be involved in turning on the replicase activity. Adapted from Ghabrial SA and Patterson JL (1999) *Encyclopedia of Virology*, 2nd edn., pp. 1808–1812. New York: Academic Press, with permission from Elsevier.

and cleavage of a C-terminal peptide, which leads to dephosphorylation and the conversion of p88 to p78, may play a role in the release of the plus-strand RNA transcripts from virions (**Figure 4**).

Biological Properties

There are no known natural vectors for the transmission of the fungal totiviruses. They are transmitted intracellularly during cell division, sporogenesis, and cell fusion. Although the yeast totiviruses are effectively transmitted via ascospores, the totiviruses infecting the ascomycetous filamentous fungi are essentially eliminated during ascospore formation. The leishmaniaviruses are not infectious as purified virions and are propagated during cell division. The giardiavirus GLV and the unclassified IMNV, on the other hand, are infectious as purified virions. Successful transfection of the protozoa *Giardia lamblia* has also been accomplished via electroporation with plus-strand RNA transcribed *in vitro* from GLV dsRNA. Whereas IMNV causes a myonecrosis disease in its crustacean host, GLV is associated with latent infection of its flagellated protozoan human parasite *G. lamblia*. GLV is released into the medium without lysing the host cells and the extruded virus can infect many virus-free isolates of the protozoan host.

There are no known experimental host ranges for the fungal totiviruses because of the lack of suitable infectivity assays. As a consequence of their intracellular modes of transmission, the natural host ranges of fungal totiviruses are limited to individuals within the same or closely related vegetative compatibility groups. Furthermore, mixed infections with two or more unrelated viruses are common, probably as a consequence of the ways by which fungal viruses are transmitted in nature. Dual infection of yeast with ScV-L-A and ScV-L-BC and the filamentous fungus *Sphaeropsis sapinea* with SsRV-1 and SsRV-2 are examples of mixed infections involving totiviruses. Dual infection of *H. victoriae* with Hv190SV and the chrysovirus Hv145SV is an example of a mixed infection involving two unrelated viruses belonging to two different families, a totivirus and a chrysovirus.

With the exception of IMNV, an unclassified virus tentatively assigned to the family *Totiviridae*, which causes a myonecrosis disease in shrimp, totiviruses are generally associated with symptomless infections of their hosts. A possible exception to this rule is Hv190SV, since mixed infections with Hv190SV and Hv145SV are associated with a debilitating disease of the fungal host. The disease phenotype and the two viruses are transmitted via hyphal anastomosis and diseased isolates are characterized by reduced growth, excessive sectoring, aerial mycelial collapse, and generalized lysis (**Figure 5**). The disease phenotype of *H. victoriae*, the causal agent of Victoria blight of oats, is of special interest not only because diseased isolates are hypovirulent, but also because of the probable viral etiology. The disease phenotype was also transmitted by incubating fusing protoplasts from virus-free fungal isolates with purified virions containing both the Hv190S and 145S viruses. The frequency of infection and stability of the newly diseased colonies, however, were very low, and verification of transmission was based on virus detection by immune electron microscopy. A systematic molecular approach based on DNA-mediated transformation of a susceptible virus-free *H. victoriae* isolate with full-length cDNA clones of viral dsRNAs is currently being pursued to verify the viral etiology of the disease phenotype and elucidate the roles of the individual viruses in disease development.

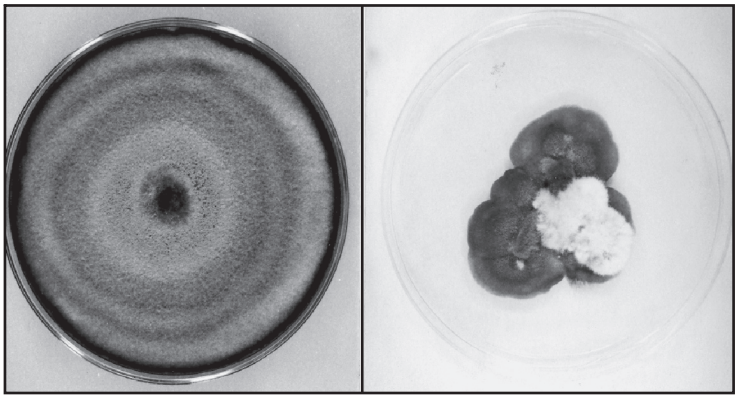

Figure 5 Colony morphology of virus-free (healthy), virus-infected (diseased) isolates of *Helminthosporium victoriae*. The colonies were grown for a week on potato dextrose agar medium at room temperature. The healthy colony shows uniform mycelial growth that extends to the entire plate, whereas the diseased colony is stunted and shows excessive sectoring.

A transformation vector for *H. victoriae* based on the hygromycin B resistance marker was constructed and used to transform an *H. victoriae* virus-free isolate with a full-length cDNA clone of Hv190SV dsRNA. The Hv190SV cDNA was inserted downstream of a *Cochliobolus heterostrophus GPD1* promoter and upstream of an *Aspergillus nidulans trpC* terminator signal. The hygromycin-resistant transformants expressed the Hv190SV CP, as determined by Western-blotting analysis. Transformation of a normal virus-free fungal isolate with a full-length cDNA of Hv190SV dsRNA conferred a disease phenotype. Symptom severity varied among the transformants from symptomless to severely stunted and highly sectored (**Figure 6**). Symptom severity correlated well with the level of viral capsid accumulation. Integration of the viral genome in the host DNA was verified by Southern blot hybridization analysis and expression of the viral dicistronic mRNA was demonstrated by northern analysis. Like natural infection, the primary translation product of the *CP* gene (p88) was phosphorylated and proteolytically processed to generate p83 and p78. The CP assembled into virus-like particles indistinguishable in appearance from empty capsids normally associated with virus infection. The empty capsids accumulated to significantly higher levels than in natural infections. Although the RdRp was expressed and packaged, no dsRNA was detected inside the virus-like particles or in the total RNA isolated from mycelium. Despite inability to launch dsRNA replication from the integrated viral cDNA, the demonstration that the ectopic 190SV cDNA copies were transcribed and translated and that the resultant transformants exhibited a disease phenotype provides convincing evidence for a viral etiology for the disease of *H. victoriae*. The role of the Hv145SV in disease development, however, has yet to be elucidated.

Virus–Host Relationships

The yeast killer system, comprised of a helper totivirus (ScV-L-A) and associated satellite dsRNA (M-dsRNA), is one of the very few known examples where virus infection is beneficial to the host. The ability to produce killer toxins by immune yeast strains confers an ecological advantage over sensitive strains. The use of killer strains in the brewing industry provides protection against contamination with adventitious sensitive strains. Totiviruses maintain only the genes that are essential for their survival (RdRp and CP), but make efficient use of host proteins. The host cells have evolved to support only a defined level of virus replication, beyond which virus infection may become pathogenic. Because of amenability to genetic studies, the yeast–virus system has provided significant information on the host genes required to prevent viral cytopathology. A system of six chromosomal genes, designated superkiller (or SKI) SKI2, SKI3, SKI4, SKI6, SKI7, and SKI8, negatively control the copy number of the totivirus ScV-L-A and its satellite M-dsRNAs. The only crucial function of these genes is to block virus multiplication. Mutations in any of these

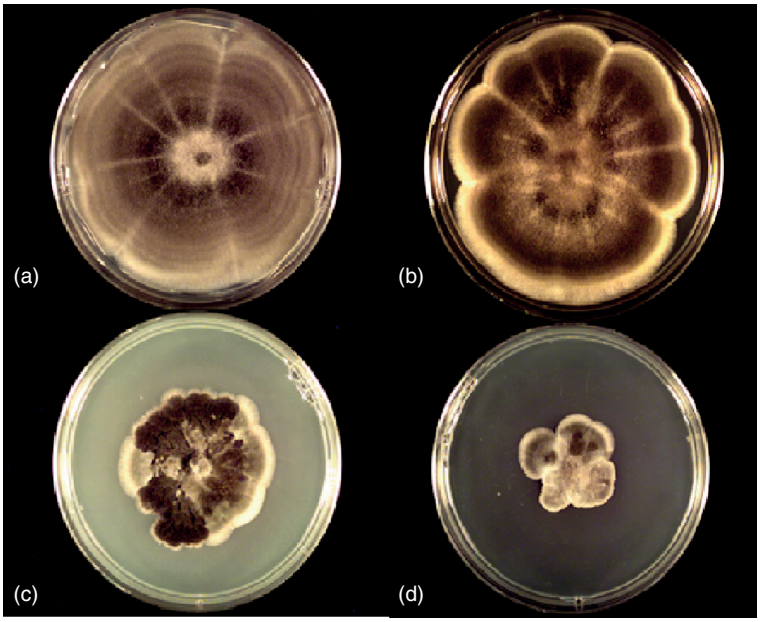

Figure 6 Colony morphology of a virus-free *Helminthosporium victoriae* isolate transformed with a full-length cDNA clone of the totivirus Hv190SV dsRNA. Colonies transformed with vector alone (a) or with recombinant vector containing full-length cDNA to Hv190SV dsRNA (b–d) were grown for a week at room temperature. Note that colonies (b)–(d) show increasingly more severe symptoms (reduced growth and sectoring).

SKI genes lead to the development of the superkiller phenotype as a consequence of the increased copy number of M-dsRNA. The SKI genes affect primarily the initiation of translation rather than the stability of mRNA, and are thus part of a cellular system that specifically blocks translation of nonpolyadenylated mRNAs (like the plus-strand transcripts of totiviruses). About 30 chromosomal genes, termed MAK genes (for maintenance of killer), are required for stable replication of the satellite M-dsRNA. Only three of these MAK genes are necessary for the helper virus (ScV-L-A) multiplication. Mutants defective in any of 20 MAK genes show a decreased level of free 60S ribosomal subunits. Since the *mak* mutations affecting 60S subunit levels are suppressed by *ski* mutations, and since the latter act by blocking translation of nonpolyadenylated mRNAs, the level of 60S ribosomal subunits is critical for translation of nonpolyadenylated mRNAs.

The Hv190S totivirus that infects the plant pathogenic fungus *H. victoriae* utilizes host-encoded proteins (a protein kinase and a protease) for post-translational modification of its CP. Phosphorylation and proteolytic processing of CP may play a role in regulating transcription and the release of plus-strand transcripts from virions (**Figure 4**).

The *H. victoriae*-virus system is well characterized and provides a useful model system for studies on virus–host interactions in a plant pathogenic fungus. A major attribute of this system is the fact that the virus-infected *H. victoriae* isolates exhibit a disease phenotype (**Figure 5**), which is rare among fungal viruses. Modulation of fungal gene expression and alteration of phenotypic traits as a consequence of mycovirus infection are little understood, with the exception of the chestnut blight fungus–hypovirus system. It was previously demonstrated that the fungal gene *Hv-p68* is upregulated as a result of virus infection and proposed that upregulation of this gene might play a role in virus pathogenesis (**Figure 7**). Hv-p68, a novel alcohol oxidase/RNA-binding protein, belongs to the large family of FAD-dependent GMC oxidoreductases with 67–70% sequence identity to the alcohol oxidases of methylotrophic yeasts. Hv-p68, however, shows only limited methanol-oxidizing activity and its expression is not induced in cultures supplemented with methanol as the sole carbon source (**Figure 7**). The natural substrate for Hv-p68 is not known, but the structurally similar alcohol oxidases are known to oxidize primary alcohols irreversibly to toxic aldehydes. Overexpression of Hv-p68 and putative accumulation of toxic intermediates was proposed as a possible mechanism underlying the disease phenotype of virus-infected *H. victoriae* isolates. Overexpression of Hv-p68 in virus-free fungal isolates, however, resulted in a significant increase in colony growth and did not induce a disease phenotype. Thus, overexpression of Hv-p68 *per se* is not sufficient to induce the disease phenotype in the absence of virus infection. If the function of *Hv-p68* is similar to that of the homologous alcohol oxidases of methylotrophic yeasts or other filamentous fungi, that is, irreversible oxidation of primary alcohols into aldehydes, then overexpression of Hv-p68 could lead to an accumulation of toxic aldehydes and development of disease phenotype. The finding that colonies overexpressing the Hv-p68 protein did not exhibit the disease phenotype and grew more rapidly than the nontransformed wild-type suggests that accumulation of toxic aldehydes did not occur, and that such aldehydes were probably assimilated into carbohydrates via the xylulose monophosphate pathway.

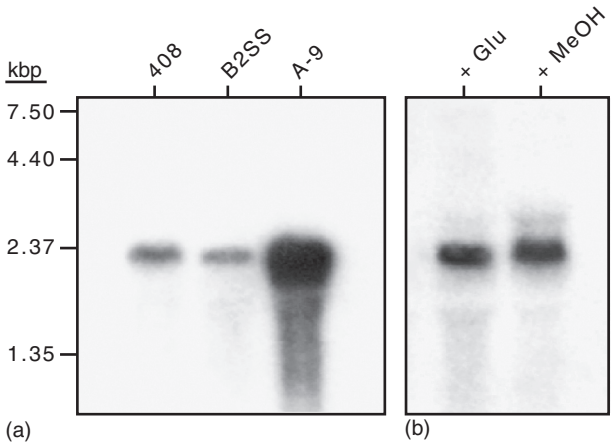

Figure 7 Northern analysis of Hv-p68 mRNA transcript levels. (a) Total RNA (25 μg) isolated from the virus-free isolates 408 and B-2ss and the virus-infected isolate A-9 were electrophoresed on a formaldehyde/ agarose gel, blotted, and hybridized under high stringency conditions with a radiolabeled probe for Hv-p68. Hv-p68 mRNA, 2.25 kbp in size, was detected in RNA samples from all three *H. victoriae* isolates. The level of Hv-p68 transcript in cultures of the virus-infected isolate A-9, however, was at least 15-fold higher than that for the virus-free isolates. (b) Total RNA (30 μg) isolated from cultures of the virus-free isolate B-2ss grown for 3 days in minimal medium supplemented with either glucose (Glu) or methanol (MeOH). Similar amounts of Hv-p68 mRNA were detected in total RNA isolated from fungal cultures supplemented with either glucose or methanol, as a carbon source. Reproduced from Soldevila AI and Ghabrial SA (2001) A novel alcohol oxidase/RNA-binding protein with affinity for mycovirus double-stranded RNA from the filamentous fungus *Helminthosporium* (*Cochliobolus*) *victoriae*. *Journal of Biological Chemistry* 276: 4652–4661, with permission from the American Society for Biochemistry and Molecular Biology, Inc.

Hv-p68, which co-purifies with viral dsRNA (mainly that of Hv145SV), is a multifunctional protein with alcohol oxidase, protein kinase, and RNA-binding activities. Hv-p68 is detectable as a minor component of Hv190SV capsid. Recent evidence strongly suggests that Hvp68 is the cellular protein kinase responsible for phosphorylation of the capsid proteins. The RNA-binding activity of Hv-p68 has been demonstrated by gel mobility shift and northwestern blot analysis. Furthermore, the RNA-binding domain of Hv-p68 was mapped to

the N-terminal region that contains the ADP-binding domain. Because dsRNA-binding proteins are known to sequester dsRNA and suppress antiviral host defense mechanisms, it is feasible that overexpression of the dsRNA-binding protein Hv-p68 may lead to the induction of the disease phenotype by suppressing host defense. This idea is consistent with the finding that overexpression of Hv-p68 led to enhancement in the accumulation of Hv145S dsRNA. The role of Hv145SV in the development of the disease phenotype, however, is not yet clear. Furthermore, it is curious that Hvp68 co-purifies with Hv145S dsRNA since the latter is predicted to be confined to the viral capsids where virus replication takes place. Recent results, however, suggest that a significant proportion of the Hv145V dsRNA does not appear to be encapsidated. Considering the multifunctional nature of the Hv-p68 protein, additional studies are needed to determine whether or not Hv-p68 upregulation has a role in viral pathogenesis.

Evolutionary Relationships among Totiviruses

Sequence comparison analysis of the predicted amino acid sequences of totivirus RdRps indicated that they share significant sequence similarity and characteristically contain eight conserved motifs. This sequence similarity was common to all totiviruses so far characterized including the totiviruses that infect the yeast, smut, and filamentous fungi, as well as those infecting parasitic protozoa. As indicated earlier, the viruses infecting filamentous fungi (members of the newly proposed genus *Victorivirus*) express their RdRp separate from the CP by an internal initiation mechanism,

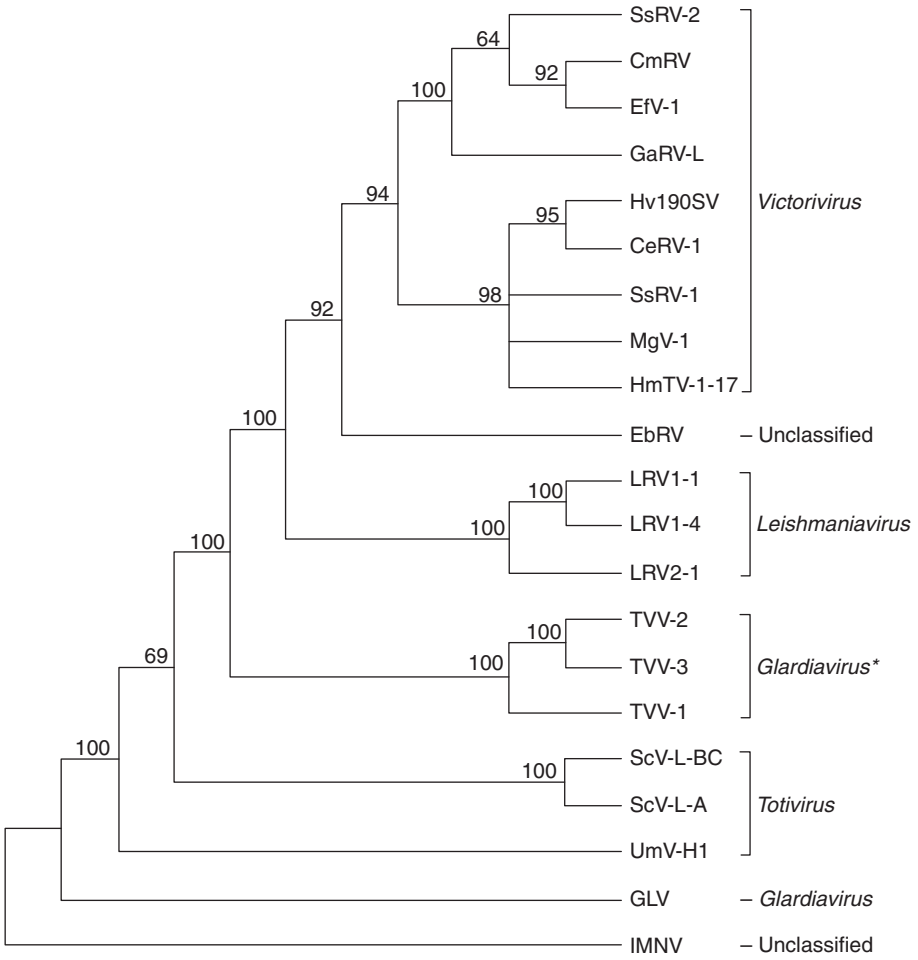

Figure 8 Neighbor-joining phylogenetic tree constructed based on the RdRp conserved motifs and flanking sequences. The RdRp sequences were derived from aligned deduced amino acid sequences of members of the family *Totiviridae* using the program CLUSTAL X. Motifs 1–8 and the sequences between the motifs, as previously designated by Ghabrial SA in 1998, were used. See **Table 1** for virus name abbreviations and GenBank accession numbers. The phylogenetic tree was generated using the program PAUP*. Bootstrap numbers out of 1000 replicates are indicated at the nodes. The tree was rooted with the RdRp of the penaeid shrimp infectious myonecrosis virus (IMNV), an unclassified virus tentatively assigned to the family *Totiviridae*, which was included as an outgroup.

whereas the other members of the family *Totiviridae* express their RdRps as fusion proteins (CP–RdRp), mainly via a ribosomal frameshifting mechanism. Phylogenetic analysis based on multiple alignments of amino acid sequences of totivirus RdRp conserved motifs (**Figure 8**) reflects these differences as the viruses infecting filamentous fungi (victoriviruses) are most closely related to each other and form a distinct large well-supported cluster (bootstrap value of 94%). Likewise, phylogenetic trees based on the CP sequences showed similar topology to those based on RdRp sequences (**Figure 9**). The fact that independent alignments of CP and RdRp sequences give similar phylogenetic relationships (**Figures 8** and **9**) further supports the creation of a new genus to accommodate the viruses infecting filamentous fungi.

The leishmaniaviruses LRV1, LRV2, and LRV4 (percent sequence identities of 46%) are most closely related to each other and form a discrete cluster with 100% bootstrap value. This is also true for the two yeast viruses ScV-L-A and ScV-LBC (RdRp identity of 32%), members of the genus *Totivirus*. UmV-H1, the third member in the genus *Totivirus* forms a phylogenetic clade distinct from the cluster of the two yeast viruses. This may reflect the difference in RdRp expression strategy between these viruses since UmV-H1 expresses its RdRp via the generation of a polyprotein followed by proteolytic processing to release the viral protein, whereas the yeast viruses express their RdRps as CP–RdRp fusion proteins via a –1 ribosomal frameshifting. It is of interest that Hv190SV and related viruses (victoriviruses) are phylogenetically more closely to the leishmaniaviruses than to the yeast viruses (**Figures 8** and **9**). It was previously hypothesized that leishmaniaviruses and the fungal totiviruses are of old origin having existed in a single-cell-type progenitor

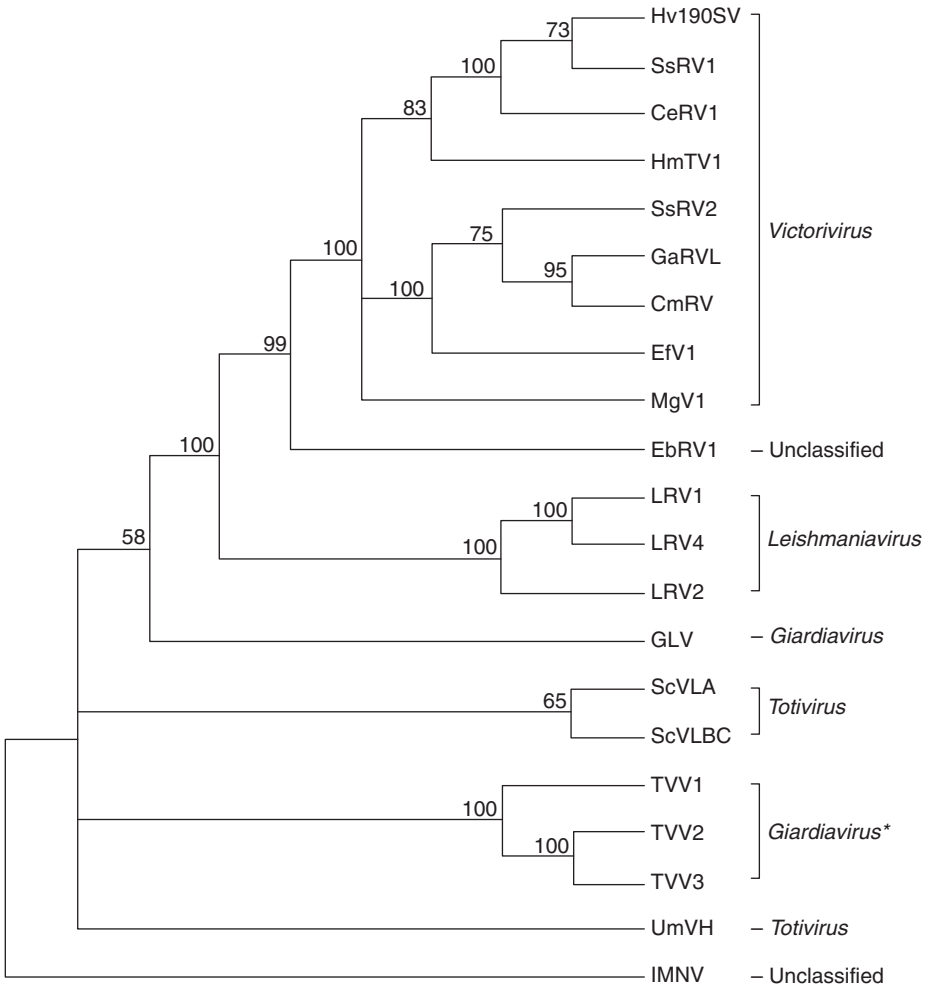

Figure 9 Neighbor-joining phylogenetic tree constructed based on the complete amino acid sequences of the capsid proteins of viruses in the family *Totiviridae*. The CP multiple sequence alignment was performed with the program CLUSTAL X and the phylogenetic tree was generated using the program PAUP*. See **Table 1** for virus name abbreviations and GenBank accessions numbers. Bootstrap numbers out of 1000 replicates are indicated at the nodes. The tree was rooted with the CP of the penaeid shrimp infectious myonecrosis virus (IMNV), an unclassified virus tentatively assigned to the family *Totiviridae*, which was included as an outgroup.

prior to the divergence of fungi and protozoa. The finding that the unclassified Eimeria brunetti RNA virus 1 (EbRV-1), which infects an apicomplexan parasitic protozoa, is more closely related to members of the new genus *Victorivirus* than to protozoal viruses is consistent with this idea. EbRV-1 may represent an intermediate progenitor in the evolution of 'victoriviruses'.

It is worth noting that the classification of TVV1, TVV2, and TVV4 as tentative members of the genus *Giardiavirus* is not supported by phylogenetic analyses based on the totivirus CPs or RdRps since they do not cluster with GLV, the type species of the genus *Giardiavirus*. The trichomonas vaginalis viruses are most closely related to each other as they form a distinct phylogenetic cluster with 100% bootstrap support (**Figures 8** and **9**). It would probably be justifiable to create a new genus in the family totiviridae to accommodate these viruses.

Taxonomic considerations of totiviruses may benefit greatly from elucidating the capsid structure of representatives of the genera *Leishmaniavirus* and *Giardiavirus* (including the tentative members TVVs). Furthermore, resolving the capsid structure of the unclassified viruses EbRV-1 and IMNV may prove useful for their taxonomic placement. Information on the genome organization and RdRp expression strategy of EbRV-1 is lacking and such information would be crucial in determining whether a novel genus in the family *Totiviridae* should be created for EbRV-1. IMNV has some features that distinguishes it from totiviruses including that it expresses its CP as a polyprotein that undergoes autoproteolytic processing. It is likely that IMNV would be classified as member of a novel family of dsRNA viruses that infect invertebrate hosts.

Transcriptional Regulation in Bacteriophage

R A Weisberg, D M Hinton, and S Adhya, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Introduction

Most bacteriophages regulate their own gene expression, many regulate host gene expression, and a few even regulate genes of other phages. Regulation enables temperate phages to establish and maintain lysogeny; it allows both temperate and virulent phages to carry out developmental programs in which groups of genes are expressed in an ordered, temporal sequence as their products are needed during the lytic growth cycle, and it

helps phages to commandeer the transcriptional resources of their hosts. In this article we describe the biological roles and mechanisms of regulation employed by several extensively studied model phages of *Escherichia coli*: temperate phage λ and virulent phages T4, T7, and N4. We emphasize transcriptional regulation, although we present examples of regulated RNA and protein stability as well. Investigations of these regulatory strategies have not only elucidated much about phage biology, but have also yielded many insights into regulatory mechanisms that are used by the host. We also describe several other strategies found in some less extensively studied phages.

Transcript Initiation and Elongation by Host RNA Polymerase

When a phage chromosome enters a cell, it encounters a host RNA polymerase (RNAP) that has specific requirements for promoter recognition. Prokaryotic cellular RNAPs consist of a large, multisubunit core, consisting of two copies of the α subunit, and one each of the β, β′, and ω subunits. Core has the ability to synthesize RNA, while a sixth subunit, σ-factor, is needed to identify and bind to promoters, and to initiate RNA synthesis at specific start sites. Primary σ-factors are used during exponential growth for the expression of housekeeping genes while alternate σ factors are needed to transcribe bacterial genes required under certain growth conditions or at times of stress. Many phages direct the synthesis of transcription factors that interact with, modify, or replace host σ. Another class of phage-encoded factors targets core subunits, and these factors can regulate either transcript initiation or transcript elongation.

Hundreds of prokaryotic σ factors have been identified, and they share up to four regions of similar sequence and function. Primary σ factors, like σ^{70} of *E. coli*, have three well-characterized regions with the potential to recognize and bind promoters. Residues in region 2 interact with a −10 DNA element (positions −12 to −7), residues in region 3 contact an extended −10 (TGn) motif (positions −15 to −13), and residues in region 4 contact a −35 element (positions −35 to −29) (**Figure 1**; the negative numbers indicate the number of base pairs upstream of the transcription start point). Only two of these three contacts are necessary for good promoter activity, and the majority of host promoters are −10/−35 promoters that use the DNA binding of regions 2 and 4. The −10/−35 promoters also require an interaction between residues in region 4 and a structure in core, called the β-flap, which is required to position region 4 correctly for its contact with the DNA.

RNAP also contacts host promoters through interactions between the C-terminal domain (CTD) of the α-subunits of polymerase core and A–T-rich sequences located between −40 and −60 (UP elements). Although RNAP contains two α subunits, they are not equivalent; one is bound to β and the other is bound to β′. Each α-CTD can interact specifically with a promoter proximal UP element, centered at position −41, or a promoter distal UP element, centered at position −52. In addition, the α-CTD domains can interact nonspecifically with DNA located in the −40 to −60 region.

Initiation of transcription from a −10/−35 promoter by host RNAP is a multistep process. After binding to the promoter through the interactions of σ^{70} with the −10 and −35 elements, the enzyme distorts a region around the −10 element, a step called isomerization, and becomes

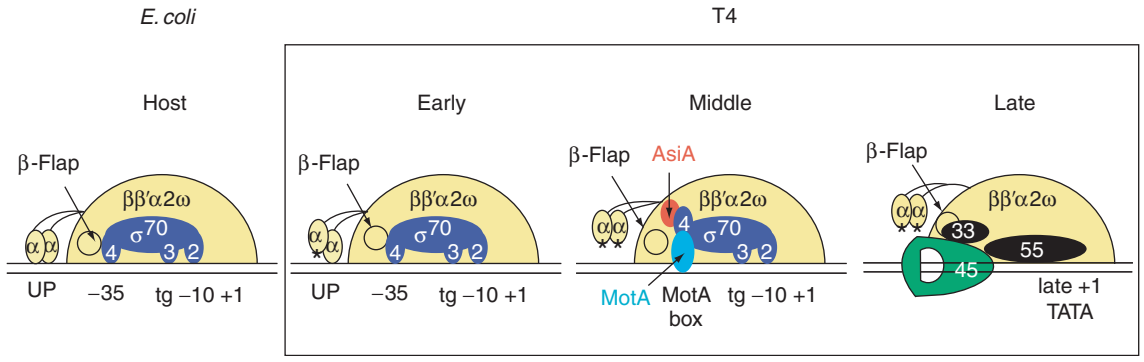

Figure 1 Changes to (*E. coli*) RNAP during T4 infection. Panels from left to right present cartoons of RNAP at host, T4 early, T4 middle, and T4 late promoters. Core polymerase (β, β′, α_2, and ω) is in tan. CTDs of α-subunits, which can interact with upstream promoter DNA (UP), and the β-flap are indicated. Region 2, 3, and 4 of σ^{70}, which recognize a −10 element, TGn, and a −35 element, respectively, are in dark blue. T4-catalyzed ADP-ribosylation of an α-CTD, which prevents the interaction of α-CTD with DNA, is denoted with a star. Recognition of a T4 middle promoter, which contains a σ^{70} −10 element and a MotA box element, requires σ^{70}-containing RNAP, the T4 activator, MotA, and the T4 coactivator, AsiA. Recognition of a T4 late promoter, which has a TATA element at −10, requires core polymerase, a T4 α-factor composed of gp33 and gp55, and the T4 activator gp45. See text for details.

competent to initiate synthesis of an RNA chain that is complementary to the template strand of the DNA and that grows in a 5′ to 3′ direction. As the chain grows, its association with the template and enzyme is stabilized, principally through the formation of 8–9 bp of RNA:DNA hybrid adjacent to the 3′-end. Upstream of this point, the nascent transcript dissociates from the template strand of the DNA, and an additional 5–6 nt fill an exit channel before the chain emerges from the enzyme. During this process, the newborn elongation complex (EC) releases its grip on the promoter and begins translocating along the template at a rate of about 50 bp $^{-1}$s. Occupancy of the exit channel by RNA weakens binding of σ^{70} to the core and facilitates σ^{70} release from the EC. However, the kinetics of σ^{70} release are controversial, and there is evidence that it can remain associated with the EC even after considerable translocation.

Transcript elongation stops when the EC reaches a sequence that encodes a transcription terminator, at which point RNAP dissociates from the template and the RNA. Two classes of terminators are known in *E. coli*: intrinsic and Rho-dependent. Intrinsic terminators are nascent transcripts that can form a stable, base-paired stem–loop or hairpin that is followed by a U-rich stretch. Termination occurs within the U-rich stretch, typically 6–7 nt from the base of the hairpin. Although the nascent terminator transcript is sufficient for termination, the efficiency can be altered by proteins. Rho protein, which is necessary for termination at the second class of terminator, binds to nascent RNA upstream of the termination point. Once bound, it can use ATP to translocate in a 5′ to 3′ direction toward the EC. It is believed that termination occurs when Rho catches up to a paused EC.

Phage T4

T4 is the best-characterized member of the T4-type phages of the family *Myoviridae*, consisting of phages distinguished by a contractile tail. T4 has a 169 kbp linear chromosome, which is terminally redundant and circularly permuted. Consequently, the T4 genome is shown as a circle (**Figure 2**). Injection of the DNA into the host initiates a pattern of T4 gene expression that results in a burst of phage about 20 min after infection. The production of phage proteins is regulated primarily at the level of temporally controlled transcription through the synthesis of early, middle, and late RNAs.

T4 Early Transcription

Productive T4 infection requires exponentially growing cells. Consequently, polymerase containing σ^{70} is the major species present when T4 infects. A top priority for T4 is to rapidly commit the host polymerase to its agenda.

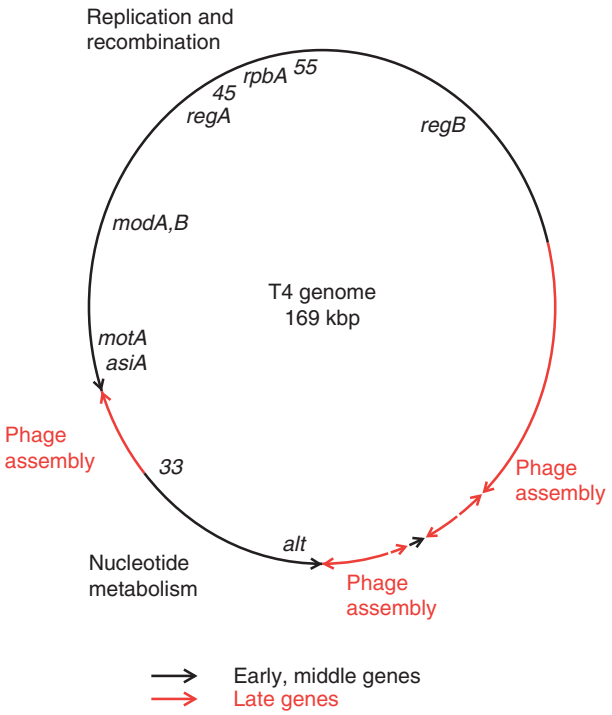

Figure 2 Map of bacteriophage T4. The 169 kbp linear T4 DNA is represented as a circle because it is circularly permuted and terminally redundant. Black regions contain early/middle genes, which include genes whose products are needed for DNA replication and recombination and nucleotide metabolism. Red regions contain late genes, whose products are primarily involved in phage assembly. The positions of specific genes referred to in the text are also shown.

It accomplishes this task through multiple strategies. Immediately after infection, T4 programs strong transcription from its early promoters, which are recognized by σ^{70} containing host RNAP. These promoters are needed for expressing early genes, many of which encode proteins that are involved in quickly moving the host resources to the phage, such as nucleases that degrade the host DNA and proteins that will be needed for middle gene expression. T4 early promoters have the recognition features of the σ^{70}-dependent −10/−35 promoters, but these promoters also have the extended −10 sequence for σ^{70} region 3 and UP elements for α-CTD contact. Consequently, the 40 or so early promoters are extremely strong, and they compete very efficiently with the more than 600 host promoters for productive transcription initiation by the available polymerase.

To increase further the advantage of early promoters over host promoters, T4 encodes a protein, Alt, that chemically modifies host RNAP by ADP-ribosylation. This modification specifically increases the activity of T4 early promoters relative to those of the host. Alt is actually present within the phage head, and it is injected

into the host along with phage DNA. Thus, the Alt modification begins immediately after infection. Although Alt-dependent ADP-ribosylation affects a minor fraction of many *E. coli* proteins, it primarily modifies a specific residue (Arg265) on one of the α-subunits. It is thought that this modification occurs on the same α on every polymerase, but which α-subunit is unknown. Arg265 is located within the CTD of the α-protein, and normally this residue directly contacts UP element DNA. However, ADP-ribosylation of Arg265 eliminates this DNA interaction. Sequence differences between T4 early promoters and host promoters in the −40 to −60 region (the α-CTD binding sites) may explain how this asymmetric ADP-ribosylation favors T4 early promoters.

T4 transcription gains another advantage over the host early after infection because T4 DNA itself is modified, containing glucosylated, hydroxymethyl cytosines. This modification protects the phage genome from multiple nucleases that are encoded by T4 early genes and digest unmodified host DNA within the first few minutes of infection. In addition, T4 encodes an early protein (Alc) that specifically terminates transcription on unmodified host DNA.

T4 Middle Transcription

T4 middle gene expression begins about 1 min after infection. Middle genes include genes that encode T4 replication proteins, transfer RNAs, and proteins that will be needed later to switch from middle to late promoter recognition. At the start of middle transcription, two early gene products, the ADP-ribosylating enzymes ModA and ModB, complete the ADP-ribosylation of Arg 265, resulting in the modification of both α-subunits. This prevents any contact between the α-CTD domains and the −40 to −60 sequences, thereby further decreasing initiation from host promoters. In addition, ADP-ribosylation of the second α-subunit now lessens the activity of T4 early promoters. Thus, the action of ModA/ModB should contribute to the switch from T4 early to T4 middle transcription. Early gene expression is also decreased by the action of another early gene product, RegB endoribonuclease, which cleaves within the sequence GGAG present in the ribosome binding site of many early transcripts. Although RegB is present even after late gene expression has begun, and some middle and late T4 transcripts contain the RegB recognition sequence, only cleavage of early RNA is observed. In particular, the mRNA of the T4 MotA protein, which is required for middle promoter activation (see below), is an RegB substrate. Evidence suggests that the secondary structure of the mRNA is important for RegB recognition, but the exact nature of RegB specificity is not yet understood.

T4 middle RNA is synthesized using two separate strategies. First, early and middle genes are located together with almost all middle genes downstream of early genes (**Figure 2**). Consequently, transcription from T4 early promoters produces middle RNA as these early transcripts extend into middle genes. Although there has been speculation that this extension involves an active T4 antitermination process, perhaps like that of λ (below), definitive evidence for such a mechanism has not been found and the control of this extension is not yet understood.

Second, T4 activates the initiation of transcription at more than 30 middle promoters. These promoters contain the σ^{70} −10 element and are dependent on RNAP containing σ^{70} for transcription. However, they lack the σ^{70} −35 element and have instead a different consensus sequence, the 'MotA box', centered at −30 (**Figure 1**). Activation of middle promoters occurs by a process called σ appropriation and requires two T4-encoded proteins, MotA and AsiA. MotA is a transcription activator that interacts both with the MotA box and with the far C-terminus of σ^{70}, a region that contains some of the residues that normally interact with the β-flap. AsiA is a small protein that binds tightly to σ^{70} region 4. When MotA is present, AsiA coactivates transcription from T4 middle promoters. By itself AsiA also inhibits transcription from σ^{70}-dependent promoters that require an interaction with the −35 element.

AsiA binds to multiple residues in σ^{70} region 4 and dramatically changes its conformation. Some of these residues normally interact with the −35 element, and some with the β-flap, but the structure that results from AsiA binding no longer interacts with either. Thus, AsiA binding inhibits transcription from σ^{70}-dependent promoters that require these interactions. Furthermore, by removing the interaction of σ^{70} with the −35 sequences, AsiA helps MotA interact with the MotA box, centered at −30. This is because the 9 bp MotA box includes sequences that would normally interact at least indirectly with σ^{70} region 4. In addition, AsiA frees the far C-terminus of σ^{70} to interact with MotA, since the structural changes prevent this portion of σ^{70} from interacting with the β-flap.

Interestingly, AsiA binds rapidly to free σ^{70}, but poorly, if at all, to σ^{70} that is present in polymerase. Because there is an excess of core relative to σ^{70} in *E. coli*, very little free σ^{70} is available at any given time. Consequently, the binding of AsiA to σ^{70} must occur when σ^{70} is released from core, which occurs in this case after initiation at early promoters. Thus, transcription from early promoters directly promotes the switch to middle transcription, helping to coordinate the start of middle transcription with the vitality of early transcription.

T4 Late Transcription

Late genes primarily encode proteins needed to form virions and to process replicated T4 DNA. The switch

from middle to late transcription begins about 6 min after infection. The synthesis of some early and middle proteins decreases because translation of their mRNA is repressed by the T4-encoded middle protein, RegA, which competes with ribosomes for binding to the translational initiation sites of some middle mRNAs. RegA binds to an AU-rich motif but the precise requirements for binding are unknown. In addition, middle RNA synthesis decreases because the previous ADP-ribosylation of α-CTD and the binding of a T4 middle protein, RpbA, to core polymerase favor transcription from late promoters, described below, over transcription from middle promoters.

Transcription from T4 late promoters is accomplished by host core polymerase in combination with three phage-encoded middle proteins: gp33, gp55, and gp45 (**Figure 1**). Gp55 shares sequence similarity with σ region 2, and like region 2, gp55 recognizes and contacts a specific DNA element, in this case TATAAATA, centered at position −10 (**Figure 1**). Gp55 interacts with gp45 and the β′-subunit of RNAP. Gp33 interacts with gp45 and the β-flap of RNAP. Gp45 forms a ring that encircles T4 DNA and can move along it in either direction. Interaction of RNAP-bound gp33 with DNA-bound gp45 connects RNAP to DNA upstream of the gp55 DNA contact. Thus, gp33 and gp55 together can be considered a T4 σ-factor for late promoters. Interestingly, gp45 is also the DNA polymerase clamp protein, a processivity factor that is needed to keep T4 DNA polymerase from dissociating from DNA during replication. As a consequence, transcription from late promoters requires active DNA replication, because gp45 is loaded onto the DNA through its role as the DNA polymerase clamp. This connection of late transcription to the replication of phage DNA serves to coordinate the expression of late genes, whose functions are primarily DNA packaging and capsid assembly, with the amount of phage DNA. T4 late transcription continues until 20 min after infection, when the fully formed phage with the packaged phage genomic DNA are released through lysis of the cell.

Phages T7 and T3

T7 and T3 belong to the family *Podoviridae*, comprising phages with short tails. Their virions respectively contain about 39.9 and 38.7 kbp of double-stranded nonpermuted DNA. A short segment is directly repeated at each end ('terminal redundancy'). The chromosomal arrangement of genes with identical functions is similar in the two phages, and to several other sequenced phages of the family, in accord with the modular evolution of phages. We will describe the transcriptional regulation of T7, because it is the best-studied member of the entire group, mentioning T3 when appropriate. The genetic map and the transcription pattern of T7 are shown in **Figure 3**. T7 encodes 56 open reading frames (ORFs) most of whose functions are known. The ORFs include three cases of programmed translational frameshifting.

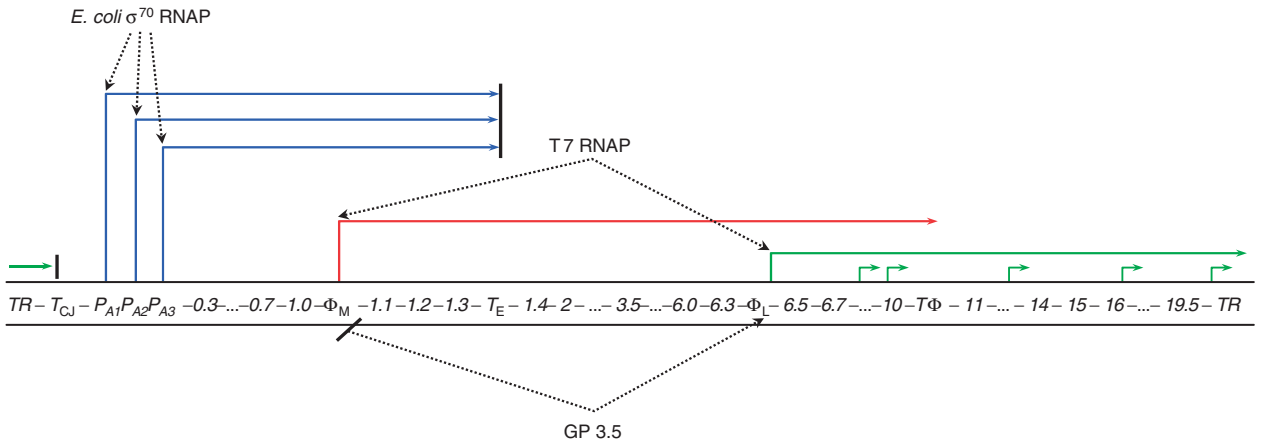

Figure 3 Phage T7 promoters, transcripts, repressors, and activators. Only genes and sites mentioned in the text are shown, and the diagram shows the gene order as it appears in packaged DNA. *Escherichia coli* RNAP transcribes the early promoters, P_{A1}, P_{A2}, and P_{A3} (blue arrows), and T7 RNAP transcribes the middle and late promoters, Φ_M and Φ_L (red and green arrows, respectively). Five other T7 RNAP-dependent promoters located downstream of Φ_L are also shown. T_E, T_Φ, and T_{CJ} are the terminators discussed in the text. TR means terminal repeat. The transcript from Φ_L (green arrow) continues through the left terminal repeat and ends at T_{CJ} because T7 chromosome ends are joined by a single copy of the terminal repeat during DNA replication (see text). Activation and repression of Φ_L and Φ_M by Gp3.5 are indicated by dotted lines ending in an arrow and bar, respectively. A bar across the transcript arrow heads signify terminated transcripts.

Temporal Expression of Genes

Studies of T7 protein synthesis after infection of the host show three temporal stages of gene expression. Early or class I genes (genes *0.3* to *1.3*), middle or class II genes (*1.4* to *6.3*) and late or class III genes (*6.5* to *19.5*) with some overlap, as described later. All T7 genes are transcribed from the same strand, from left to right. The genes in each class are physically contiguous, and the three groups, I, II and III, are also positioned from left to right in the phage chromosome in that order.

Early genes are transcribed by host σ^{70}-RNAP, and their products modify the intracellular environment so as to facilitate phage development. Only gene *1.0* in this group is essential for phage growth; it encodes a single polypeptide RNA polymerase (T7 RNAP) that specifically transcribes the class II and III genes. The class II gene products are involved in phage-specific DNA metabolic reactions, whereas the class III genes encode DNA packaging, virion assembly, and host cell lysis proteins.

DNA Entry and Coupled Transcription

Transcription of T7 and T3 phage DNA, unlike that of some other phages, starts before the complete genome is injected into the host. After adsorption of the phage, the products of phage genes *14*, *15*, and *16* are released from the virion and form a tunnel from the tail tip across the outer and inner membranes of the host for DNA entry into the cytosol. However, only 850 bp from the left end of the phage chromosome (**Figure 3**), which include the major early promoters P_{A1}, P_{A2}, and P_{A3}, enter the host. Transcription from these promoters by host RNAP must begin before additional DNA can enter. The reason for the barrier to further DNA entry is not known, but it is DNA sequence independent. Mutations that allow DNA entry in the absence of transcription map in the middle of gene *16*, suggest that the middle segment of Gp16 is at least partly responsible for the blockade. Although transcription from the three early promoters in the 850 bp region is sufficient, T7 RNAP-mediated transcription takes over in completing the DNA-entry process in normal infection.

Early Transcription

As mentioned earlier, T7 transcription begins immediately after infection at the strong adjacent P_{A1}, P_{A2}, and P_{A3} promoters, although several weak promoters, as well as some RNAP binding sites, which do not initiate transcription, are distributed in the class I region (not shown in **Figure 3**). The importance, if any, of these other promoters and the RNAP binding sites is not known. Transcription from the early promoters continues after complete genome entry and terminates at different sites with incomplete efficiency within the ~8000 bp long polycistronic transcription unit or at a Rho-independent terminator (T_E) located at the end of the transcription unit encompassing genes *0.3–1.3*. T7 early transcription terminates at T_E both *in vivo* and *in vitro*, but T3 early transcription terminates at T_E only *in vivo*, suggesting the involvement of a termination factor in the latter phage.

Middle Transcription

Transcription of the class II genes (from *1.4* to *6.3*) by T7 RNAP begins about 4–6 min and continues until about 15 min after infection. These genes are transcribed from several T7 RNAP specific promoters, of which the major one, Φ_M, is shown in **Figure 3**. Note that three class I genes – *1.1*, *1.2*, and *1.3* – are also transcribed by T7 RNAP because they are located downstream of the middle promoter Φ_M but upstream of the early terminator T_E (**Figure 3**). T7 but not host RNAP ignores the T_E terminator when transcribing genes *1.1* to *1.3*. Transcription from Φ_M terminates weakly at the T7 RNAP terminator, T_Φ, which is located between genes *10* and *11*. Specific transcription from Φ_M can be demonstrated *in vitro*, but only on templates that lack the class III promoters, indicating that a mechanism exists for high level transcription from Φ_M *in vivo*. It has been suggested that Φ_M has much-reduced affinity for T7 RNAP compared to that of class III promoters, but the middle promoter is stimulated *in vivo* by an unusually high local concentration of T7 RNAP, which is encoded by an adjacent gene.

Late Transcription

There are several T7 RNAP promoters that direct expression of late genes (**Figure 3**). The first late promoter, Φ_L, directs transcription of all genes located to the right of gene *6.3*, from gene *6.5* to the last gene, *19.5*. The late genes are transcribed from 8 min after infection until cell lysis occurs. Compared to the strength of Φ_M, Φ_L is intrinsically strong. Note that class III genes *6.5* through *10* are transcribed from both Φ_M and Φ_L, presumably because these gene products are needed in larger amounts. Although T7 RNAP initiating at Φ_L also terminates at T_Φ with reduced efficiency, all late transcription terminates at site T_{CJ}. T_{CJ} is downstream of Φ_L in phage DNA that is actively replicating and transcribed within infected cells, but the two sites are separated by the ends of the packaged T7 chromosome (**Figure 3**). This is because replication produces concatemers – repeating units of nonredundant T7 sequence that are separated by the terminal repeat – and packaging produces the chromosome ends from the concatemers. T_{CJ} has the sequence 5′-ATCTGTT with no secondary structure potential. It acts as a transcription pause site *in vitro*.

T7 RNA Polymerase

T7 RNAP is a single subunit enzyme of 98 000 Da. It recognizes a 19 bp sequence (consensus: TAATACGACTCACTATAGG) centered on position −8 from the start point of transcription (+1), which is the first G of the final GG sequence. There are 17 identified middle and late promoters that are used exclusively by T7 and not by host RNAP. T7 RNAP does not recognize host promoters and many of the host terminators, whether the latter are Rho-dependent or Rho-independent. T7 RNAP can utilize both T7 and T3 promoters but T3 RNAP is somewhat specific. The open complexes made by T7 RNAP distort at least 10 bp of double-stranded promoter DNA and are unstable until short RNA oligomers are made. Both T3 and T7 RNAP initiate transcription with 5′-GG. Significantly, the T7 enzyme catalyzes RNA synthesis 5–10 times faster than the host RNAP. As mentioned, besides Φ_M and Φ_L, there are several other promoters distributed among class II and III genes that are transcribed by T7 RNAP, and transcription from these promoters increases the products of certain genes. The 3′-ends of the RNA made by the phage enzyme without the aid of any other factors at T_Φ are also different from that by the host enzyme, $G(U)_6G\text{-}3'$ for T7 versus $G/C(U)_{6\text{-}7}\text{-}3'$ for the host. As mentioned below, the termination efficiency is modulated by the phage protein Gp3.5. T3, but not T7, RNAP needs the *E. coli* protein DnaB helicase for initiation, elongation, and termination of replication *in vivo*. DnaB is essential for both phage DNA replication and RNA synthesis in high salt *in vitro*. The significance of the sharing of a protein between transcription and replication is not known.

Regulation of Transcription

T3 and T7 regulate gene expression mainly at the level of transcription. We mentioned that the gene products made from early transcripts create a favorable environment for phage growth and produce T7 RNAP. At this point, transcription of class II genes begins. As soon as the synthesis of middle proteins reaches an optimal level, both early and middle transcription are turned off, and the transcription machinery is directed exclusively to expression of late genes. The temporal control and relative amounts of transcription of different genes are achieved in several ways. First, temporal control is facilitated by positioning of the three groups of genes, I, II, and III, in the order from left to right; and second, mechanisms exist to switch from early to middle and from middle to late transcription (below). In addition, some gene products are needed in large amounts for a sustained period. The corresponding genes are located in areas of overlapping transcription and possess additional, strategically located promoters in the phage chromosome. For example, as noted earlier, genes *1.1* through *1.3* are transcribed as part of both early and middle transcription units. Next, differential levels of transcription of some class I genes are achieved by 'polarity', that is, expression of promoter proximal genes in higher amounts than promoter distal ones. Polarity is caused by Rho-dependent transcription termination signals in the early transcription unit. Finally, the mode of entry of T7 DNA into the host is also an important element in temporal control of transcription.

There are three components of the early to middle switch, and all are due to the products of early transcription. First, gene *0.7* product inactivates host RNAP. Gp0.7 is a seryl–threonyl protein kinase that phosphorylates the β- and/or β′-subunits of host RNAP. Phosphorylation decreases early transcription to about 25%. The kinase inactivates itself in a timely fashion after it is no longer needed. Second, T7 RNAP, the gene *1.0* product, accumulates. This enzyme recognizes the middle and late promoters. The host RNAP activity is also inhibited by the third factor, the middle gene *2.0* product. Gp2.0 binds to the host RNAP in a 1:1 stoichiometry. Although Gp2.0 is essential for phage growth, Gp0.7 is not. Much needs to be learned about Gp2.0 action.

The switch from middle to late transcription requires the product of middle gene *3.5*. This protein binds to T7 RNAP, forming a complex that inhibits transcription strongly from Φ_M but weakly from the late promoter, Φ_L. Biochemical experiments have shown that Gp3.5 inhibits the transition from the initiating to the elongating complex. The Φ_M–T7 RNAP complexes are much weaker than the corresponding late promoter complexes. Gp3.5 destabilizes the former complexes more readily than the latter ones. Interestingly, Gp3.5 has three additional functions. It is a lysozyme, which is required for release of progeny phage after infection, it stimulates DNA replication, and, indirectly, it enhances termination at T_{CJ}. Ordinarily, T_{CJ} is a pause site for T7 RNAP, and Gp3.5 increases pausing at this site.

RNA Processing

The long polycistronic RNA molecules made at early, middle, and late times after phage infection are cut at specific sites by the host enzyme, RNase III, to yield discrete, relatively stable mRNAs. The processing sites in early T7 RNA have been studied in more detail. RNase III cleaves at specific sites within hairpin structures that are located between coding sequences. Although some of the RNA molecules that result from RNase III cleavage are translated more efficiently than the uncut RNA, RNase III cleavage is not essential for phage growth.

Phage N4

The virulent phage N4 uses transcription strategies that differ significantly from those of T7 or T4. Early genes are located at the left end of the N4 chromosome, in the first 10 kbp of the ~70 kbp, linear, double-stranded DNA. Transcription of the early genes requires a phage-coded, virion-encapsulated polymerase, vRNAP, which is injected into the host along with the phage DNA. This polymerase is distantly related to the T7 family of RNA polymerases (above). N4 early promoter sequences have a conserved motif and a sequence that can form a hairpin with a stem of 5–7 nt and a loop of 3 nt in single-stranded DNA. *In vivo* transcription by vRNAP requires the activity *E. coli* gyrase and *E. coli* SSB (*Eco*SSB), the host single-stranded DNA binding protein that is normally a member of the host DNA replication machinery. It is thought that gyrase-catalyzed, negative supercoiling of the DNA leads to local melting and extrusion of the hairpin, which then provides the features needed for polymerase promoter recognition. *Eco*SSB melts the complementary strand hairpin while the template strand hairpin, which is resistant to SSB melting, remains available for vRNAP recognition. In addition, SSB prevents annealing of the RNA product to the template DNA. Thus, *Eco*SSB acts as an architectural transcription factor as well as a recycling factor that makes the template DNA available for multiple rounds of early transcription.

Middle N4 genes encode the N4 replication proteins and are located within the left half of the N4 genome. Middle genes are transcribed by a second phage-encoded RNA polymerase, N4 RNAPII, composed of the N4 early products p4 and p7. This polymerase is also a member of the T7 polymerase family. N4 middle promoters contain an AT-rich sequence at the transcription start site. By itself, N4 RNAPII is inactive on double-stranded DNA and has very limited activity on single-stranded DNA. Active transcription requires another N4 protein, gp2, which interacts specifically with single-stranded DNA and with N4 RNAP II. It is thought that an as yet unidentified protein binds to the promoter element while gp2 stabilizes a single-stranded region at the promoter start and brings N4 RNAPII to the transcription start site. This system differs significantly from the other well-characterized phage transcription systems and may provide a good model system for investigating mitochondrial transcription, which is also carried out by a member of the T7 polymerase family.

Transcription of N4 late genes, which are located in the right half of the phage genome, requires *E. coli* RNA polymerase. Late promoters have regions of limited similarity to σ^{70} DNA elements and when present in linear DNA, they are weak promoters for σ^{70} polymerase. Transcription *in vivo* and with linear templates *in vitro* requires the N4 SSB protein. Surprisingly, the single-stranded DNA-binding function of SSB is not needed for this activation. Rather a transactivating domain of SSB that interacts with the β'-subunit of *E. coli* RNA polymerase core is required. The mechanism of this activation is not known, but is thought to occur at a step after initial binding of RNA polymerase to the promoter. Thus, this late N4 system should also provide insight into a mode of transcriptional activation that has not been previously characterized.

Phage λ and the Regulation of Lysogeny and Lysis

Lambda is the founding member of a large family of temperate bacteriophages that are related by common gene organization and limited sequence similarity. Although λ belongs to the *family Siphoviridae* by virtue of its long, noncontractile tail, several close relatives are not members of this group. Lambda chromosomes isolated from virions consist of about 49 kbp of linear, nonpermuted, mostly double-stranded DNA. Complementary single-stranded extensions of 12 bases at each end enable the chromosome to circularize by end-joining after it is transferred from the virion into an infected cell. Transcription of all phage genes, both early and late, is catalyzed by host RNAP. Infection with λ, unlike infection with virulent phages, does not always lead to cell lysis and liberation of progeny phage. Instead, infected cells frequently survive and give rise to lysogens – cells that contain a quiescent, heritable copy of the λ chromosome called prophage (**Figure 4**). The prophage expresses few genes and replicates in synchrony with the host, so that each daughter cell also contains a prophage. The 'decision' between lytic growth and lysogen formation after infection is controlled at many levels (below). Indeed, λ, like other temperate species, has evolved sophisticated mechanisms to ensure that a substantial fraction but not all infected cells survive and become lysogenic, and that intermediate responses, for example, survival without inheritance of a prophage (abortive lysogeny), are rare.

Once a lysogen has formed, loss of the prophage, or 'curing', is infrequent. Lambda and its relatives insert their chromosomes into specific sites in the bacterial chromosome during the establishment of lysogeny and remain there during subsequent cell division. Although site-specific prophage insertion is widespread, it is not a general feature of lysogeny; some temperate phages that are not closely related to λ use other strategies that also ensure prophage retention. For example, phage Mu, inserts its chromosome nonspecifically, while phage P1 does not insert at all, but instead exists in lysogens as a single-copy plasmid whose replication is coupled to that of the host chromosome. Lysogeny is not a dead end; the prophage can switch into an

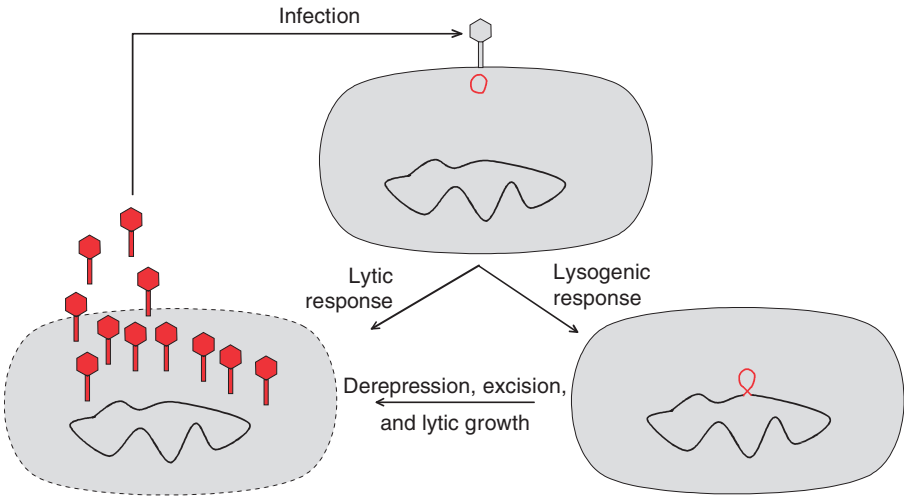

Figure 4 The λ life cycle. After infection, the linear phage chromosome enters the cell and the single-stranded ends cohere to form a ring (in red, top panel). When the infected cell enters the lytic cycle, early and late phage genes are fully expressed, phage DNA replication ensues, the resulting replicas are packaged into phage heads, and the cell lyses, releasing infectious particles into the environment (left bottom panel). When the infected cell enters the lysogenic cycle, the phage expresses mainly early genes to a limited extent. Among these genes are *cI* and *int*. CI prevents further phage gene expression, and Int catalyzes insertion of the phage into the bacterial chromosome (lower right panel). The resulting lysogen passes a copy of the inserted, repressed prophage to its descendents. When repression fails, the prophage excises and enters the lytic cycle.

active state in which many virus genes are expressed, the prophage is excised from the bacterial chromosome, and normal lytic growth ensues (**Figure 4**). This transition, known as the genetic (or, more correctly, epigenetic) switch, is normally infrequent but can be induced experimentally by treatment of cells with DNA damaging agents. Such treatment causes a signal cascade that leads to autoproteolytic cleavage of repressor, a phage protein that prevents most phage gene expression (below). Experimental induction of lysogens by DNA damage is not universal; lysogens of some temperate phages, such as P2, are not inducible.

The Establishment and Maintenance of Lysogeny

Immediately after infection, host RNAP initiates transcription at the λ early promoters, P_L and P_R (**Figure 5**). P_R directs the transcription of the *cII* gene, whose product is the central effector of the lysogenic response. CII protein promotes lysogeny by activating the coordinate initiation of transcription at three λ promoters: P_{RE}, P_{Int}, and P_{aQ} (**Figure 5**). P_{RE}, the promoter for repressor establishment, directs the transcription of the *cI* gene, and P_{RE} activation thus provides a burst of CI protein synthesis shortly after infection. CI, or repressor, prevents transcription of nearly all λ genes in an established lysogen, and, indeed, is required for the maintenance of lysogeny. CI blocks the initiation of early transcripts by binding to operator sites that overlap P_L and P_R (below). It blocks late gene transcription indirectly, by preventing the

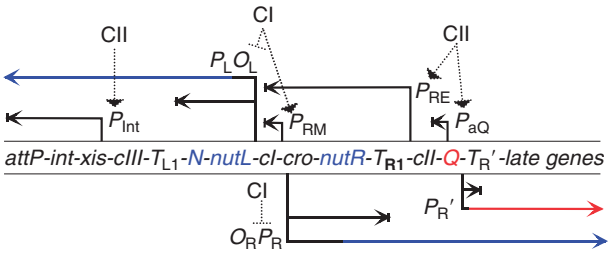

Figure 5 Phage λ promoters, transcripts, repressors, activators, and antiterminators. Only genes and sites mentioned in the text are shown. The top, light, horizontal line represents a DNA strand written with 5′ to 3′ chemical polarity, and the parallel bottom line represents the complementary strand written 3′ to 5′. Activation or repression of individual promoters by CI and CII proteins is indicated by dotted lines terminated by an arrowhead or bar, respectively. Transcripts and their orientation are indicated by heavy solid lines with arrowheads, with each transcript adjacent to the transcribed strand. A bar across an arrowhead indicates a terminated transcript. T_{L1} and T_{R1} are the first of several transcription terminators in the P_L and P_R operons, respectively, and T_R' is the first terminator in the P_R', or late operon. N suppresses terminators by binding to ECs after they transcribe the *nutL* and *nutR* sites (see text). This is indicated by a color change from black to blue in the transcript. Q suppresses termination at T_R' and downstream terminators by binding to the EC shortly after initiation at P_R' (see text). This is indicated by a color change from black to red in the transcript.

synthesis of Q, an early protein that activates transcription of late genes (**Figure 5**). CI is not only a repressor, it is also an activator. It activates the initiation of transcription at P_{RM}, the promoter for repressor maintenance,

a second promoter for *cI* transcription. Thus, once *cI* transcription has initiated from P_{RE}, it is self-sustaining. This is essential to maintain lysogeny because CI prevents continued transcription of *cII*.

P_{Int}, the second CII-activated promoter, directs the transcription of the *int* gene. Int protein or integrase is a topoisomerase that binds to specific sequences within the phage and host 'attachment sites'. These two sites differ from each other in the number, type, and disposition of Int binding sites. The phage attachment site also contains sequences that specifically bind several molecules of IHF, a host-encoded DNA bending protein that promotes the formation of a recombinogenic structure that can capture the bacterial attachment site. Int then uses its topoisomerase activity to catalyze breakage, exchange, and rejoining of the four DNA strands at specific positions within the two sites. This inserts the prophage into the bacterial chromosome and ensures its inheritance by the progeny of the infected cell. Reversal of insertion, or excision, is rare as long as CI continues to repress transcription (below).

Finally, P_{aQ}, the third CII-activated promoter, directs the synthesis of an antisense RNA that inhibits the production of Q, a phage protein that promotes transcription of late genes. Inhibition of Q synthesis increases the frequency of lysogeny after infection by delaying the production of late phage proteins that would kill the cell. Once lysogeny is established, repressor prevents further transcription of Q, as noted earlier.

The rate of CII accumulation after infection is controlled by the action of several phage and host gene products, a few of which are described in more detail below. Initially, λ Cro protein and, eventually, CI inhibit initiation of the *cII* transcript at P_R. Lambda N protein promotes transcript elongation through *cII* by suppressing T_{R1}, a rho-dependent transcription terminator (**Figure 5**). Host RNase III in concert with the antisense OOP RNA (not shown in **Figure 5**) cleaves the *cII* transcript. Finally, host FtsH protease degrades CII, but λ CIII protein inhibits its degradation. The net effect of these multiple layers of control is probably to make the lysis–lysogeny decision responsive to internal and environmental cues. A complete quantitative description of the kinetic details of the response is cherished goal of systems biologists.

Dimers of CII and dimers, tetramers, and octamers of CI bind to specific sites that overlap the promoters they regulate. Both use a helix–turn–helix DNA binding motif to recognize their sites. CII binds specifically to sequences that straddle the −35 element of the relevant promoters, and binding is thought to activate transcription initiation through contacts between the tetramer and σ^{70} RNAP. These contacts enhance binding of RNAP to the promoter and isomerization of the bound complex. CI dimers bind to repeated tandem operator sites that flank and interpenetrate each promoter: O_{L1}, O_{L2}, and O_{L3} for P_L, and O_{R1}, O_{R2}, and O_{R3} for P_R. One dimer binds to each operator, and neighboring dimers can interact cooperatively with each other as well as with dimers bound near the other promoter as shown in **Figure 6**. Cooperative interactions strengthen operator binding and make it more sensitive to changes in CI concentration, thus sharpening the transition between full repression and full derepression and decreasing the probability of biologically unproductive intermediate states. Repressor dimers bound to O_{L1} and O_{L2} occlude binding of RNAP to P_L, and, similarly, binding to O_{R1} and O_{R2} occludes P_R. Repressor bound at O_{R2} has an additional function; it contacts the σ-subunit of RNAP bound to P_{RM}, promoting isomerization of the bound enzyme and subsequent *cI* transcription. O_{R3} binds repressor relatively weakly and is not required for repression

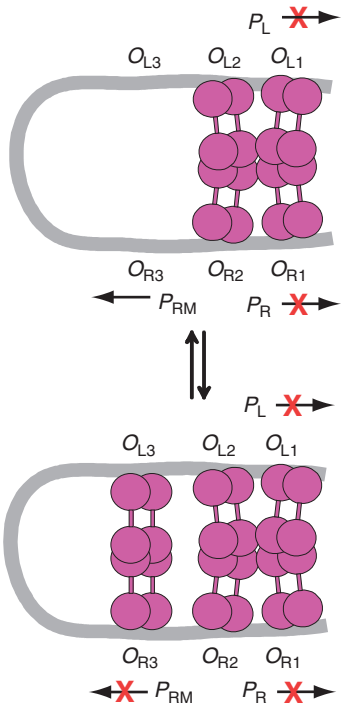

Figure 6 Binding of repressor. The pairs of purple dumbbells represent repressor dimers bound to subsites of O_L and O_R. One end of each dumbbell represents the N-terminal portion of the protein, which contains a DNA-binding domain. The other end represents the C-terminal portion of the protein, which contains regions that can participate in cooperative interactions with similar regions in neighboring bound dimers to form tetramers, and with a tetramer bound to a distant operator to form an octamer. At low concentrations of repressor, the cooperative interactions and the intrinsic affinities of the binding sites lead to occupancy of subsites 1 and 2 of each operator. In this configuration, promoters P_L and P_R are repressed and promoter P_{RM} is activated (top of figure). At higher concentrations of repressor, all six subsites are occupied and all three promoters are repressed (bottom of figure). Repression is indicated by a red 'X' over the arrows representing transcripts.

of P_R. This operator is occupied only at relatively high repressor concentration, and occupancy prevents a further increase in concentration by repressing P_{RM}. Thus, *cI* transcription from P_{RM} is both positively and negatively autoregulated.

Prophage Excision

If the level of repressor in a lysogen drops below the level needed to inhibit transcription, the prophage expresses genes needed for excision and lytic growth. Two λ proteins, Int and Xis, are needed for prophage excision. Int, as noted earlier, catalyzes breakage and rejoining of DNA strands. Xis is a directionality factor; it is required for excision and inhibits insertion. Analogous directionality factors are produced by many other temperate phages. Xis molecules bind specifically and cooperatively to sequences within the attachment sites and help to recruit Int to an adjacent binding sequence. This favors recombination between the two attachment sites that flank the prophage and inhibits recombination between the phage and host attachment sites. Interestingly, when Xis concentration is limiting, the host-encoded Fis protein can alleviate the deficiency. It is likely that Fis and IHF, the other host-encoded protein needed for recombination, help to couple the efficiencies of insertion and excision to the physiological state of the host.

Although Int and Xis are encoded by adjacent genes, the protein levels are differentially controlled so that the efficiency and direction of recombination are coupled to the appropriate stages of the phage life cycle. In infected cells destined for lysogeny, *int* but not *xis* is transcribed from CII-activated P_{Int} (**Figure 5**). Xis, which is made from the P_L transcript, is unstable, so it inhibits insertion only briefly when transcription from P_L is repressed after infection. After prophage induction, both *int* and *xis* are transcribed from P_L, and their products promote rapid prophage excision. Excision is usually followed by phage DNA replication and the expression of late genes. Although excision is not a prerequisite for the subsequent events, it is necessary for synthesis of concatemers of λ DNA, a substrate for packaging phage chromosomes into virions.

Lytic Growth

Lambda lytic growth is broadly similar to that of virulent phages, although the regulatory strategies differ considerably. The Cro, N, and Q proteins regulate transcription mainly during lytic growth. None of them is produced in lysogens because CI directly represses their syntheses. Cro is a transcriptional repressor, similar to CI in binding specificity and structure. However, subtle differences in binding specificity and the absence of cooperative interactions weaken Cro repression of P_L and P_R, and adapt it to serve as a negative regulator of early gene transcription during lytic growth. Cro is essential for lytic growth because it represses transcription of *cII*, thus enabling a fraction of infected cells to enter the lytic pathway. Both N and Q are 'antiterminators'; they act during transcript elongation to suppress termination. N enhances expression of early, and Q of late genes (**Figure 5**). Nearly all λ genes are located downstream of terminators and therefore require antitermination for full expression. *Cro* and *N* are exceptions, and, indeed, they are normally expressed before any other λ proteins are produced.

What is the role of terminators in λ biology? Their role in the expression of early genes is unclear, since termination is rapidly and efficiently suppressed as N accumulates after infection. Possibly the delay in early gene expression until the concentration of N reaches an effective level influences the lysis–lysogeny decision. Indeed, it has been shown that the efficiency of translation of the N message is increased by RNase III cleavage, and that the intracellular concentration of RNase III varies with the growth phase of the culture. Alternatively, or in addition, termination adds to the effect of repressor in silencing early gene expression in lysogens. In any event, early gene terminators are likely to confer some evolutionary advantage because several are conserved in phages related to λ. By contrast, the role of termination in controlling late gene expression is clear because P_R', the promoter for these genes, is constitutive. Thus, termination prevents transcription of late genes in lysogens and premature transcription of late genes during lytic growth.

Antitermination by N and Q is limited to λ transcription because both proteins bind specifically to phage nucleic acid before they act. N binds nascent transcripts of the *nutL* and *nutR* sites, which are located downstream of P_L and P_R, respectively (**Figure 5**). RNA binding alters N structure and facilitates its transfer to the nearby elongation complex, where it acts to suppress termination. Several host proteins enhance N-dependent antitermination: NusA, NusB, NusE/RpsL, and NusG. Some of these proteins bind *nut* RNA, some bind the elongation complex, and one, NusA, binds N. All of these proteins have roles in host biology that are independent of N, and their abundance and activity might link the efficiency of antitermination to as yet unknown aspects of host physiology. Nevertheless, N is clearly the central actor since some level of antitermination has been observed *in vitro* in the absence of all of the Nus factors and the *nut* site when N is present in excess. Despite considerable effort, the location of the N binding site on the EC and the nature of the antiterminating modification are still unknown. The modification is stable *in vitro* in the presence of NusA and persists *in vivo* for considerable time and distance after it has been established. Persistence is important for λ physiology since important terminators, notably those preceding the *Q* and *xis* genes, are located more than 5 kbp from the *nut* sites.

Q binds to a site in the nontranscribed region of the λ late promoter, P_R' (**Figure 5**). It is transferred from this site to the EC after synthesis of a 16 or 17 nt transcript. At these points the EC pauses because the σ^{70}-subunit, which has not yet been released, binds to a transcribed DNA sequence that resembles the extended −10 regions of certain genuine *E. coli* promoters. Sigma-70 interacts with Q after its transfer to the EC, but the locations of any additional contacts are unknown. Q modification of the EC decreases the duration of the 16/17 pause and suppresses downstream terminators.

Q and N suppress nearly all terminators that have been tested, both intrinsic and rho-dependent, and also increase the average rate of elongation. The mechanisms of suppression and, indeed, of termination are controversial. It is widely accepted that formation of the hairpin stem of intrinsic terminators disrupts the upstream (5′) segment of the RNA:DNA hybrid, which consists mainly of relatively weak rU:dA base pairs. It is not clear how hairpin formation is linked to hybrid disruption, and what the subsequent steps in termination consist of. Among the mechanisms that have been considered to explain N and Q action are inhibition of hairpin formation, strengthening of the weak RNA:DNA hybrid, and increase of elongation rate so that the EC escapes from the termination zone.

It is interesting that the termination/antitermination mode of gene control is not general among temperate phage. For example, it has not been found in phages Mu or P2, which regulate transcription exclusively through activators and repressors of initiation. However, several interesting variants of the termination/antitermination strategy have been discovered in other phages. In lysogens of the mycobacterial phages L5 and Bxb1, the repressor arrests the progress of the EC by binding to numerous 'stoperator' sites in the phage chromosome and physically blocking further translocation. The repressor of coliphage P4 also prevents transcript elongation, but by a quite different mechanism. P4 repressor is an RNA that activates termination by pairing with phage transcripts upstream of terminators. It has been suggested that the resulting RNA:RNA duplexes alter the secondary structure of the transcripts in such a way as to favor termination. Finally, HK022, an *E. coli* phage related to λ, uses antitermination to express its early genes but lacks a protein analogous to N. Instead, the HK022 P_L and P_R operons encode short, structured RNA segments that bind to the EC and suppress downstream terminator sites as efficiently as N does for λ. These RNAs act exclusively *in cis*, thus limiting antitermination to phage transcripts.

Conclusions

Both temperate and virulent phages alter the transcriptional and translational machinery of their hosts to suit their own ends. We have described phage-encoded mechanisms that change promoter utilization, transcript elongation rate, and transcript termination efficiency. These changes can be modest or drastic, ranging from chemical modification of a host RNAP subunit to synthesis of a new and structurally dissimilar polymerase. The selective advantage conferred by some of these changes is poorly understood and may be an adaptation to evolutionary pressures that are not apparent in laboratory conditions. An example that we have not previously described is the existence of phage-encoded transfer RNAs that duplicate or augment existing host activities. Among the differences between the regulatory strategies used by temperate and by virulent phages is the lethal character of some mechanisms used by the latter group. Most striking among these is degradation of host DNA, which can be seen soon after infection by T4 and T7. Another is inactivation of host RNAP. Temperate phages can also kill their hosts, but this typically occurs after the phage enters the lytic growth pathway. The essence of the temperate lifestyle is peaceful coexistence of the prophage and the host. A prophage that conferred a selective disadvantage on its lysogenic host would probably not last long in nature. If there is a consistent difference between the regulatory strategies of the two phage types, it is the ability of temperate species to prevent the expression of genes that harm the host. In contrast, the essence of being a lytic phage is to invade, take over, and destroy as efficiently as possible. Nevertheless, the extent of this difference should not be exaggerated. Some virulent phages have close relatives that are known only as prophage-like components of bacterial chromosomes, and some temperate phages have close relatives that have lost elements required for repressing gene expression and are, at first view, indistinguishable from virulent species. In any event, the tactics of both the temperate and virulent phages have taught researchers many elegant mechanisms for gene expression and control.

Glossary

Alleles Mutually exclusive forms of the same gene on homologous chromosomes.
Codon A sequence of three nucleotide bases in a gene that specifies an amino acid to be incorporated into a protein during its synthesis.
Encephalopathy Brain disease resulting from infectious agents such as prions.
Genetic polymorphism The regular occurrence in a population of two or more components of a gene with greater frequency than can be explained by recurrent mutation.
Mutation A permanent inheritable change in the genetic material of a host.
Prion Small, proteinaceous infectious particles that resist inactivation by procedures that affect nucleic acids; they are believed to be the causative agents of scrapie and other spongiform encephalopathies of animals and humans.
Prion protein A normal cellular version of the infectious prions encoded by the prion protein gene; its cellular function is not well understood.

Introduction

Prion diseases, also known as transmissible spongiform encephalopathies, constitute a group of fatal, human, and animal subacute neurodenerative diseases caused by an unconventional agent. Strong evidence indicates that their etiology and pathogenesis involve modification of a host-encoded normal cellular protein known as the prion protein (PrP^{C}). A unique hallmark of this group of diseases includes their sporadic occurrence without any apparent environmental source of infection or genetic association with prion protein gene mutations or as a result of disease transmission from infected humans and animals. Neuropathologically, most prion diseases manifest with widespread neuronal loss, spongiform lesions, and astrogliosis. Characteristically, no signs of inflammation are detected in pathologic samples. However, the presence of an abnormal, pathogenic prion protein, often called a scrapie prion protein (PrP^{Sc}) after the first recognized prion disease, scrapie, is demonstrable in the brain and often in other tissues of humans and animals affected by prion diseases. The incubation period of acquired forms of prion diseases is usually measured in years and sometimes in decades.

Etiologic Agent of Prion Diseases

Studies that characterized the causative agents of prion diseases initially focused on understanding the agents responsible for scrapie in sheep. This disease is the most common prion disease of animals and was first reported in the 1730s in England. Before the 1980s, prion diseases were widely believed to be caused by 'slow viruses' despite the fact that no viral particles or disease-specific nucleic acids were identified in association with scrapie transmission in laboratory animals. The scrapie agent could not be grown in cell culture, a feature that hampered research to characterize the agent. The successful transmission of scrapie to laboratory mice in 1961 contributed to overcoming this hurdle and greatly facilitated efforts to understand the nature of the agent. Quantitation of infectivitiy in a sample, however, still was tedious and required a year to complete.

Two distinctive properties of the scrapie agent led to the suspicion that the agent was devoid of nucleic acids and, thus, may not be a virus but primarily composed of a protein. These properties included (1) resistance of the scrapie agent to procedures, such as treatment with ultraviolet light and ionizing radiation, that normally

inactivate other microorganisms, including viruses and (2) the reduction of the infectivity of the scrapie agent by procedures that denature or degrade proteins. The concept that the scrapie agent might replicate in the absence of nucleic acids or might just be a protein was postulated as early as the 1960s by Alper and colleagues, Pattison and Jones, and Griffith. In 1982, Prusiner and colleagues described the successful purification of a hydrophobic protein, the presence of which was required for scrapie transmission in laboratory animals. Prusiner introduced the term 'prion' to describe this protein by borrowing and mixing the first few letters from the descriptive phrase 'proteinaceous infectious' particle. Since then, additional evidence has accumulated indicating that prions may be acting alone in causing prion diseases. However, the critical steps in the production, propagation, and pathogenesis of this infectious protein remain unclear. As a result, the study of prions has become an important, relatively new area of biomedical investigation. Some critics of the prion hypothesis still believe that nucleic acids undetected by current methods may play a crucial role in the pathogenesis of prion diseases.

Prions appear to be composed largely or entirely of the abnormal protein designated as PrP^{Sc}. This protein is an abnormal conformer of a host-encoded cellular protein, PrP^{C}, which in humans is encoded by the prion protein gene located on the short arm of chromosome 20. PrP^{C} is a structural component of cell membranes of neurons and other tissues. Its normal function is poorly understood. However, it appears to be involved in supporting neuronal synaptic activity, copper binding, and neuroprotective functions by interacting with other cell-surface proteins.

The underlying pathophysiologic mechanism in the occurrence of prion diseases involves the biochemical conversion of PrP^{C} into the pathogenic PrP^{Sc}. This conversion occurs by a poorly defined post-translational autocatalytic process, possibly requiring the aid of cofactors such as proteins or nucleic acids. The initial instigating PrP^{Sc} molecule may originate from exogenous sources or within the brain from somatic or germline prion protein gene mutations. Knockout mice devoid of the prion protein gene are resistant to scrapie infection, indicating that the production of PrP^{C} is required for the generation and propagation of PrP^{Sc}. During its conversion, PrP^{Sc} acquires more β-sheet structure that renders it resistant to proteolytic enzymes, conventional disinfectants, and standard sterilization methods. A higher proportion of the tertiary structure of PrP^{C}, on the other hand, is composed of α-helices which make it more sensitive to denaturation by proteinase-K treatment. Removal of the neuroprotective functions of PrP^{C} as more of it becomes converted to the pathogenic PrP^{Sc} and accumulation of PrP^{Sc} in neurons have been suggested as major contributory factors in the underlying pathogenesis of prion diseases and widespread neuronal death.

Prion Diseases of Animals

Prion diseases of animals include scrapie in sheep, goats, and moufflon; bovine spongiform encephalopathy (BSE) in cattle; feline spongiform encephalopathy in domestic and zoo cats; ungulate spongiform encephalopathy in exotic zoo ruminants; chronic wasting disease (CWD) in deer, elk, and moose; and transmissible mink encephalopathy (TME) in mink (**Table 1**). Epidemiologic evidence indicates that feline and ungulate spongiform encephalopathies were caused by the BSE agent possibly transmitted via consumption of BSE-contaminated feed. Although strong evidence is lacking, speculations have persisted that scrapie in sheep may have been the original source of prion diseases in other animals, such as BSE and CWD.

TME occurred in outbreaks among ranched mink primarily in the US but also in Canada, Finland, Germany, and Russia. The last known outbreak of TME occurred in 1985 in Wisconsin. Nonepizootic cases of TME have not been reported.

Scrapie

Although scrapie was recognized as a distinct clinical entity of sheep over 250 years ago, many aspects of the disease including its natural origin in flocks and the precise means by which it usually spreads remain uncertain. Experimentally, the disease was first transmitted by intraocular inoculation of scrapie brain extracts. In the 1940s, more than 1500 sheep developed scrapie from receipt of a vaccine against louping ill virus that contained scrapie-contaminated lymphoid tissue.

Scrapie transmission may occur by different postulated mechanisms. A commonly cited source of transmission, for example, is the placenta and amniotic fluid of scrapie-infected ewes. These tissues are known to harbor the infectious agent and can cause scrapie when fed to sheep. They may contaminate pastures and barns that, in turn, may remain potentially infectious for years. Another possible source of spread is feces because prion replication occurs in gut lymphoid tissues after oral inoculation in sheep and goats. The importance of oral transmission is supported by experimental studies that detected prions in sheep tonsils examined early during the incubation period. Other poorly defined scrapie transmission mechanisms include (1) the vertical transfer of the scrapie agent and (2) the possible chance occurrence of scrapie caused by hypothesized rare, spontaneous changes in the animal's cellular prion protein.

Scrapie occurs endemically in many countries, including Europe and North America. Australia and New Zealand have sizable sheep populations but are generally recognized as free of the disease. To protect their 'scrapie free' status, these countries have established extensive

Table 1 Animal and human prion diseases

Type of prion disease	*Affected host*	*Year first described or identified*
Animal prion diseases		
Scrapie	Sheep and goats	1730s
Bovine spongiform encephalopathy	Cattle	1986
Chronic wasting disease	Deer, elk, and moose	1967
Transmissible mink encephalopathy[a]	Mink	1947
Feline spongiform encephalopathy[b]	Domestic and wild cats	1990
Ungulate spongiform encepahlopathy[b]	Exotic ruminants (e.g., kudu, nyala)	1986
Human prion diseases		
Kuru		1950s
Sporadic CJD		1920s
Iatrogenic CJD		1974[c]
Variant CJD		1996
Familial CJD		1924
Gerstmann–Sträussler–Scheinker syndrome		1936
Fatal familial insomnia		1986

[a]The last known outbreak of transmissible mink encephalopathy occurred in 1981 in Wisconsin.
[b]The known feline and ungulate spongiform encephalopathies are believed to have resulted from BSE transmission.
[c]The first report of iatrogenic CJD was in a recipient of cornea obtained from a CJD decedent; human pituitary growth hormone-associated CJD was first reported in 1985 and dura mater graft-associated CJD in 1987.
CJD, Creutzfeldt–Jakob disease.

safeguards to prevent the introduction of scrapie into their herds from imported animals.

The breed of sheep and polymorphisms of the prion protein gene can greatly influence susceptibility to scrapie. Experimental transmissions with scrapie-infected tissues, for example, have confirmed the differing susceptibility to scrapie of different breeds of sheep. Other studies of Suffolk sheep in the US indicated that susceptibility to scrapie was highly correlated with a polymorphism in the prion protein gene at codon 171 (glycine or arginine); the presence of arginine confers resistance to the disease.

Chronic Wasting Disease

Mule deer, white-tailed deer, and Rocky Mountain elk are the major known natural hosts for CWD. In 2005, a hunter-killed moose was confirmed with CWD in Colorado, suggesting that this member of the deer family too is a natural host. The disease was first identified as a fatal wasting syndrome of captive mule deer in the late 1960s in research facilities in Colorado. Subsequently, it was identified in mule deer in a research facility in Wyoming and then in captive elk in facilities in both Colorado and Wyoming. In 1977, CWD was first recognized as a spongiform encephalopathy.

In the early 1980s, the disease was recognized in free-ranging elk. By the mid-1990s, CWD was regarded as endemic in deer and elk in a contiguous area in northeastern Colorado and southeastern Wyoming. The known geographic extent of CWD has increased dramatically in the US since 1996. As of mid-2006, CWD in free-ranging cervids had been reported in 74 counties of 11 states, including Colorado, Kansas, Illinois, Nebraska, New Mexico, New York, South Dakota, Utah, West Virginia, Wisconsin, and Wyoming. In Canada, since 2001, CWD has been identified in wild deer and elk in Saskatchewan and since 2005 in several mule deer in Alberta.

Among cervids, CWD is most likely transmitted by direct animal contact or indirectly by exposure to a contaminated environment. Unlike other prion diseases, CWD is highly communicable in its natural host, particularly among captive cervids. In addition to becoming emaciated, animals with CWD characteristically develop polydipsia, polyuria, increased salivation, and difficulty in swallowing. These characteristics probably contribute to residual contamination of the environment that appears to be a very important source of transmission.

CWD does not appear to occur naturally outside the cervid family. It has been transmitted experimentally by intracerebral injection to laboratory mice, ferrets, mink, squirrel monkeys, goats, and cattle. However, experimental studies have not demonstrated transmission of CWD to cattle after oral challenge or after having cattle reside with infected deer herds.

No human cases of prion disease with strong evidence of a link with CWD have been identified despite several epidemiologic investigations of suspected cases. In addition, transgenic mice experiments indicate the existence of a significant species barrier against CWD transmission to humans. Nevertheless, concerns remain that this species barrier may not provide complete protection to humans against CWD and that the level and frequency of human exposures to CWD may increase with the spread of CWD in North America.

As a precaution, efforts to reduce human exposure to the CWD agent are generally recommended. Meat from depopulated CWD-infected captive cervids has not been allowed to enter the human food or animal feed supply. To minimize their risk of CWD exposure, hunters are encouraged to consult with their state wildlife agencies to identify areas where CWD occurs and to continue to follow advice provided by public health and wildlife agencies.

Bovine Spongiform Encephalopathy

Prion diseases became a focus of worldwide attention after a large outbreak of BSE in cattle emerged in the UK and spread to other countries. This attention increased dramatically when evidence accumulated indicating that the BSE agent was responsible for the occurrence of variant Creutzfeldt–Jakob disease (CJD) in humans. By far the largest number of BSE cases was reported from the UK, followed by other European countries.

Although BSE was first recognized in the UK in 1986; earlier cases probably occurred since the early 1980s. The number of UK BSE cases increased rapidly in the second half of the 1980s and early 1990s, peaked in 1992 with 37 280 confirmed cases, and has markedly declined since then (**Figure 1**). In 2005, the number of confirmed UK BSE cases had dropped to 225.

Clinically, the signs of BSE include neurologic dysfunction, including unsteady gait with falling and abnormal responses to touch and sound. In some animals, the onset of BSE can be insidious and subtle and may be difficult to recognize. During the early phase of the UK BSE outbreak, the public media introduced the popular term 'mad cow' disease to describe the strange disease causing fearful and aggressive behavior in some of the cattle infected with BSE.

Although the original source of the BSE outbreak is unknown, the two most accepted hypotheses are cross-species transmission of scrapie from sheep and the spontaneous occurrence of BSE in cattle. Data on the latter hypothesis may become available with increased detection and monitoring rates of atypical, as well as typical cases of BSE. According to the first hypothesis, transmission of scrapie to cattle occurred because of the practice of feeding cattle protein derived from rendered animal carcasses including those of scrapie-infected sheep. In the past, cattle feed rendering in the UK involved several treatment steps, including exposure of the feed to prolonged heating in the presence of a hydrocarbon solvent. Some researchers have suggested that omission of these steps in the late 1970s and early 1980s in the UK contributed to the emergence of BSE by allowing scrapie infectivity to survive the rendering process. Regardless of the origin of BSE, the epidemiologic evidence indicates that feeding cattle rendered BSE-infected carcasses greatly amplified the BSE outbreak. Several other factors may have contributed to the emergence of BSE in the UK, including a relatively high rate of endemic scrapie, a high population ratio of sheep to cattle, and the inclusion of rendered meat and bone meal at high rates in cattle feed.

Since the BSE outbreak was first detected, an estimated >2 million cattle have been infected with BSE in the UK. Approximately half of these BSE-infected cattle would have been slaughtered for human consumption, potentially exposing millions of UK residents. Beginning in 1988, UK animal and public health authorities implemented several protective measures to prevent further exposure of animals and humans to BSE-infected cattle products. The implementation of these measures, particularly animal feed bans, led to the dramatic decline in the UK BSE outbreak.

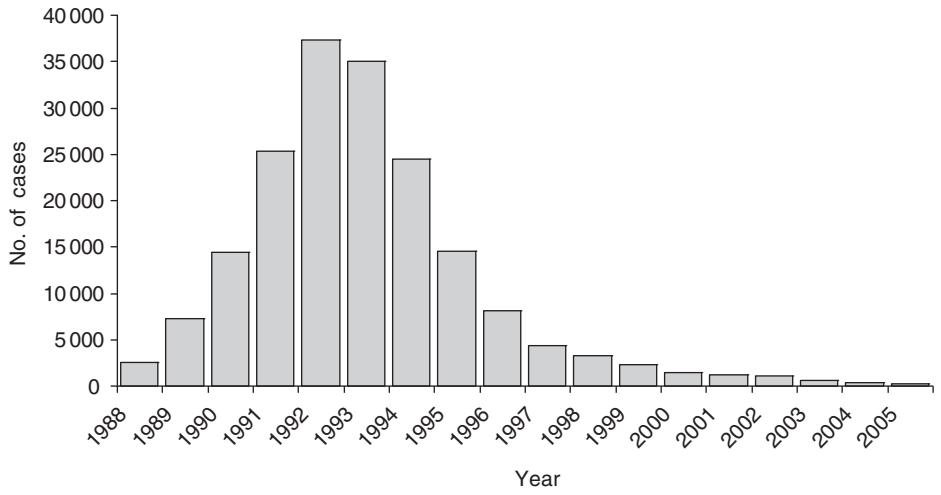

Figure 1 Bovine spongiform encephalopathy cases reported in the UK. BSE cases shown are by year of restriction: 442 BSE cases identified before 1988 are not included.

BSE was reported for the first time outside the UK in Ireland in 1989 and in Portugal and Switzerland in 1990. By August 2006, the number of countries that reported one or more BSE cases in native cattle increased to 25, including 21 countries in Europe. The four countries outside Europe that reported BSE cases are Canada, Israel, Japan, and the US. The BSE outbreak appears to be declining in most European countries, although some cases continue to occur.

In North America, BSE was first detected in 1993 in a cow that had been imported into Canada from the UK. Rendered cohorts of this cow may have been responsible for the 11 BSE cases subsequently identified during 2003–06 among cattle born in Canada; one of these cases was identified in Washington State but was later traced to a farm in Canada. At least six of these 11 BSE cases were born after the 1997 ruminant feed ban which was instituted to prevent BSE transmission among cattle. Because of the continued occurrence of new BSE infections after the 1997 ruminant feed ban, a specified risk material ban was recently instituted in Canada to further reduce cattle exposure to BSE by excluding potentially infectious nervous tissues from all animal feed. In 2005 and 2006, respectively, BSE was confirmed in an approximately 12-year-old cow born and raised in Texas and 10-year-old cow from Alabama. The source of BSE infection for these two cows remains unknown.

Because cattle carcasses were included in the production of animal feed, potential transmission of BSE to other animals was considered during the early phase of the BSE outbreak in the UK. BSE-like diseases were identified in zoo animals (ungulate spongiform encephalopathy) beginning in the late 1980s and in domestic cats (feline spongiform encephalopathy) beginning in 1990, indicating the potential for the BSE agent to cross the species barrier and spread to other animals. This development led to the establishment of enhanced CJD surveillance in the UK to monitor the possible transmission of BSE to humans.

Prion Diseases of Humans

Prion diseases of humans include kuru, CJD, variant CJD, Gerstmann–Sträussler–Scheinker syndrome (GSS), and fatal familial insomnia (FFI) (**Table 1**). Kuru is a fatal ataxic disease that was first described in the 1950s among the Fore tribe of the highlands of Papua New Guinea. In 1959, W. J. Hadlow described the similarity of the neuropathology of this disease with that of scrapie. In 1963, Gajdusek and colleagues successfully transmitted kuru by inoculating kuru brain tissue intracerebrally into chimpanzees, making this disease the first human prion disease to be successfully transmitted to experimental animals.

Kuru is the first epidemic human prion disease to be investigated. Since its investigation began in 1956, over 2700 cases have been documented. Strong epidemiologic evidence suggests that kuru spread among the Fore people by ritualistic endocannibalism. After this practice ended in the late 1950s, no children born after 1959 developed the disease and the number of new cases dramatically declined. Likely incubation periods of seven male cases recently reported by Collinge and colleagues ranged from 39 to 56 years and the incubation periods may have been up to 7 years longer. These male cases and four female cases had kuru from July 1996 to June 2004. The majority of these 11 kuru patients were reported to be heterozygous at the polymorphic codon 129 of the prion protein gene, a genotype associated with extended incubation periods and resistance to prion disease.

Creutzfeldt–Jakob Disease

CJD is the most common form of prion disease in humans. It was first recognized in the 1920s and bears the name of two German neurologists, Creutzfeldt and Jakob, who separately reported patients with rapidly progressive neurodegenerative diseases. Two of the patients initially reported by Jakob had the typical neuropathological features that we now recognize as CJD.

CJD is usually characterized by the onset of dementia, ataxia, or behavioral abnormalities. Later in the course of the illness, CJD patients commonly develop dysarthria, movement disorders such as myoclonus and tremors, and akinetic mutism. The presence of a characteristic electroencephalogram (EEG) finding of triphasic, periodic sharp wave complexes can be demonstrated with multiple testing in about 75% of patients. Elevated levels of 14-3-3 proteins in the cerebrospinal fluid (CSF) can also be demonstrated in most CJD patients. Elevated CSF 14-3-3 is a marker for rapid neuronal death and in the appropriate clinical context can often help in making a premortem diagnosis of CJD. This test is nonspecific, however, and may be elevated in other neurologic conditions that result in rapid neuronal death. More recently, magnetic resonant imaging (MRI) findings showing high intensity in the basal ganglia and cortical regions of the brain have been correlated with a CJD diagnosis. The median age of CJD patients at the time of death is 68 years with approximately 70% of cases occurring between 55 and 75 years of age. Typically, the disease progresses rapidly over a period of several weeks. Over 50% of the patients die within 6 months and 80% within 1 year of disease onset. A definitive diagnosis of CJD can only be made by histopathologic or immunodiagnostic testing of brain tissues obtained at autopsy or biopsy. Histopathologic examination of brain tissue demonstrates the hallmark triad of spongiform lesions, neuronal loss, and astrogliosis. Immunodiagnostic assays, such as immunohistochemistry and

Western blot testing, that show the presence of PrP^{Sc} confirm the CJD diagnosis.

Historically, three different forms of CJD have been reported: sporadic, iatrogenic, and familial CJD. Sporadic CJD occurs in the absence of outbreaks with no known environmental source of infection. Decades of research has not identified a specific source of infection for sporadic CJD that accounts for about 85% of patients. Spontaneous generation of the pathogenic prions was hypothesized as a cause for sporadic CJD, possibly resulting from random somatic mutations or errors during prion protein gene expression. Iatrogenic CJD, on the other hand, is associated with transmission of the CJD agent via medical interventions such as administration of contaminated human pituitary hormones and the use of contaminated dura mater grafts and neurosurgical equipment. Familial CJD has been associated with the presence of inheritable prion protein gene mutations. Beginning in the mid-1990s, the emergence of a variant form of CJD, linked with BSE transmission to humans, was reported. This newly emerged disease differs from other forms of CJD by the young age of affected patients and its clinical and pathologic features (**Table 2**).

Sporadic CJD is a heterogeneous disorder that can be further subdivided into five different subtypes based on the Western blot characteristics of protease-resistant fragment of PrP^{Sc} and the polymorphism at codon 129 of the host prion protein gene. These different subtypes correlate with characteristic clinical and neuropathologic phenotypes. The most common subtype is associated with a 21 kDa PrP^{Sc} fragment, designated type 1, and the presence of methionine at the polymorphic codon 129 of the prion protein gene.

Variant Creutzfeldt–Jakob Disease

In 1996, the identification of a cluster of young patients with a prion disease was reported in the UK as part of the CJD surveillance system that was established in response to concerns about the potential spread of BSE to humans. Because the patients' age and their clinical progression and neuropathologic profile were different from other endemic CJD patients, the term 'new variant CJD' was initially used to describe this emerging prion disease in humans. This term was later shortened to variant CJD. Since 1996, the number of variant CJD cases increased and strong scientific evidence indicated that variant CJD resulted from BSE transmission to humans. As of June 2007, a total of 202 variant CJD patients was reported worldwide, including 165 patients from the UK, 21 from France, four from Ireland, three from the US, two each from Netherlands and Portugal, and one each from Canada, Italy, Japan, Saudi Arabia, and Spain. At least seven of the non-UK variant CJD patients (two each from the US and Ireland, and one each from Canada, France, and Japan) were believed to have acquired variant CJD during their past residence or visit in the UK.

Variant CJD can be distinguished from the more common classic CJD by the clinical and laboratory findings (**Table 2**). The median age at death of variant CJD patients is 40 years younger than sporadic CJD patients (28 and 68 years, respectively), but their median illness duration is longer (14 and <6 months, respectively). Unlike classic CJD patients, variant CJD patients predominantly have psychiatric manifestations at onset with delayed appearance of frank neurologic signs and the typical 'pulvinar sign' on the MRI. The diagnostic EEG

Table 2 Clinical and pathologic characteristics distinguishing variant Creutzfeldt-Jakob disease (variant CJD) from classic CJD

Characteristic	*Variant CJD*	*Classic CJD*
Median age (range) at death (years)	28 (14–74)	68 (23–97)[a]
Median duration of illness (months)	13–14	4–5
Clinical presentation	Prominent psychiatric/behavioral symptoms, painful sensory symptoms, delayed neurologic signs	Dementia, early neurologic signs
Periodic sharp waves on electroencephalogram	Almost always absent	Often present
'Pulvinar sign' on magnetic resonance imaging[b]	Present in >75% of cases	Very rare or absent
Presence of 'florid plaques' on neuropathologic Sample	Present in great numbers	Rare or absent
Immunohistochemical analysis of brain tissue	Marked accumulation of PrP-res[c]	Variable accumulation
Presence of agent in lymphoid tissue	Readily detected	Not readily detected
Increased glycoform ratio on Western-blot analysis of PrP-res	Present	Not present
Genotype at codon 129 of prion protein	Methionine/valine[d]	Polymorphic

[a]US CJD surveillance data 1979–2001.
[b]Symmetrical high signal in the posterior thalamus relative to that of other deep and cortical gray matter.
[c]Protease-resistant prion protein.
[d]A patient with preclinical vCJD related to blood-borne transmission was heterozygous for methionine and valine.

finding that is common in classic CJD patients is very rare in patients with variant CJD. For unknown reasons, all variant CJD patients tested to date had methionine homozygosity in the prion protein gene at codon 129, which is polymorphic for methionine or valine. This homozygosity is present in approximately 35–40% of the general UK population. Similar to classic CJD, a definitive diagnosis of variant CJD requires laboratory testing of brain tissues. In addition to the spongiform lesion, neuronal loss, and astrogliosis typical of most prion diseases, the neuropathology in variant CJD patients is characterized by the presence of numerous 'florid plaques', consisting of amyloid deposits surrounded by a halo of spongiform lesions.

Studies in the UK have indicated the probable secondary person-to-person transmission of the variant CJD agent in three patients by blood collected up to 3.5 years before variant CJD onset in the donors. Because a large proportion of the UK population has potentially been exposed to the BSE agent, concerns still exist about additional secondary spread of the agent via blood products and possibly via contaminated surgical instruments.

Prion Diseases of Humans Associated with Genetic Mutations

One of the intriguing properties of prion diseases in humans is the fact that they can be both infectious and inheritable. The inherited or genetic forms of prion diseases are associated with insertion, deletion, or point mutations of the open reading frame of the prion protein gene. At least 24 different point mutations of the prion protein gene have been described in association with human prion diseases. These genetic prion diseases have widely varying clinical and neuropathologic manifestations. Historically, genetic forms of prion diseases, in part based on their phenotypical expression, were classified as familial CJD, GSS, and FFI. Beginning in 1989, many types of insertion mutations associated with markedly heterogeneous phenotypes have been reported in familial clusters.

In addition to influencing susceptibility to variant CJD, the polymorphism at codon 129 markedly influences the clinicopathologic phenotype of several inherited prion diseases. The most striking example of this influence is the phenotype associated with codon 178 mutation that substitutes aspartic acid with asparagine. Patients who have this mutation in combination with methionine on the mutant allele at codon 129 present with the FFI phenotype, whereas patients who have valine at codon 129 of the mutant allele present with the familial CJD phenotype. The codon 129 polymorphism may also influence the age at onset and duration of illness in some prion diseases.

Familial CJD

Patients with familial CJD generally have clinicopathologic phenotype similar to nongenetic forms of CJD. The disease has a dominant inheritance pattern and over half of affected family members carrying the mutation eventually die of CJD. Familial CJD has been reported among many family clusters from Canada, Europe, Japan, Israel, the US, and several Latin American countries. It is most frequently associated with a mutation substituting glutamic acid with lysine at codon 200 of the prion protein gene. Arguably, familial CJD associated with codon 200 mutation is the most common inheritable form of prion disease in humans. The largest familial cluster was reported among Jews of Libyan and Tunisian origin. About 14 other less-frequent mutations associated with familial CJD have been reported from many countries.

Gerstmann–Sträussler–Scheinker syndrome

The term GSS is used to describe a heterogeneous group of inherited human prion diseases that are characterized by a long duration of illness (median: ~5 years) and the presence of numerous PrP-amyloid plaques, primarily in the cerebellum. GSS carries the name of three physicians who in 1936 reported the disorder among patients spanning many generations of an Austrian family. The disease in this family was later shown to be associated with a mutation at codon 102 of the prion protein gene and may have been first identified as early as 1912.

At least 13 different types of prion protein gene mutations or a combination of mutations in at least 56 kindred or families have been reported in association with the GSS phenotype. Familial clusters with the GSS phenotype have been reported from Canada, Europe, Japan, Israel, Mexico, and the US. Many of the GSS mutations are associated with a greater degree of variability in the disease phenotype than other inherited forms of prion diseases. The most frequent GSS mutation results in leucine for proline substitution at codon 102 and is coupled with methionine at the polymorphic codon 129 of the mutant allele. Patients with this mutation commonly manifest with ataxia, dysarthria, movement disorders, and possibly dementia and akinetic mutism. The illness can last for up to 6 years in some patients with the GSS 102 mutation. In other forms of GSS, an illness duration exceeding 20 years has been reported.

Fatal familial insomnia

FFI is a human prion disease with predominant involvement of the thalamus, resulting in a clinical phenotype characterized often by intractable insomnia and autonomic nervous system dysfunction, including abnormalities in temperature regulation, increased heart rate, and hypertension. The neuropathologic lesions are more severe in the thalamus than other regions of the brain. FFI is primarily associated with a mutation at codon 178

of the prion protein gene resulting in a substitution of aspartic acid with asparagine in combination with methionine at the polymorphic codon 129 of the mutant allele. Occasionally, sporadic FFI cases with no apparent mutation in the prion protein gene have been reported. FFI has been identified in Australia, Canada, Japan, the US, and several European countries.

Glossary

RDA (representational difference analysis) PCR-based technique for the identification and cloning of DNA sequences (e.g., virus DNA) present in a particular cell but not in a matched reference cell.

Introduction

Viruses are responsible for about 15–20% of all cancers worldwide. Human tumor viruses constitute a heterogeneous group of viruses, which are causally linked to the development of malignant diseases in humans. Conventionally, the term is confined to those viruses that are likely to cause cancer by malignant conversion of infected cells. Accordingly, the human tumor viruses include the Epstein–Barr virus (EBV), the Kaposi's sarcoma-associated herpesvirus (KSHV), the high-risk human papillomaviruses (HPV), the hepatitis B virus (HBV), the hepatitis C virus (HCV), and the human T-cell leukemia virus (HTLV-1). Other viruses, such as HIV, support tumor development and growth indirectly, for example, by inhibiting the immune response to the tumor but do not infect the progenitors of malignant cells. Besides their systematic differences, most tumor viruses share several of the following features:

- establishment of chronic or long-term persistent infection;
- presence of viral gene functions, which interfere with cellular growth control, apoptosis control, DNA repair, or genomic stability; and
- capacity to transform cells in culture and/or to be oncogenic in experimental animal systems.

These features are not unique to tumor viruses but also shared by other human viruses, which are not yet clearly demonstrated but were suspected to cause human malignancies. These include some subtypes of human adenoviruses, the human polyomaviruses (BK, JC), many subtypes of papillomaviruses, and HTLV-2.

Virally induced tumors contain mostly viral genomes or parts of viral genomes, frequently integrated into the cellular genomes. As a hallmark of their infection prior to malignant conversion, many virally induced tumors are clonal in respect to integrated viral sequences. All human malignancies caused by tumor viruses are rare consequences of the infection and develop after long-term viral persistence. This indicates the necessity of rare secondary events, which are crucial to viral oncogenesis. Among them could be accumulation of genetic damage including cellular mutations induced by viral or nonviral factors, including physical and chemical carcinogens.

EBV-Associated Lymphoproliferative Malignancies

EBV, a member of the *Herpesviridae*, was the first virus to be linked to the oncogenesis of a human malignant disease. In 1964 it was identified by Epstein, Achong, and Barr in a B-cell line derived from an African Burkitt's lymphoma. Besides Burkitt's lymphoma, there are two other histologically and clinically distinct types of EBV-associated B-cell lymphoma, Hodgkin's disease and the lymphomas of immunosuppressed individuals. These three EBV-associated lymphoid malignancies differ in the patterns of the viral latent-gene expression and seem to be derived from cells at different positions in the B-cell differentiation pathway. Besides B-lymphoid malignancies, the virus was also found associated with some rare types of T-cell and natural killer (NK) cell lymphomas.

Lymphocyte Transformation *In Vitro*

EBV is capable of immortalizing human primary B lymphocytes, which resemble phenotypically activated B lymphocytes and are capable of proliferating permanently in culture. Cell lines usually contain EBV genomes as nonintegrated covalently closed circular double-stranded DNA in various copy numbers. Due to a block in structural gene expression, the transformed cells usually do not synthesize progeny viruses; instead, they express a series of latency-associated genes, which are also active in various combinations in human malignancies associated with EBV. These genes include five EBV-associated nuclear antigens (EBNA1, 2, 3A–C), two latent membrane proteins (LMP1, 2), and several noncoding RNAs. Most of these genes have important functions in the viral latent persistence. EBNA2 and LMP1 are essential for the *in vitro* transformation of B cells, as has been confirmed by using recombinant forms of EBV that lack individual latent genes. These studies have also highlighted a crucial role for EBNA1, EBNA-LP, EBNA3A, and EBNA3C in the transformation process. The main transforming protein of EBV is LMP1. It fulfills the criteria of a classic oncogene (e.g., rodent-fibroblast transformation). Although it lacks any homology to cellular proteins, LMP1 functionally mimics co-stimulatory receptors of the tumor necrosis factor (TNF) superfamily. Independent of a TNFR ligand, it exerts its pleiotropic effects, including the induction of cell-surface adhesion molecules and activation antigens, and the upregulation of anti-apoptotic proteins. These signals account for both the growth- and survival-stimulating functions of LMP1.

Lymphomas in Immunosuppressed Individuals

Individuals who are compromised in their cellular immunity (T-cell immune reaction) are at risk for the development of EBV-positive B-cell lymphoproliferative diseases. These include the immunoblastic lymphomas in patients with genetic immunodeficiencies, in AIDS patients, and the post-transplantation lymphomas (PTLs) in patients under immunosuppressive therapy after organ transplantation. PTLs are polyclonal or monoclonal lesions, which mostly arise within the first year of allografting, when immunosuppression is most severe. Almost all of these early onset tumors are EBV positive. The growth-stimulating EBV latent genes including EBNA2 and LMP1 are expressed; it suggests that the PTL consists of virus-transformed cells, which closely resemble *in vitro*-transformed lymphocytes that grow out in the absence of effective T-cell surveillance.

Hodgkin's Lymphoma

EBV-induced infectious mononucleosis was recognized as a risk factor for the development of Hodgkin's lymphoma. This malignant tumor is characterized by the predominance of a nonmalignant infiltrate which vastly outnumbers the malignant cells (Hodgkin cells, Reed–Sternberg cells: HRS cells). All HRS cells within a tumor are part of the same clone and are probably derived from crippled germinal-center cells that have been rescued from the germinal-center reaction.

The infiltrate distinguishes the subtypes, the nodular sclerozing (NS), mixed cellularity (MC), and rarer lymphocyte-depleted (LD), which are to different extents associated with EBV. Approximately 40% of Hodgkin's lymphoma in the developed world is associated with EBV and between 50% and 90% of MC and LD subtypes. The EBV genome in the tumor is clonal and present in every HRS cell which is evidence for a causal role in the pathogenesis of Hodgkin's lymphoma. The HRS cells express a particular subset of latent-cycle proteins – EBNA1, LMP1, and LMP2. A plausible pathogenetic role for the virus could be the prevention of apoptosis in cells that have undergone a defective germinal center reaction. In particular, LMP1 by stimulating co-stimulatory (TNFR) pathways is capable of replacing a T-cell signal that prevents apoptosis. Whether EBV continues to contribute to the malignant phenotype at the time of tumor presentation is not known to date.

Burkitt's Lymphoma

Burkitts lymphoma is a worldwide distributed B-cell lymphoma with defined subtypes. Whereas only 15–25% of the sporadic form, which prevails in Europe and Northern America, is EBV associated, the endemic form is nearly to 100% positive for EBV. Endemic Burkitts lymphoma is a frequent childhood tumor in the humid lowlands of eastern and central Africa. It presents in children around 8 years of age as a unilateral swelling of the jaw. Due to early metastasis the disease is usually multifocal at diagnosis.

Burkitt's lymphoma and derived cell lines (from both EBV-positive and EBV-negative cases) are now confirmed to be of germinal-centroblast origin. In this stage of B-cell development, the germinal-center reaction of the B cell (including somatic hypermutations of the V chains and isotype switching) is almost finished and cells are starting to enter the memory compartment. Common denominators of all BL forms are chromosomal translocations, which result in increased expression of the cMYC protein. The contribution of EBV to the pathogenesis of Burkitt's lymphoma remains still unclear. The most compelling evidence of EBV's involvement in endemic BL is the high frequency (98%) of tumors carrying viral DNA and the presence of clonal EBV in all of the tumor cells. The viral gene expression is limited to mainly EBNA1. The transforming LMP1 protein is absent and even seems to be incompatible with the growth of BL cells *in vivo*. Thus, the virus might have an initiating role in which growth-transforming B-cell infections establish a pool of target cells that are at risk of a subsequent *MYC* translocation. Epidemiological evidence indicates that co-infection with malaria and HIV is an important co-factor, which increases tumor incidence, possibly by chronic stimulation of the B-cell system.

Lymphoid Malignancies with T-Cell or NK-Cell Characteristics

EBV is also associated with three types of T-cell malignancies. In particular, the nasal T-cell lymphoma has a high rate of association. It is an extranodal lymphoma of the angiocentric type, which primarily develops in the nosal caveola. The tumor is relatively frequently found in Southeast Asia. Frequently nasal EBV-associated lymphomas resemble the phenotype of NK cells (CD3−/CD56+). The EBV-gene expression includes EBNA1, LMP1, and LMP2 in various extents.

EBV-Associated Carcinomas

The infection of epithelia by EBV eventually results in malignant transformation and the development of carcinomas. Such EBV-associated cancers are the anaplastic nasopharyngeal carcinoma (NPC), a subset of gastric adenocarcinomas and certain salivary gland carcinomas.

Nasopharyngeal Carcinoma

NPCs are highly malignant neoplasias, which mostly occur in adults between the ages of 20 and 50 years. The prognosis is poor; most frequently, NPC presents with early metastasis into cervical lymph nodes and the skull. The anaplastic (undifferentiated) form of NPC (aNPC) shows the most consistent worldwide association with EBV (virtually 100% worldwide). The anaplastic type of the NPC is recognized as a separate clinical entity. It differs from other types of NPC by its low grade of differentiation of the tumor cells and a characteristic tendency to extended lymphocyte infiltrations. The aNPC is particularly common in areas of China and Southeast Asia, reaching a peak incidence of around 20–30 cases per 100 000. An etiologic role of the virus in tumor development is supported by following characteristic features of the tumor cells: (1) virtually all aNPC contain EBV-DNA, and (2) the viral episomes in the tumors are monoclonal. From this observation one can deduce that the infection event has occurred prior to tumorigenesis. This assumption is supported by the presence of monoclonal EBV-genomes in the noninvasive progenitor lesions, the *in-situ*-NPC. (3) Besides EBNA1, the tumors express LMP2 and partly (40%) the viral oncoprotein LMP1. The lack of LMP1 expression in some tumors however seems to be a secondary late event since it has been reported that the premalignant lesions of NPC all express LMP1. Thus, the presence of the growth-signal-mediating LMP1 and LMP2 is additional evidence for the causal role of the virus in tumorigenesis.

Other Carcinomas

EBV is present in a high proportion (>90%) of lymphoepithelioma-like gastric carcinomas, which morphologically closely resemble NPC. About 5–25% of gastric adenocarcinomas are also associated with EBV. These tumors display a restricted pattern of EBV latent-gene expression, including EBNA1 and LMP2A. A possible role of EBV in the pathogenesis of gastric carcinomas seems to be confined to late tumorigenesis, which is suggested by the absence of EBV infection in premalignant gastric lesions. A subset of salivary gland carcinomas have also been found to be EBV-positive including the expression of latent genes like EBNA1 and LMP1 and 2 in parts of the tumors. Recently, EBV has also been detected in some carcinomas of the breast and liver.

Malignant Diseases Related to the KSHV

By using a polymerase chain reaction (PCR)-based technique for the selective amplification of unknown sequences ('representational difference analysis') Chang and co-workers identified in 1994 a new human herpesvirus in the tissue of Kaposi's sarcoma (KS). The new virus was designated as human herpesvirus type 8 (HHV8) or KSHV. It is highly associated with KS but also found in several rare lymphoproliferative conditions, including Castleman's disease and body cavity-based lymphoma (synonymous: primary effusion lymphoma).

Kaposi's Sarcoma

The tumor was first described in 1872 by Moritz Kaposi as 'multiple idiopathic pigmented sarcoma of the skin'. It is a

multifocal, proliferative lesion of spindle-shaped cells with slit-like vascular spaces in skin and mucous membranes of the oral cavity, gastrointestinal tract, and pleura. The tumor cells, termed KS spindle cells, are likely of endothelial origin. KSs can be grouped into four clinical subtypes: (1) classic, (2) endemic or African, (3) transplantation-associated or immunosuppressive therapy-associated, and (4) epidemic or HIV/AIDS-associated. Based on the following evidence, a causal role of KSHV in the pathogenesis of KS is now widely accepted: (1) KSHV genomes are regularly detected in all subtypes of KS; (2) KSHV is present in the endothelial and spindle cells, the neoplastic component of the tumor; and (3) epidemiological and prospective cohort studies in HIV-infected individuals show high correlation of KSHV infections with a later development of KS. Viral gene expression in the latently infected KS cells is likely to support the growth of tumor cells. Among the viral proteins synthesized are a viral homolog of a D-type cyclin (vCYC), which is capable of stimulating the cell cycle in the G1 phase, and a viral homolog of FLICE-inhibitory protein (vFLIP), which is a potent suppressor of extrinsic apoptosis. Furthermore, latently infected KS spindle cells produce the 'latency-associated nuclear antigen' (LANA-1) that is required for the replication of circular viral episomes and the activation of a wide range of cellular genes.

B-Lymphoid Malignancies

'Multicentric Castleman's disease' (MCD) is a lymphoproliferative condition, characterized by enhanced B-cell proliferation and vascular proliferation in expanded germinal centers. In these lesions KSHV can be detected. In a proportion of B cells surrounding the follicular centers of MCD, several viral proteins were found to be expressed. These include LANA-1, the viral interleukin-6 (vIL-6), and the several proteins with homology to interferon regulatory factors (vIRF-1/K9, K10.5/LANA-2, K10). The signal transduction cascades induced by these viral proteins might be relevant for the pathogenesis of this disease. The second B-lymphoid malignancy associated with KSHV is the 'primary effusion lymphoma' (synonymous: body cavity-based lymphoma). This rare lymphoma develops mostly in AIDS patients in the spaces of pleura, pericard, or peritoneum.

Papillomaviruses as Major Cause of Human Cancers

There is nowadays sufficient evidence that certain, so-called 'high-risk' types of HPV are carcinogenic to humans in the cervix (HPV16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 66). In developing countries, carcinoma of the cervix uteri is the most frequent type of female cancer. Even in industrialized countries, in spite of extensive preventive screening, this cancer is among the most frequent female malignancies. HPV DNA can be found in virtually all cervical cancers, and the early genes E6 and E7 are usually expressed. The most prevalent type in epidermoid carcinomas is HPV16. HPV18 may be preferentially associated with adenocarcinomas. Other high-risk types have been detected in a few cases of squamous cell carcinoma each. HPV DNA was also demonstrated in more than 50% of the less-prevalent carcinomas of the vulva and penis (basaloid and warty tumors), the vagina, and the anus; HPV16 is again the most frequent type, followed by HPV18. HPV6 and HPV11 with a lower carcinogenic potential were detected in verrucous carcinomas of vulva, penis, and anus.

HPV16 and other members of the high-risk papillomavirus group immortalize primary human keratinocytes and induce resistance to differentiation stimuli. Histological abnormalities can be observed in stratifying keratinocyte cultures that resemble those in precancerous, intraepithelial lesions *in vivo*. The cells are not tumorigenic in nude mice initially, but quickly change to an aneuploid karyotype, which is in keeping with frequently occurring abnormal mitoses in HPV16-positive lesions. At higher passage level, malignant clones reproducibly arise, which indicates that HPV infection is sufficient to induce cancer cells in combination with additional spontaneous or virus-induced modifications. The viral genes E6 and E7 are required to trigger these effects. They encode proteins that inactivate tumor suppressors and modulate cell-cycle regulation, DNA repair, and apoptotic processes, for example, by interacting with the cellular proteins p53, p105-RB (the retinoblastoma protein), p21, p27, Bak, and PDZ domain proteins. E6 activates the catalytic subunit of the telomerase as an important step in cell immortalization. E6 and E7 induce chromosomal instability, mitotic defects, and aneuploidy, which will finally contribute to tumor progression. The E6 and E7 proteins of low-risk viruses display much lower affinities to the cellular proteins, in parallel with a lower or non-detectable transforming potential *in vitro*.

Much attention has been paid to the possible role of viral DNA integration in tumor progression. HPV18 DNA appears integrated into the cellular genome in almost all cervical cancers, and HPV16 DNA in about two-thirds of the cases. This is in contrast with benign and premalignant lesions, where the viral DNA usually persists extrachromosomally. There is no evidence for a specific integration site, but HPV DNA has been repeatedly detected in the vicinity of the *myc* proto-oncogene in combination with an overexpression of the cellular gene. Probably, more important is the upregulation of viral oncogene expression following critical integration events, which result in a clonal selection of the affected cells.

The persistence of viral DNA and the continual expression of transforming genes in advanced cancers suggest that HPV functions are also involved in the maintenance of the malignant phenotype. An experimental suppression of E6 and E7 expression inhibited the proliferation of HPV-positive cervical cancer cell lines and reduced the cloning efficiency in semisolid medium, thus indicating that the viral proteins are still modulating the growth of malignant cells.

The genital tract HPVs are also responsible for many HPV infections at extragenital mucosal sites such as the oral cavity, the oropharynx, and most notably the larynx. However, cancers arising in this field harbor HPV DNA less frequently than genital tumors (oral cavity and larynx on average about 25%, oropharynx 35%, preferentially carcinoma of the tonsil). The reason for the striking difference between the genital and aerodigestive tracts is not known. Either the etiology of many oral and laryngeal cancers is unrelated to HPV, or the relevant HPV types are not yet characterized or the viral DNA is no longer necessary for cancer cells and is finally lost.

Different HPV types induce various proliferative skin lesions that are benign, like plantar, common and flat warts. An association between HPV and skin cancer becomes obvious in epidermodysplasia verruciformis (EV). EV patients are infected with a subgroup of HPVs, which induce characteristic persisting macular lesions disseminated over the body. Many EV patients develop squamous cell skin carcinomas, mainly at sun-exposed sites, which suggest a co-carcinogenic effect of ultraviolet light. The DNA of HPV5 or 8 persists extrachromosomally in high copy number in more than 90% of the cancers. HPV14, 17, 20, or 47 were occasionally detected. The prevalence of specific HPVs is in striking contrast with the plurality of HPV in benign lesions and has been interpreted as reflecting a higher oncogenic potential of these types.

The carcinogenic potential of HPV8 could be clearly demonstrated in transgenic mice with the early genes of HPV8 under control of the keratin 14 promoter, which regularly develops papillomas with moderate and severe dysplasia and carcinomas in 6% of animals without any further treatment with physical or chemical carcinogens. E6 turned out to be the major oncogene in the mouse skin, necessary and sufficient for carcinogenesis. In contrast with genital HPV, no complex formation could be detected between HPV8 E6 and the cellular p53 protein, which suggests different strategies of transformation. Human keratinocytes transduced with recombinant retroviruses expressing HPV8 E7 invaded the dermis when tested in organotypic skin cultures.

A high prevalence of HPV DNA in squamous and basal cell carcinomas of the skin, particularly of immunosuppressed but also of immunocompetent patients, has been demonstrated by highly sensitive PCRs. Evidence is accumulating for many novel HPV types related to EV HPVs and cutaneous types. That there is a strong association between genital HPV16 and rare squamous cell neoplasms from the finger is remarkable. Individual skin tumors were frequently noted to be infected by several HPVs. No single HPV type predominates in skin cancers of non-EV patients, so far as is known. HPV DNA persists at very low concentrations in many skin cancers, usually at less than one genome copy per cancer cell. The relevance of these findings to the pathogenesis of cutaneous cancer remains to be determined. The possibilities discussed above for carcinomas of the aerodigestive tract are also valid for skin carcinomas.

Chronic Hepatitis B and C in Hepatocarcinogenesis

Hepatocellular carcinoma (HCC) is among the most common fatal malignancies in humans worldwide. An association with HBV from the Hepadnavirus family was suggested by the geographical coincidence of a high incidence of HCC in Southeast Asia and equatorial Africa with high rates of chronic HBV infections, frequently contracted congenitally. Prospective studies demonstrated about a 100-fold increased risk of hepatoma among carriers of the HBV surface antigen (HBsAg). Integrated HBV DNA can be detected in a large proportion of the tumors from high-risk areas and in hepatoma-derived cell lines. HBV is the first human tumor virus against which vaccination programs have been initiated on a broad basis. First signs of a decrease in the incidence of hepatoma in populations vaccinated in the 1970s substantiate the viral role in cancer development.

Liver cancer usually develops only after several decades of chronic HBV-induced hepatitis and may thus be triggered by accumulating genetic damage due to inflammation and continuous cell regeneration. A specific contribution of HBV might be expected from *cis* effects following integration of viral DNA, but except for a few case reports no consistent evidence has been obtained for the activation of particular proto-oncogenes. A transactivation of transcription may be more relevant; this can be achieved by the viral X protein, the large surface protein, and a truncated $preS_2/S$ protein. The viral $preS_2/S$ gene, which normally encodes a surface protein, appears frequently disrupted in cancers as a consequence of DNA integration and then gives rise to the transactivator. All HBV transactivators exert pleiotropic effects via the protein kinase C/raf-controlled signal pathway, finally activating transcription factors such as AP-1 and NF-κB and proliferation. The analysis of viral integration patterns and functional assays suggest that at least one transactivator may function in most hepatomas.

Mutations in the p53 tumor suppressor gene occur in about 30% of human hepatomas. They are observed more often in countries with dietary contamination by mutagenic aflatoxin and seem to be a late event in liver carcinogenesis. The X protein was shown to interact with elements of the DNA repair system, which may increase the mutation rate of p53.

Two types of large HBsAg with deletions at the $preS_1$ and $preS_2$ regions were detected in 60% of HCC patients. The preS mutant proteins can initiate endoplasmic reticulum stress to induce oxidative DNA damage and genomic instability. Liver cancer arose not only in mice transgenic for the X gene but also in mice transgenic for preS mutants.

More recently, seroepidemiological evidence was obtained for a correlation between HCV infections and hepatoma. Antibodies against HCV were detected in between 13% and over 80% of liver cancer patients around the world. Over 60% of acute hepatitis C becomes chronic and may progress to cirrhosis and HCC. Latency periods between primary infection and cancer are usually measured in decades, but in some cases the intervals are rather short (5–10 years). The cumulative prevalence of hepatoma in cirrhotic HCV-infected patients is over 50%, indicating that HCV substantially increases the risk of HCC. HCV is related to flaviviruses and pestiviruses and is the first human tumor-related virus with an RNA genome and no DNA intermediate during replication. The role of the virus in carcinogenesis is not yet clear. Liver injury during chronic hepatitis may be responsible for malignant conversion, but there is also some evidence that HCV is more directly involved. HCV appears to persist and replicate in hepatocytes during malignant transformation. Viral proteins interact with many host-cell factors and affect cell signaling, transcription, translation, proliferation, and apoptosis. The HCV capsid core protein and the nonstructural proteins NS3 (a serine proteinase), NS4B, and NS5A revealed transformation potential in tissue culture. Both HCV core and NS5A target the Wnt-β-catenin pathway, which appears crucial in human HCC. As discussed for HBV, HCV also induces endoplasmic reticulum and oxidative stress.

The Role of HTLV-1 in the Oncogenesis of Adult T-Cell Leukemia/Lymphoma

In 1977 adult T-cell leukemia/lymphoma, a malignancy of CD4-positive T lymphocytes, was first recognized as a distinct clinical entity by Uchiyama, Takatsuki, and colleagues. Three years later, in 1980, Poeisz, Gallo, and co-workers isolated the first human retrovirus, HTLV-1 from the lymphoma-subtype of ATLL. HTLV-1, but not the closely related HTLV-2 is highly associated with ATLL. Besides ATLL, HTLV also is linked to the pathogenesis of a chronic neurodegenerative disorder, called HTLV-associated myelopathy/tropical spastic paraparesis.

Transformation of T Cells

HTLV-1-infected T lymphocytes derived from leukemic and nonleukemic patients, in contrast to normal T cells, regularly give rise to permanent cultures, which are capable of expressing all viral proteins. The virus *in vitro* has immortalizing capacity: primary human T lymphocytes can be transformed to permanent growth in tissue culture, which phenotypically resembles ATLL cells. A nonstructural regulatory protein of the virus, Tax, is capable of mediating the transformation. Besides regulating viral transcription, this multifunctional protein interferes with cellular control of survival, proliferation, and genomic stability. It combines many features characteristic of oncogenes, among them the ability to immortalize primary human T cells to permanent growth. These cells closely resemble HTLV-1-transformed and patient-derived T cells. Tax is also capable of inducing malignant growth in animal models. In HTLV-1 Tax transgenic mice it induces leukemia which is similar to the clinical pattern of ATLL.

Adult T-Cell Leukemia/Lymphoma

About 1–3% of all HTLV-infected individuals develop ATLL, mostly after several decades of asymptomatic viral persistence. Typically, the disease manifests at the age of 40–60 years. Frequent symptoms are cutaneous lesions, pulmonary complications, hepatosplenomegaly, and hypercalcemia, which at least in part can be attributed to the capacity of the malignant cells to infiltrate organs. Generally, ATLL is categorized into four forms: (1) acute, (2) chronic, (3) smoldering, and (4) lymphoma-type, which are all associated with HTLV-1. The smoldering and chronic ATLL are less-severe forms of the disease, which may convert to the aggressive acute ATLL. The lymphoma-type is characterized by the presence of extensive lymphadenopathy in the absence of blood or bone marrow involvement. Acute ATLL is the most frequent form (more than 55%) and until now barely curable and mostly fatal. Leukemia cells exhibit an unusual and characteristic morphology with lobulated nuclei. Regarding the surface phenotype they resemble T helper cells, from which they are probably derived (CD4), expressing high amounts of the interleukin 2 receptor (IL2Rα). Viral gene expression including the Tax gene is rather low and the role of the protein for the maintenance of the malignant proliferation unclear. A causative role of HTLV-1 in ATLL is now generally accepted because of the following evidence: (1) the geographic correspondence of ATLL and HTLV-1; (2) the almost 100% association of HTLV-1 and ATLL; (3) the clonal integration of the provirus in

ATLL cells, which indicates infection prior to malignant transformation; and (4) the oncogenic capacity of HTLV-1 and its oncoprotein Tax in animal models.

General Conclusions and Future Perspectives

In most cases, long latency periods of many years or several decades elapse between primary infection by tumor viruses and first symptoms of cancer. All human tumor viruses are widespread in the world population. They contribute to malignant disease, mainly by initiation of oncogenesis, but regular infection does not immediately result in cancer. Thus, all human tumor viruses are important or necessary risk factors for particular cancers, but require additional events to induce malignant disease. This implies that in principle, all virally induced cancers can be prevented by protective immunization. As examples, vaccination against HBV and recently, against high-risk HPV are powerful prophylactic means to fight the associated cancers. The low manifestation rates of virus-induced malignancies also imply that the mere proof of an infection with a tumor virus is of limited value for the management of patients and cancer prevention. Specific diagnostic tests have to be designed that evaluate parameters of the viral infection more closely related to malignant conversion. In many but not all cases, continuous viral expression is detectable in malignant tumors, which raises the prospect of virus-specific pharmacological interference for adjuvant cancer therapy or cancer immunotherapy. For instance, the neoplastic phenotype of HPV-positive genital carcinoma cells seems to be affected by viral functions and may thus be a promising therapeutical target. Even in cases, in which primary infection and initial growth transformation apparently lead, through tumor progression, to a constitutive form of proliferation where viral gene products are not necessary for growth, virus may be used to target the tumor. For instance, stimulating specifically the immune response against viral antigens may be an appropriate future strategy.

Glossary

Icosahedron A solid having 20 faces and 12 vertices.
Open reading frame Region of a genome that can be translated into a protein.
Phylogeny The complete evolutionary history of group of animals, plants, bacteria, viruses, etc.
Pseudoknot RNA structure formed by base-pairing between nucleotides within the loop subtending a stem and nucleotides outside of this loop.

sgRNA Subgenomic RNA, derived from a viral RNA genome during replication, serves as mRNA for the expression of genes that are translationally silent in the genomic RNA.
Vein-clearing Yellowing along the leaf veins.

The Family and Its Distinguishing Features

The members of the family *Tymoviridae* are presented in **Table 1**. Like the family itself, the genus *Tymovirus* derives its name from the type species, *Turnip yellow mosaic virus*. Turnip yellow mosaic virus (TYMV) was first isolated in 1946 and is by far the most intensively studied member of the family. Indeed, TYMV is one of the best-characterized plant viruses. The family was recently created in recognition of the close relationships between the genera *Tymovirus*, *Marafivirus*, and the founding member of newly created genus *Maculavirus*, grapevine fleck virus (GFkV). Poinsettia mosaic virus (PnMV) is currently a family member unassigned to a genus. Complete genome sequences are available for the type species of each of the three genera of the *Tymoviridae* and for PnMV.

The members of the family *Tymoviridae* are characterized by their icosahedral, nonenveloped, ~29 nm virions, that can readily be visualized by negative-staining electron microscopy (EM). Infections produce a characteristic

mixture of filled, infectious virions and empty or near-empty capsids. Regular surface features, representing prominent peaks formed by pentamers and hexamers of coat protein (CP) molecules, are evident by EM (**Figure 1**).

The genomes of members of the *Tymoviridae* are composed of a single positive-stranded RNA generally 6.0–6.5 kb long, although the genome of GFkV is 7.5 kb long. Subgenomic (sg) RNAs of 1 kb or less are associated with CP expression. All *Tymoviridae* genomes have a distinctive skewed nucleotide composition that is rich in C residues (32–50%). The unifying characteristic of the genome design of all *Tymoviridae* members is the presence of a long open reading frame (ORF) that covers most of the genome and encodes the replication polyprotein with identifiable domains: methyltransferase, papain-like proteinase, helicase, and RNA-dependent RNA polymerase (RdRp) in order N- to C-terminal (**Figure 2**). The CP ORF is situated downstream of the polyprotein ORF, to which it is fused in the marafivirus and PnMV genomes. Close familial relationships are easily discerned from alignments of the sequences of the RdRp and CP genes.

Most viruses in the family have narrow host ranges. Many of the tymoviruses have been isolated from noncrop hosts and have thus far not presented major disease threats to crops. Marafiviruses are associated with significant crop losses, perhaps resulting from their more effective transmission by flying insects.

Tymoviruses

Properties and Distinguishing Characteristics

Although virtually all information about tymoviruses has been derived from studies on TYMV, it is considered to be generally applicable to the other members of the genus. Virions of tymoviruses contain genomic RNAs 6.0–6.7 kb long and produce a single 3′ collinear sgRNA less than 1 kb in length encoding the ~20 kDa CP. Their genomes include a distinctive 16-nt-long 'tymobox' sequence, and the genomes of most species possess a 3′ tRNA-like structure (TLS) that can be efficiently esterified with valine. The genomes encode three ORFs (**Figure 2**), two of which almost completely overlap: the overlapping protein (OP) and replication protein (RP) ORFs, which begin at AUG codons separated by only 4 nt. Tymoviruses replicate in all major tissues of their host plants, and accumulate to high levels (more than 0.1 mg g^{-1} leaf tissue). Both filled and empty or near-empty particles accumulate. They are readily transmitted mechanically under laboratory conditions, and are spread over limited distances by beetle vectors in nature. Infection produces mosaic symptoms and a distinctive cytopathy that is evident upon EM observation by the appearance of small vesicles on the surface of chloroplasts, together with vacuolation and clumping of chloroplasts.

Capsid Structure

Virions of tymoviruses are highly stable ~29 nm, $T = 3$ icosahedra formed by 180 copies of the single CP, arranged as 12 pentamers and 20 hexamers. These groupings form the vertices with fivefold and sixfold symmetry that constitute the surface peaks visible upon high-resolution EM observation (**Figure 1**). Intersubunit stabilization is provided primarily by hydrophobic protein–protein contacts, allowing the formation of stable shells that appear to be devoid of RNA. These empty or near-empty capsids can account for about one-third of the particles present in infected tissues and are readily identifiable by internal staining in negative-contrast EM (**Figure 1**). They

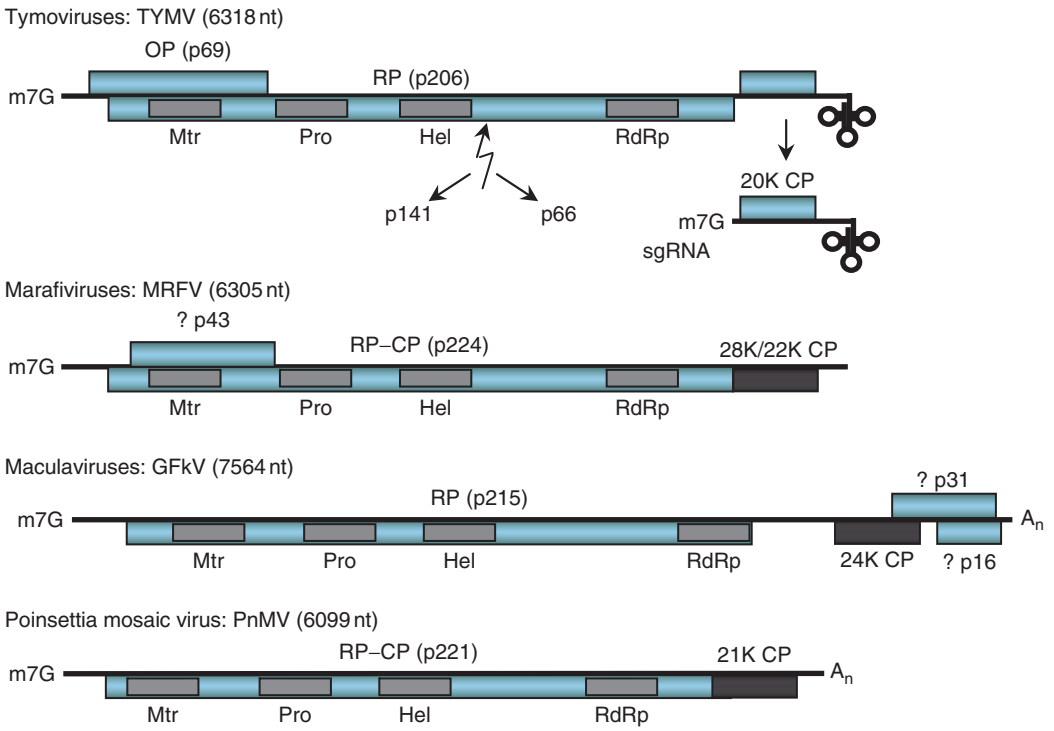

Figure 2 Genomes of the type members of the genera of the family *Tymoviridae* and of PnMV. All genomes have a 5′-m7GpppG cap, but the 3′ terminal structures vary. TYMV has a valine-specific tRNA-like structure (cloverleaf), GFkV and PnMV have a poly(A) tail, while MRFV has neither. The known or predicted (?) expressed ORFs are indicated with the molecular weight (K, kDa) of the predicted protein. The RPs all possess methyltransferase (Mtr), papain-like proteinase (Pro), helicase (Hel), and RdRp domains. The TYMV RP is cleaved as indicated, and similar cleavages are expected for the other viruses. The TYMV OP is the viral movement/RNAi suppressor protein. The TYMV CP is expressed from a sgRNA, and all other CPs are probably also expressed from sgRNAs (not shown). The 28 kDa MRFV CP (whose true size is likely to be closer to 25 kDa) may be produced by proteolytic cleavage from the RP–CP fusion protein, and an analogous event may occur with PnMV. Expression of the MRFV p43 and GFkV p31 and p16 has not yet been validated.

sediment as the 'top component' at 45–55S in CsCl density gradients, and readily separate from the 'bottom component', the infectious 110–120S virions that contain the genomic RNA. Minor components of intermediate density contain a range of subgenomic-size RNAs that can be translated to yield CP. Roughly equimolar amounts of genomic and sgRNAs are encapsidated, but the precise disposition of sgRNA in the various particles has not been determined. Like many other viral CPs, tymoviral CPs fold into eight-stranded, β-barrel, jelly-roll structures. However, unlike some other CPs, there is no positively charged domain at the N terminus for interaction with RNA and charge neutralization during packaging. Charge neutralization is thought to be provided by polyamine molecules (mostly spermidine) associated with the RNA. The crystal structures of empty and infectious particles have been determined for TYMV and physalis mottle virus. Consistent with the dominance of protein–protein interactions in particle stabilization, empty and infectious particles have very similar structures.

Packaging signals in tymoviral RNAs have yet to be identified, though RNA recruitment may involve conserved hairpins in the 5′ untranslated region (UTR) and interaction of C-rich segments of the RNA with CP at low pH. Localized areas of low pH (5–6) have been postulated to arise at the surfaces of photosynthesizing chloroplasts. Tymoviral replication occurs in characteristic vesicles that form at the chloroplast surfaces (see below), and capsid formation is most active near these vesicles, suggesting a possible coupling between replication and encapsidation during infection. Despite much effort, there has been no success in developing a cell-free packaging system. These efforts have focused on the possible role of 'artificial top component' (ATC) capsids as decapsidation and encapsidation intermediates. ATCs are protein shells devoid of RNA that can be made from infectious virions by treatments such as freeze–thawing and exposure to high pH and pressure. They are similar in structure to infectious virions, but lack a capsomere of six CP molecules that is ejected during the treatment, allowing RNA escape.

Genome Organization

Tymoviral genomic RNAs possess a 5′-m7GpppG cap and terminate at the 3′ end in -CC(A) except for

dulcamara mottle virus (DuMV) that is in most cases part of a TLS. The typical tymoviral TLS is just over 80 nt long, has a distinctive pseudoknot close to the 3′ terminus, and is a close structural mimic of cellular $tRNA^{Val}$. A valine-specific anticodon is present, and the 3′ terminus can be specifically aminoacylated with valine. The valylated RNAs of some, though not all tymoviruses, can form a tight complex *in vitro* with the GTP-bound form of translation elongation factor eEF1A. Most molecules of encapsidated RNA lack the terminal A residue in the -CC(A) end, which is thought to be added by the host tRNA-specific CCA-nucleotidyltransferase at the beginning of infection. The main roles of the TYMV TLS are thought to be (1) as a 3′ enhancer of translation initiation, (2) as a regulator of the onset of RNA replication by modulating access by the polymerase to the 3′ end, and (3) in maintaining an intact-CCA 3′ end. A minority of tymoviral genomic RNAs have 3′ UTRs that lack the typical valine-specific TLS (DuMV, erysimum latent virus, and nemesia ring necrosis virus, NeRNV).

Tymoviral RNAs act as cap-dependent messenger RNAs. Of the three ORFs, two (OP and RP) are expressed directly from the genomic RNA, whereas the third (CP) is expressed from the 5′-capped sgRNA (**Figure 2**). Although the sequence contexts around the OP and RP initiation codons vary, 4 nt always separates these closely spaced AUGs. The RP ORF covers most of the viral genome, and encodes the ~200 kDa RP, the only viral protein essential for supporting viral RNA replication in protoplasts. This ORF encodes discrete domains (**Figure 2**) that are discernable by virtue of sequence relationships to similar domains encoded by a wide variety of positive-stranded RNA viral genomes. Particularly the RdRp domain is well conserved and appropriate for phylogenetic comparisons. Closely related, yet distinct, tymoviral genomes have RdRp domains with about 70% nucleotide sequence identity. The RP is translated as a precursor protein that subsequently undergoes maturation cleavage catalyzed by the papain-like proteinase domain. The single known cleavage separates the RdRp domain from the remainder of the RP; thus, for TYMV, the precursor p206 is processed to yield p141 and p66.

The OP ORF almost entirely overlaps the RP ORF. Its length and the sequence of the encoded protein are highly variable. OPs range between 49 and 82 kDa, and have only 25–40% amino acid sequence identity between the most closely related pairs of viruses. OP expression is needed for establishment of infection and for spread of the virus in plants. The OP is a suppressor of the host RNA silencing antiviral response and is also believed to be the viral movement protein. It is a substrate for ubiquitin-dependent degradation by the proteasome. Long-distance movement of the virus in plants requires expression of the CP.

The CP ORF initiates close to the end of the RP ORF, sometimes even a little upstream. CP sequences are variably conserved among tymoviruses, with 36–86% amino acid sequence identity between the most closely related pairs of viruses.

Tymoviral genomes possess a highly conserved sequence, the 16 nt tymobox (–GAGUCUGAAUUGCUUC–) with small variations in some viruses, especially wild cucumber mosaic virus, just upstream of the CP ORF. The tymobox and its associated 'initiation box' sequence CAA(U/G) positioned 8 or 9 nt downstream of the tymobox are believed to serve as the core elements of the sgRNA promoter. The tymobox overlaps with the 3′ end of the RP ORF, resulting in the presence of the tripeptide – ELL – near the C terminus of all RPs.

Replication Cycle

The ultrastructural changes that reflect viral replication activity and that result in the distinctive pathology of the chloroplasts have been particularly well described for TYMV. As is typical of positive-stranded RNA viruses, the replication cycle is completed entirely in the cytoplasm, and RNA replication occurs in association with membranes, specifically the chloroplast outer membrane. Vesicles 50–80 nm in diameter form as invaginations of the two outer membranes of chloroplasts. They form before the appearance of virions, which are initially found close to vesicle clusters and later throughout the cytoplasm; in some cases, empty capsids accumulate in nuclei. The RdRp has been localized to zones on chloroplasts that are rich in vesicles, and this localization depends on protein–protein interaction between the proteinase and RdRp domains of the mature RPs p141 and p66, respectively.

RNA replication occurs via the production of full-length minus strands, whose synthesis in TYMV is directed by the 3′ terminal –CCA serving as promoter and initiation site. No other minus-strand promoter elements have been identified in the 3′ UTR. As mentioned above, the tymobox appears to function with the initiation box as the core of the promoter directing sgRNA synthesis by internal initiation on the minus strand. The sgRNA of TYMV has a m7GpppA 5′ terminus.

Studies on the functions of viral proteins and of *cis*-acting sequences in the genomic RNA have been greatly facilitated by the use of 'infectious clones', that is, molecularly cloned cDNA versions of the genome from which infectious RNA can be derived.

Infection and Transmission

Tymoviruses cause chlorotic mosaic, vein-clearing, and mottling symptoms, generally without strong stunting. Host ranges are mostly narrow, and to date, no tymoviruses infecting monocot plants have been isolated. Tymoviruses

are transmitted over limited distances by chrysomelid beetles, and some are weakly seed-transmissible. They can also be transmitted mechanically.

Phylogenetic Relationships and Species Demarcation

In the past, serology using antisera raised against intact virus was the main criterion in classifying tymoviruses and in distinguishing between species. This is no longer the most convenient approach, however, and it has in fact been shown that distinct viruses whose genomic and CP sequences have identities less than 80% and 90%, respectively, can appear to be serologically identical. This seems to be due to similar or identical dominant epitopes within otherwise distinct CPs.

The study of relationships among tymoviruses and to other viruses will undoubtedly in the future rely on the interpretation of sequences derived from the genomic RNA. The phylogenetic trees based on the sequences of the CP and the RdRp (**Figure 3**) show similar relationships, both among the tymoviruses and to the other members of the family *Tymoviridae*. This suggests that recombination between these coding regions has not been a strong evolutionary force among the *Tymoviridae*. However, the genome of NeRNV, which has a tobamoviral-type TLS capable of aminoacylation with histidine, indicates that recombination can occur and shape tymoviral genome evolution. The complete genome sequences are available for 13 tymoviruses or tentative tymoviruses (**Table 1**).

Alignments based on the RP protein sequences indicate that the capilloviruses, carlaviruses, trichoviruses, and potexviruses, all members of the *Flexiviridae*, are the next most closely related virus groups. More distant sequence relationships indicate that members of the family *Tymoviridae* belong to the alpha-like virus group.

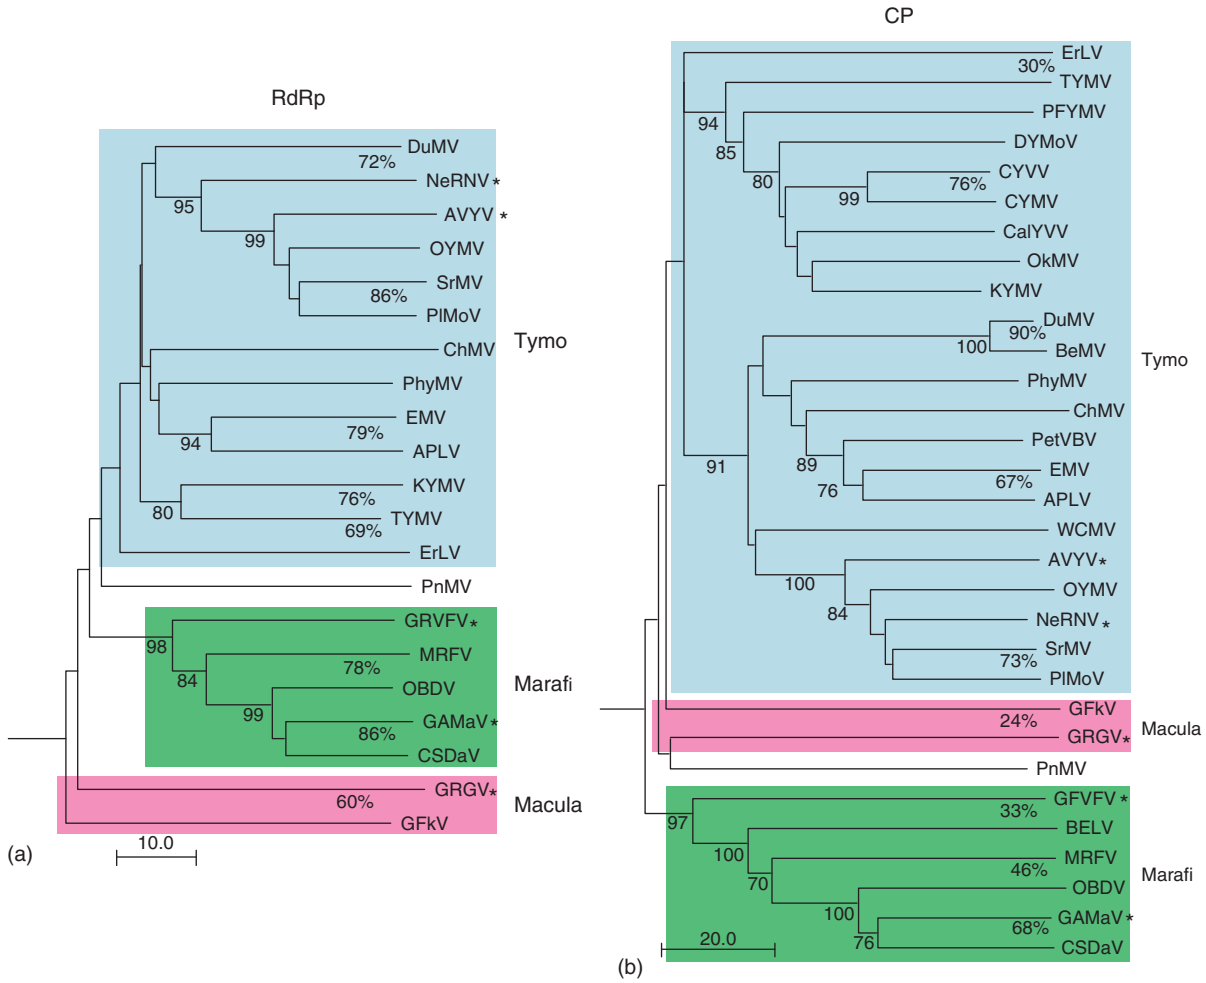

Figure 3 Phylogenetic trees showing the relationships between members of the family *Tymoviridae* based on neighbor-joining amino acid alignments of (a) the core RdRp domain and (b) the CP sequences. Bootstrap values (%) are indicated at well-supported nodes, and percent identities taken from pairwise alignments are indicated between selected sequences. Branch lengths reflect the number of amino acid differences. Viruses from each of the three genera are separately shaded as marked. Viruses with tentative taxonomic status are marked with an asterisk.

Marafiviruses

Properties and Distinguishing Characteristics

Three current members of the genus *Marafivirus* are viruses principally infecting monocots (grasses), while another infects citrus and the two tentative marafiviruses were isolated from grapevine. Plant host ranges are narrow. The genomes are 6.3–6.8 kb long, with a single ORF encoding an RP/CP fusion protein covering most of the genome. Two forms of the same CP (~25 and ~21 kDa) are found in virions. A single 3′-collinear sgRNA (<1 kb) encoding the smaller form of the CP is produced during infection. A slightly modified form of the tymobox sequence, termed 'marafibox', is present in the genome near the junction between the RdRp- and capsid-coding sequences. Marafiviruses are phloem-limited and not mechanically transmissible. The grass-infecting marafiviruses are transmitted by cicadellid leafhoppers in a persistent-propagative manner, involving virus replication in the insect.

A distinctive feature of the marafiviruses is the presence of two CPs in the virions, a major CP ~21 kDa form and a minor N-terminally extended 22–28 kDa form. The latter is thought to arise by proteolytic release from the polyprotein, whereas the former is expressed from the sgRNA. The production of this sgRNA is probably under the control of the marafibox, a 16 nt sequence (–CA(A/G)GGUGA AUUGCUUC–) very closely related to the tymobox, and the –CA(A/U)-initiation box located 8 nt downstream. The roles of the two forms of CP are unclear.

Virion Structure, Genome Organization, Replication Cycle, and Phylogenetic Relationships

Marafiviruses produce virions and empty capsids that are similar to those produced by tymoviruses when observed by negative-staining EM. However, due to the phloem-limited replication of marafiviruses, the yield of virus is low, limiting the usefulness of EM for viral identification. Complete genome sequences are available for four confirmed or tentative marafiviruses (**Table 1**).

Marafivirus genomic RNAs appear to be 5′-capped but they lack the 3′-TLS that is distinctive of tymoviruses. Apart from maize rayado fino virus (MRFV), marafivirus genomes possess a 3′ poly(A) tail. Almost the entire genome of marafiviruses is devoted to encoding a large 224–240 kDa polyprotein, which includes replication-associated and CP domains (**Figure 2**). The relationships between the CP and RdRp domains of the marafiviruses and other members of the family *Tymoviridae* are indicated in **Figure 3**. The polyprotein is believed to be proteolytically processed by the viral proteinase at two sites, between the helicase and RdRp domains as in tymoviruses, and between the RdRp and CP domains. Although the only experimentally mapped polyprotein cleavage site in a member of the family *Tymoviridae* is that occurring in TYMV, amino acid sequence alignments have discerned probable cleavage sites occurring immediately downstream of Gly-Gly or Gly-Ala dipeptides at the helicase–RdRp and RdRp–CP junctions in marafivirus polyproteins.

At the present state of relative paucity in marafivirus genome sequences, the taxonomic implications of evident variation in genome organization are uncertain. In addition to lacking a poly(A) tail, MRFV is the only marafivirus possessing a significant overlapping ORF, encoding a putative 43 kDa protein, whose expression *in vivo* has not been verified. Related but strongly interrupted coding sequences have been discerned overlapping the methyltransferase domains of other marafiviral genomes and, based on sequence similarities to tymoviral OP, it has been postulated that these sequences represent variously degenerate versions of the tymoviral OP. The loss of OP during evolution may explain the phloem limitation of marafiviruses. Citrus sudden death-associated virus (CSDaV) is the only marafivirus with an additional ORF near the 3′ end of the genome. This ORF almost completely overlaps the CP ORF and could encode a 16 kDa protein.

The three grass-infecting marafiviruses, MRFV, OBDV, and Bermuda grass etched-line virus, are serologically related, but are not serologically cross-reactive with tymoviruses or more distantly related viruses. Despite the indications of genome variability mentioned above, the marafiviruses do form a phylogenetic group with interspecies relationships similarly close to those between the various tymoviruses (**Figure 3**). Sequence relationships among the RP and CP ORFs clearly link the marafiviruses to the other members of the *Tymoviridae*. Like the tymoviral CPs, marafivirus CPs lack a cluster of basic amino acids at the N terminus.

Infection and Transmission

The best-studied marafiviruses are MRFV and OBDV. They cause stunting and chlorotic leaf spots or streaks, general leaf discoloration, or enations on leaf and stem veins. Cytological symptoms are restricted to the phloem and adjacent parenchyma cells, with clearly discernible hyperplasia and hypertrophy. These viruses are not mechanically transmissible or transmissible through seed, but are vectored in nature by leafhoppers. Significantly, MRFV and OBDV are maintained for long periods and through moults in leafhopper vectors, and transmission can occur from viruliferous vectors over a period of several weeks. OBDV replicates in the aster leafhopper (*Macrosteles fascifrons*), and the transmission behavior of MRFV is also consistent with replication in the cicadellid leafhopper (*Dalbulus maidis*). MRFV is commonly associated and co-transmitted with maize stunt spiroplasma or maize bushy stunt mycoplasma in causing economically significant outbreaks of corn stunt syndrome. OBDV can also be co-transmitted with a

mycoplasma. The presence of virus in the leafhopper vectors is not associated with detectable symptoms or loss of reproductive fitness.

The most economically significant marafivirus is probably CSDaV. This virus is believed to be the causative agent of the citrus sudden death syndrome, which has had devastating effects on orange trees in Brazil. Preliminary evidence suggests transmission by aphids. The grapevine-infecting tentative marafiviruses, grapevine asteroid mosaic-associated virus and grapevine rupestris vein-feathering virus, have no known insect vector.

Maculaviruses

Properties and Distinguishing Characteristics

Recent sequencing of the complete genome of GFkV supported the creation of the new genus *Maculavirus*. The distinguishing characteristics were the length of the GFkV genome, the absence of a tymobox/marafibox, the lack of a fused RP/CP ORF as present in marafivirus genomes, and the lack of phylogenetic clustering with either tymoviruses or marafiviruses. Grapevine red globe virus (GRGV) is a tentative member of the genus. Both viruses infect only *Vitis* species (grapevine and relatives). In common with marafiviruses, these maculaviruses are restricted to the phloem and are not sap transmissible. No insect vectors have been identified. As for all other members of the family *Tymoviridae*, maculaviruses produce ~29 nm particles with prominent surface features observable by EM. Top component and infectious bottom component particles are produced. GFkV infections are cytologically distinct from marafivirus infections through the presence of severely modified mitochondria ('multivesiculate bodies').

The genome of GFkV (7564 nt) is the longest among the members of the family *Tymoviridae*, and has the highest cytosine content (49.8%). The arrangement of RP and CP ORFs is similar to that of tymoviruses (**Figure 2**). The RP ORF encodes a 215 kDa protein with replication-associated domains that present sequence relatedness to the tymoviral and marafiviral RPs. The amino acid sequence of the RdRp domain shows the closest relationship to sister genera (59% and 67% identities with the RdRps of a tymovirus and marafivirus, respectively).

The 24.5 kDa GFkV CP has 23–31% sequence identity with CPs of tymoviruses and marafiviruses, and like other CPs of members of the family *Tymoviridae* it lacks a cluster of basic amino acids at the N terminus. The GFkV genome encodes two additional proteins from ORFs that partially overlap the CP ORF in the 3′ region of the genome. No functions for these putative proteins are predicted from sequence comparisons. Close relationship between GFkV and GRGV is rather weakly supported by sequence comparisons (**Figure 3**).

The GFkV genome is probably capped at the 5′ end and has a poly(A) tail at the 3′ end, in common with most marafiviruses and PnMV. It is the only known member of the *Tymoviridae* to lack a tymobox- or marafibox-like sequence. Nevertheless, two or more sgRNAs, ~1.3 and ~1.0 kb in length, are present in infected tissues. These RNAs appear to be packaged in both top- and bottom-component particles, in the latter case apparently together with the genomic RNA.

Poinsettia Mosaic Virus

Properties and Distinguishing Characteristics

PnMV possesses properties characteristic of both the tymoviruses and marafiviruses. The ~28 nm virus particles have the EM structure typical of the *Tymoviridae* and separate into typical top components containing the sgRNA and infectious bottom components. Like tymoviruses, PnMV is produced in high yield during infection, is not phloem-limited, and can be mechanically transmitted in the laboratory. Replication is associated with chloroplast cytopathy, though not with the appearance of the replication-associated vesicles typical of tymovirus infection. The properties and coding arrangement of the 6.1 kb RNA are more closely aligned with those of the marafiviruses (**Figure 2**). The genomic RNA is polyadenylated, contains a marafibox-related putative sgRNA promoter, and possesses a single long ORF that encodes an RP/CP fusion protein (p221). No OP ORF is present. The 21–24 kDa PnMV CP is presumably expressed from the 0.65 kbp sgRNA; the involvement of potential cleavage of the RP/CP fusion protein to produce a second CP variant is not known. Although PnMV sequences are more closely related to the marafiviruses than tymoviruses, the relationships appear to be insufficiently close to warrant inclusion in the genus *Marafivirus* (**Figure 3**).

In commercial poinsettia cultivation, PnMV is transmitted by vegetative propagation; the virus is not transmissible via seed or pollen. The natural host range is restricted to *Euphorbia* sp., especially poinsettia, *E. pulcherrima*. Symptoms appear seasonally, varying from inapparent to light mottling. PnMV is often associated with poinsettia cryptic virus (family *Partitiviridae*) and with a phytoplasma that is responsible for the desirable free-branching phenotype.

Glossary

Fibrillarin An abundant nucleolar protein that participates in the processing and modification of rRNAs and a methyltransferase.
Nucleolus A prominent subnuclear domain and the site of transcription of ribosomal RNA (rRNA), processing of the pre-rRNAs, and biogenesis of pre-ribosomal particles, and also participates in other aspects of RNA processing and cell function.
Phloem Plant vascular system used for rapid long-distance transport of assimilates and macromolecules.
Plasmodesmata Plant-unique intercellular membranous channels that span plant cell walls linking the cytoplasm of adjacent cells.

Introduction

Umbraviruses differ from other plant viruses in that they do not encode a coat protein (CP) and, thus no conventional virus particles are formed in infected plants. The name of the genus *Umbravirus* is derived from the Latin *umbra*, which means a shadow or an uninvited guest who comes with an invited one. This name reflects the way in which umbraviruses depend for survival in nature on an assistor virus, which is always a member of the family *Luteoviridae*. For transmission between plants, the CP of the luteovirus forms aphid-transmissible hybrid virus particles encapsidating umbraviral RNA. In nature, each umbravirus is associated with one particular luteovirus, although in experiments transcapsidation is not needed for umbravirus accumulation within infected plants because functions such as protection and movement of the virus RNA do not require the presence of the luteovirus or its CP. Moreover, under experimental conditions, mechanical transmission of umbraviruses can take place without the aid of an assistor virus. This implies that umbraviruses encode some product(s) that functionally compensate for the lack of a CP (see below).

Currently the genus *Umbravirus* includes seven distinct virus species: *Carrot mottle virus* (CMoV), *Carrot mottle mimic virus* (CMoMV), *Groundnut rosette virus* (GRV), *Lettuce speckles mottle virus* (LSMV), *Pea enation mosaic virus-2* (PEMV-2), *Tobacco mottle virus* (TMoV), and *Tobacco bushy top virus* (TBTV). These viruses together with the tentative members of the genus *Umbravirus* are listed in **Table 1**. Some of these viruses have been known since the early days of plant virology. The first to be described was TMoV, reported from Zimbabwe and Malawi in 1945. The most economically important umbravirus is GRV, which is endemic throughout sub-Saharan Africa. Sporadic, unpredictable outbreaks of groundnut rosette disease (actually caused by a satellite RNA of GRV) cause severe crop losses. Pea enation mosaic disease outbreaks are also sporadic and localized, but losses of nearly 90% in peas and up to 50% in field beans have been reported. One or both of the carrot-infecting umbraviruses probably occurs worldwide wherever carrots are grown, but they are uncommon in commercial crops because the insecticides used to control carrot fly also control the aphid vectors of CMoV and CMoMV. LSMV is reported only from California, USA.

Virus Properties

Although no virions are formed in plants infected with umbraviruses unaccompanied by the assistor virus, the infectivity of CMoV and GRV in buffer extracts of infected leaves is surprisingly stable: infectivity remains for several hours at room temperature and is resistant to treatment with ribonuclease. Infectivity is, however, sensitive to a treatment with organic solvents suggesting that lipid-containing structures are involved in the protection of umbravirus RNA.

Table 1 Virus members of the genus *Umbravirus*

Virus	*Abbreviation*	*Sequence*	*Accession no.*	*Assistor virus*
Carrot mottle mimic virus	(CMoMV)	Complete genomic RNA	U57305	Carrot red leaf virus (CaRLV)
Carrot mottle virus	(CMoV)			Carrot red leaf virus (CaRLV)
Groundnut rosette virus	(GRV)	Complete genomic RNA	Z69910	Groundnut rosette assistor virus (GRAV)
		Satellite RNAs	Z29702–Z29711	
Lettuce speckles mottle virus	(LSMV)			Beet western yellows virus (BWYV)
Pea enation mosaic virus-2	(PEMV-2)	Complete genomic RNA	U03563	Pea enation mosaic virus-1 (PEMV-1)
		Satellite RNA	U03564	
Tobacco bushy top virus	(TBTV)	Complete genomic RNA	AF402620	Unknown
Tobacco mottle virus	(TMoV)	Partial genomic RNA	AY007231	Tobacco vein distorting virus (TVDV)
Tentative members in the genus				
Sunflower crinkle virus	(SuCV)			Unknown
Sunflower yellow blotch virus	(SuYBV)			Unknown
Tobacco yellow vein virus	(TYVV)			Tobacco yellow vein assistor virus (TYVAV)

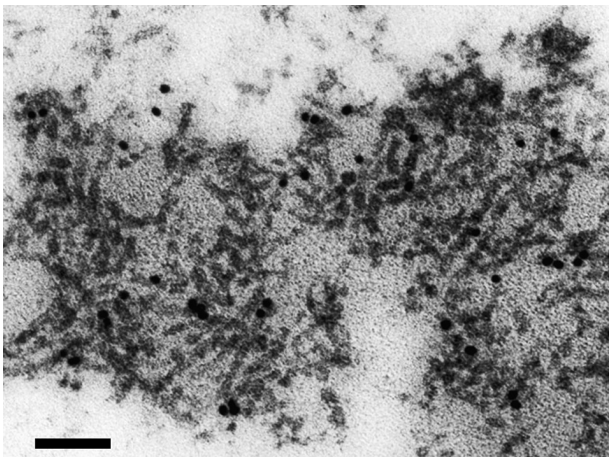

Figure 1 Electron microphotograph of a section of a *Nicotiana benthamiana* cell expressing GRV ORF3 protein. The section shows a complex of filamentous RNP particles embedded in an electron-dense matrix. The section was labeled by *in situ* hybridization with an RNA probe specific for viral RNA. Scale = 100 μm.

Indeed, in plants infected with a number of umbraviruses, including CMoV, enveloped structures ~50 nm in diameter were observed. However, an infective fraction from GRV-infected tissue contained complexes with a buoyant density of 1.34–1.45 g cm^{-3} consisting of filamentous ribonucleoprotein (RNP) particles, composed of the umbraviral ORF3 protein (see below) and virus RNA, embedded in a matrix (**Figure 1**). The relationship between the enveloped and filamentous structures is unclear.

Genome Organization and Expression

The genome of umbraviruses consists of a single linear segment of positive-sense, single-stranded RNA (ssRNA) (**Figure 2**). The complete genomic RNA sequences of CMoMV, GRV, PEMV-2, and TBTV are comprised of 4201, 4019, 4253, and 4152 nt, respectively. There is no polyadenylation at their 3′ termini and there is no information about modifications of their 5′ termini. At the 5′ end, a very short noncoding sequence precedes ORF1, which encodes a putative 31–37 kDa protein. ORF2, which overlaps the 3′ end of ORF1, potentially encodes a 63–65 kDa protein, but lacks an AUG initiation codon. It is likely that ORF1 and ORF2 are translated as a single 94–98 kDa protein by a −1 translational frameshifting mechanism; the sequence associated with frameshifting events in several animal and plant viruses is found in the region at the 3′ end of the ORF1. The predicted amino acid sequence of the ORF2-encoded product has similarities with the sequences of RNA-dependent RNA polymerases (RdRps) of viruses in the families *Tombusviridae* and *Luteoviridae* and contains all eight conserved motifs of RdRp of positive-strand RNA viruses. A short untranslated stretch of nucleotides separates ORF2 from ORF3 and ORF4, both of which almost completely overlap in different reading frames and encode 26–29 kDa products. The ORF4 contains motifs characteristic of the cell-to-cell movement proteins (MPs) of plant viruses, in particular those of cucumoviruses. The ORF3 products from different umbraviruses possess up to 50% homology to each other but show no

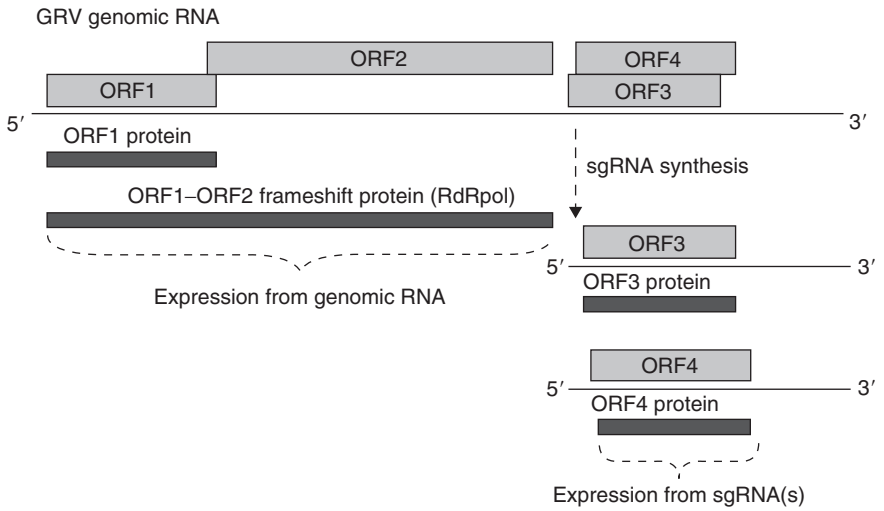

Figure 2 Organization and expression strategy of the GRV genome. Translation of the ORF1 and the ORF2 with a frameshift event results in production of the ORF1–ORF2 frameshift protein; subgenomic RNA(s) (sgRNA(s)) synthesis is required for expression of the ORF3 and ORF4. Solid lines represent RNA molecules; gray boxes represent open reading frames (ORFs); black boxes represent translation products.

significant similarity to any other viral or nonviral product. The ORF3 and OFR4 products are likely to be translated from subgenomic RNA(s) – 3′ terminal RNAs of the appropriate size were detected in GRV-infected plant tissue. It should be pointed out that the sequenced genomes of umbraviruses do not encode a potential CP(s). The essential role of the ORF3–ORF4 block in movement of umbraviruses within plants has been experimentally demonstrated and is discussed below.

Replication

Replication of umbravirus RNA presumably involves the ORF1/ORF2-encoded RdRp. Leaves of plants infected with umbraviruses contain abundant double-stranded RNA (dsRNA) including a major species of about 4.4–4.8 kbp corresponding in size to that expected for a double-stranded form of the viral genomic RNA which may be an umbravirus RNA replication intermediate. No other details of the replication mechanism have been elucidated.

Satellite RNA

Satellite RNAs are associated with some umbraviruses. In the case of GRV, satellite RNA is found in all naturally occurring isolates, and is primarily responsible for the symptoms of groundnut rosette disease. GRV satellite RNA is an ssRNA of about 900 nt which relies on GRV for its replication and, more unusually, is also required for the groundnut rosette assistor virus (GRAV)-dependent aphid transmission of GRV. Thus, unlike most virus satellite RNAs, it is essential for the biological survival (though not the replication) of its helper virus. The role of the satellite RNA in the transmission process is to mediate transcapsidation of GRV RNA by GRAV protein to form stable aphid-transmissible hybrid virus particles. Although different GRV satellite RNA variants contain up to five potential ORFs, none of the ORFs is essential for any of the functions and biological properties that have been ascribed to GRV satellites. In contrast, the satellite RNA that is associated with some isolates of PEMV-2 is not required for transcapsidation of PEMV-2 RNA by the CP of its assistor virus PEMV-1 or for aphid transmission of the hybrid particles, and other umbraviruses, such as CMoV, do not have satellite RNAs, yet are transcapsidated by their assistors and thus transmitted by aphids. The reasons for these differences have not been explained.

Cell-to-Cell Movement Function

The highly conserved ORF4-encoded proteins of umbraviruses exhibit significant sequence similarity with cell-to-cell MPs of other plant viruses, in particular the 3a proteins of cucumoviruses. Therefore, it has been suggested that this protein is involved in cell-to-cell trafficking of umbravirus RNA through plasmodesmata. This suggestion has been confirmed by a number of genetic, cytological, and biochemical approaches. By using the gene replacement strategy, it was demonstrated that that the GRV ORF4 protein could functionally replace the MPs of unrelated viruses, Potato virus X (PVX) (all the products encoded by the triple gene block and the CP) and cucumber mosaic virus (CMV) (the 3a MP and the CP). Localization of the GRV ORF4 protein has much in common with localization of MPs of other plant virus groups. The green fluorescent protein (GFP)-tagged GRV ORF4 protein targeted to

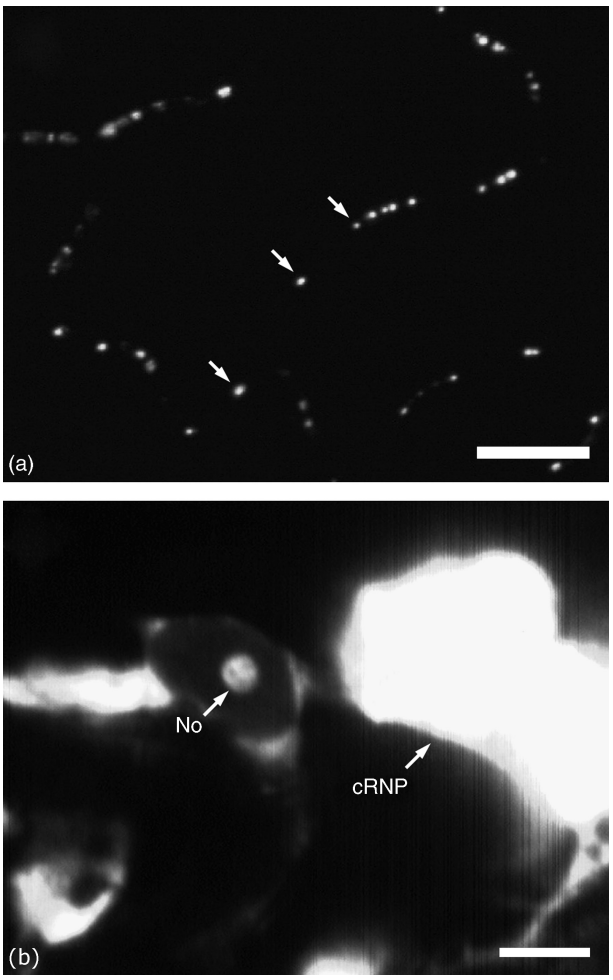

Figure 3 Confocal laser scanning images showing the localization of (a) GRV ORF4 protein fused to GFP to plasmodesmata (shown by arrows) and (b) GRV ORF3 protein fused to GFP to the nucleolus (No) and cytoplasmic inclusions containing ORF3 protein RNP particles (cRNP). Scale = 25 μm (a), 10 μm (b).

plasmodesmata (**Figure 3**(**a**)). Also, this protein formed extended tubular structures on the surface of protoplasts infected either with GRV or with the heterologous virus expressing the GFP-tagged GRV ORF4. The GRV ORF4 protein binds to RNA *in vitro* in a noncooperative manner which may make the viral RNA of the RNP complex accessible for translation and replication.

Phloem-Dependent Long-Distance Movement Function

One of the striking features of umbraviruses is their ability to move long distance within the plant without having a conventional CP. Involvement of CPs in long-distance movement of viral infection has been shown for a number of plant viruses, including tobacco mosaic virus (TMV) which utilizes the CP exclusively for its long-distance but not cell-to-cell movement function. By using the gene replacement strategy it was demonstrated that the ORF3 proteins of GRV, PEMV-2, and ToMV were able to functionally substitute for the TMV CP in the long-distance movement process. The hybrid TMV mutants expressing the umbraviral ORF3 proteins were able to move rapidly through the phloem. It was also shown that specific mutations in the ORF3 protein of PEMV-2 abolish the ability of this virus to move long distance without affecting its cell-to-cell spread within inoculated leaves.

It should be noted that the mechanisms of the long-distance movement facilitated by umbraviral ORF3 proteins is different from those mediated by suppressors of RNA silencing such as the 2b protein of CMV and the HC-Pro protein of potyviruses. Rather than supporting virus infection by suppressing the host RNA-mediated response, the ORF3 protein seems to protect RNA by binding to viral RNA. It was shown that the ORF3 proteins of GRV, PEMV-2, and ToMV increase the stability of viral RNA and protect it from RNases. Immunogold-labeling and *in situ* hybridization experiments showed that the GRV ORF3 protein accumulated in cytoplasmic granules consisting of filamentous RNP particles composed of the ORF3 protein and viral RNA (**Figure 1**). It has been suggested that these particles may be a form in which viral RNA moves long-distance through the phloem. Also the ORF3-containing RNP complex may protect viral RNA from nucleases and the RNA silencing machinery.

Involvement of the Nucleolus in Umbravirus Systemic Infection

In addition to cytoplasmic granules, the GRV ORF3 protein was also found in nuclei, predominantly targeting nucleoli (**Figure 3**(**b**)). Sequence analysis of the ORF3 proteins of umbraviruses revealed the presence of both a nuclear localization signal (NLS) and a nuclear export signal (NES), the functional roles of which in nuclear import and export of the GRV ORF3 has been confirmed experimentally by genetic analysis. Functional analysis of ORF3 protein mutants revealed a correlation between the ORF3 protein nucleolar localization and its ability to form RNP particles and transport viral RNA long distances. It was also shown that the ORF3 protein interacts with a nucleolar protein, fibrillarin, redistributing it from the nucleolus to the cytoplasm, and that such an interaction is absolutely essential for umbravirus long-distance movement through the phloem.

Interaction with Assistor Virus

Although umbraviruses accumulate and spread very efficiently within infected plants, they depend on the

assistance of luteoviruses for their survival in nature, as they require encapsidation by luteoviral CP for horizontal transmission by aphids. In turn, umbraviruses facilitate the movement of phloem-limited luteoviruses to and from the phloem, as well as the cell-to-cell movement of luteoviruses between mesophyll and epidermal cells. It was shown that the ability to promote cell-to-cell movement of luteoviruses is a unique feature of the umbraviral ORF4 MP. Moreover, the ORF4 MP of GRV can facilitate cell-to-cell movement of *Potato leafroll virus* even when it is expressed from heterologous PVX or CMV genomes. In most instances, the luteovirus partner does not depend on the umbravirus infection for its survival in nature. A complex consisting of PEMV-1 (the genus *Enamovirus*, family *Luteoviridae*) and PEMV-2 is a notable exception. Unlike other members of the family *Luteoviridae*, PEMV-1 on its own lacks the ability to move, even through the phloem; both long-distance and cell-to-cell movement functions of PEMV-1 are provided by the umbraviral component of the complex, PEMV-2. Such a strong mutual dependence and adaptation between umbraviruses and luteoviruses suggest a long co-evolution, which has resulted in establishing a range of interactions from facultative coexistence (GRV/GRAV) to complete dependence (PEMV-1/PEMV-2).

Similarity with Other Taxa

Amino acid sequence comparisons showed that the putative RdRp encoded by CMoMV, GRV, PEMV-2, and TBTV belong to the so-called supergroup 2 of RNA polymerases, as do those of viruses in the genera *Carmovirus, Necrovirus, Machlomovirus,* and *Tombusvirus*. Since these enzymes are the only universally conserved proteins of positive-strand RNA viruses, the genus *Umbravirus* might be considered to be in or close to the family *Tombusviridae*.

Host Range

Individual umbraviruses are confined in nature to one or two host plant species. For example, groundnut is the only known natural host of GRV and the entire rosette disease complex (GRV, its satellite RNA and GRAV). Experimental host ranges of umbraviruses are broader but still restricted. They usually induce a leaf mottle and/or mosaic in infected plants.

Transmission

In nature, umbraviruses are transmitted by aphids, but only from plants that are infected also with an assistor luteovirus. The mechanism of the dependent transmission is the encapsidation of the umbraviral RNA by the CP provided by the assistor virus. Hence, the transmission of the dependent umbravirus occurs in the same persistent (circulative, nonpropagative) manner as that of the assistor-luteovirus.

Prevention and Control

For the avoidance of pea enation mosaic disease, it is recommended that pea or faba bean crops should be sited away from alfalfa and clover fields. Early sowing and close spacing can reduce groundnut rosette disease incidence, probably by inhibiting the landing response of the vector. This approach is also effective against tobacco rosette disease.

However, the best control approach is to use resistant cultivars if they are available. Resistance to GRV controlled by two independent recessive genes has been found and groundnut lines possessing this resistance have been developed.

A possibility for the future is the deployment of transgenic forms of resistance. Strategies for engineering transgenic resistance against umbraviruses include the transformation of plants with translatable or nontranslatable sequences from the umbraviruses themselves or their satellite RNAs.

Glossary

Kex2p. Kexin, furin A membrane-bound proteinase in the Golgi that processes some secreted proteins in many eukaryotes.

Ustilago maydis Smut fungus. A plant pathogen infecting maize, wheat, oats, and barley that can adopt either yeast or mycelial form.

Introduction

The *Ustilago maydis* viruses belong to the genus *Totivirus* within the family *Totiviridae*. They are a related group of viruses that, like many fungal and protozoan viruses, exist as permanent passengers in their host cells, to which they are not deleterious. These are double-stranded RNA (dsRNA) viruses with similar structure and life cycle, derived from a very ancient ancestor but still possessing recognizable sequence similarities in their common protein, the viral RNA-dependent RNA polymerase (RdRp). They are not naturally infectious and are passed from cell to cell by meiosis or mitosis, although they will, inefficiently, infect protoplasts. In some cases, they provide a selective advantage to the host, encoding cellular toxins that kill cells of the same or related species that lack the virus. These killer toxins are apparently derived from cellular genes that have been co-opted by resident viruses. In some cases (as discussed below) cellular ancestors of these toxins still exist. When multiple species of genomic and satellite dsRNA exist in the fungal and protozoan dsRNA viruses, they are separately encapsidated. This is no disadvantage to viruses that do not depend on an infectious cycle for propagation.

Taxonomy

The fungal and protozoan dsRNA viruses generally fall into three groups: the totiviruses, the chrysoviruses, and the partitiviruses, all of which are closely related as judged by the sequence of their RdRps (**Figure 1**). In this scheme, only the giardiaviruses (which are presently classified as a separate genus within the family *Totiviridae*) are, rather inappropriately, marooned between the chrysoviruses and the partitiviruses. However, the *Ustilago maydis* viruses are placed closest to the *Saccharomyces* viruses, with which they have much in common. The three different *Ustilago maydis* viruses (UmVP1H1, UmVP6H1, and UmVP1H2) for which sequence information exists are more closely related to each other than to any other fungal viruses. This is now a common phenomenon among the fungal viruses, in which several similar dsRNA viruses may share the same host cell: ScV-L1 and ScV-La (*Saccharomyces cerevisiae*), DdV1 and DdV2 (*Discula destructiva*), and GaV-L1 and GaV-L2 (*Gremmeniella abietina*). However, there are cases in which two unrelated dsRNA viruses occupy the same cell (HvV145S and HvV190S; SsV1 and SsV2). Aside from the similarities in RdRp sequence, the *Ustilago maydis* and *Saccharomyces* viruses share a number of other characteristics.

Genome Structure

The totiviruses are dsRNA viruses with a single defining property: a single segment of dsRNA encodes all necessary

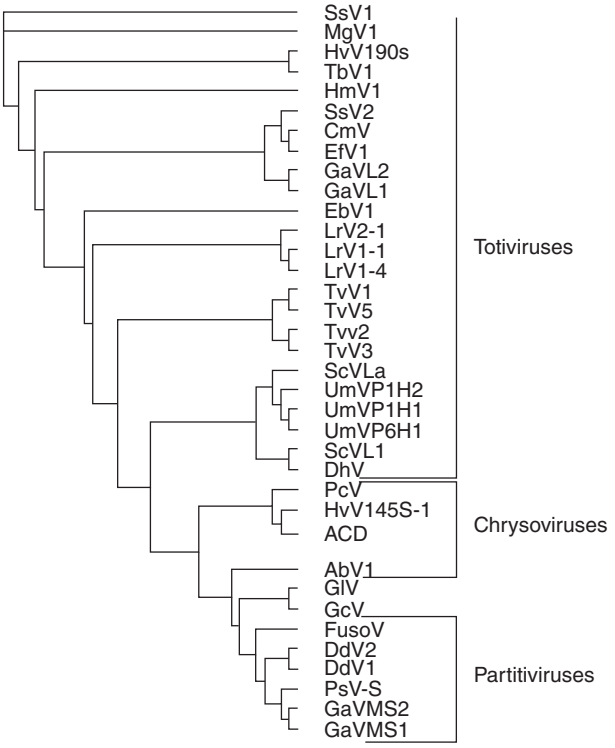

Figure 1 Cladogram of fungal and protozoan dsRNA virus RdRps. For clarity, statistics have been omitted, but each branch is supported by at least 500/1000 bootstraps. This is a Treeview rendering of a Clustal X alignment of complete RdRp sequences. Only a few of the known partitiviruses are shown due to space limitations.

viral functions. All RNA viruses of eukaryotes have the same problem of expression: eukaryotic ribosomes generally initiate only in one place on an mRNA. Encoding more than one protein on a single RNA requires some method of obviating this limitation. The totiviruses have adopted a number of strategies for this purpose: programmed ribosomal frameshifting (ScV, GLV, LRV, TVV), stop and go translation, using overlapping termination and initiation codons (HvV190S, CmRV or CmV), internal initiation (SsV or SsRV), and proteolytic processing (UmV).

The UmV dsRNAs fall into three categories: H (heavy), M (medium), and L (light). The H segments that have been partially or completely sequenced code for viral capsid and RdRp polypeptides. The M segments encode secreted polypeptides, some of which are toxins that kill susceptible cells (killer toxins). The L segments have no significant open reading frames, and are exact copies of the 3′ portions of M plus strands.

The one UmV H segment entirely sequenced (P1H1) has a single open reading frame encoding a polypeptide of 1820 amino acids with an N-terminal capsid and a C-terminal RdRp sequence. There is a putative papain-like protease between the capsid and RdRp domains, so that generation of the capsid polypeptide appears to occur by endoproteolytic cleavage. The proportion of cap and cap-pol fusion protein in ScV is quite critical for capsid assembly; too much of either results in loss of the virus. If this is the case in UmV, the proportions must be controlled by the efficiency of endoproteolytic cleavage; with some low but finite probability, the protease must fail, generating a fusion protein containing the RdRp domain. Alternatively, the RdRp domain might be packaged as a single domain, as it must be in the partitiviruses. In either case, this is a rather sloppy way of doing things, since a large proportion of the C-terminal domain must be discarded as useless. However, it is no more wasteful than the processing of the poliovirus polyprotein.

There are three main isolates of *Ustilago maydis* whose viral dsRNAs have been characterized – P1, P4, and P6, named after the killer toxins that some viral segments encode (see further ahead). Some isolates have only three viral dsRNAs (H1, M1, L1), while others may have as many as seven segments. A summary of the known coding regions of these dsRNAs is shown in **Table 1**. In all cases, only the viral plus strand has an open reading frame, and the predicted protein products have been demonstrated by *in vitro* protein synthesis, and/or by isolation *in vivo*. Presumably all totivirus mRNAs, like their genomic plus strands, are uncapped and lack polyA. This has only been directly demonstrated for ScV.

The *Ustilago maydis* Killer Toxins

The KP1, KP4, and KP6 toxins are encoded by P1M2, P4M2, and P6M1. The KP4 toxin is the best characterized of these. The KP4 toxin is synthesized as a 127-amino-acid preprotoxin from which the amino-terminal 22 amino acids are removed by signal peptidase during secretion. The resulting toxin is an unglycosylated peptide of 105 amino acids and 11.1 kDa. The KP4 toxin is the only killer toxin known to be not processed by Kex2p. Its three-dimensional structure is known (**Figure 2**). It is a monomer with five disulfides stabilizing a structure with seven beta-strands and three alpha-helices, consisting of a single beta-sheet with five antiparallel strands and two antiparallel alpha-helices at about a 45° angle to the beta-strands. Its structure is somewhat similar to that of the SMK toxin, even though the latter consists of a heterodimer. The SMK toxin is encoded by the nuclear genome of *Pichia farinosa*, rather than by a viral dsRNA, and it has essentially no primary structure similarity to the KP4 toxin. SMK is synthesized as a preprotoxin which is proteolytically processed to produce the heterodimer, so we can view the KP4 toxin as a preprotoxin that has lost

Table 1 Protein products of the UmV dsRNAs

its Kex2p sites (or SMK as a preprotoxin that has gained Kex2p sites).

The latter interpretation seems more likely, because there are other fungal proteins encoded by nuclear genomes that are highly similar to the KP4 toxin (**Figure 3**). The two proteins shown aligned with the KP4 toxin are from *Aspergillus oryzae* (BAE57860) and from *Gibberella zeae* (XP_380238). These are both predicted proteins without known function. However, both are predicted (by the SignalP 3.0 Server) to be secreted proteins, and their mature peptides are predicted to begin with the same amino-terminal amino acid sequence as the KP4 toxin, LGINCR, or with an extra amino-terminal K (in the *A. oryzae* peptide). None of these proteins has predicted Kex2p cleavage sites (xyKR, xyRR, or xyPR, where x is hydrophobic and y is anything), and the KP4 toxin is known to be processed only by signal peptidase, alone among fungal killer toxins. Five of the ten cysteines in the KP4 toxin are conserved in both of these proteins, which share 25% and 36% sequence identity with the KP4 toxin, and a sixth cysteine may also be shared. The *A. oryzae* peptide has eight total cysteines and the *G. zeae* peptide 9. Hence each would have to be missing at least one of the five disulfides present in the KP4 toxin, and if they shared the KP4 structure would have to be stabilized by other interstrand interactions. K42 is known to be critical for KP4 toxin function, but this residue is not in a region conserved in the three proteins (**Figure 3**). The SMK toxin, with a structure somewhat similar to that of KP4, has only four disulfides. The striking similarity of these three proteins, all secreted, all lacking any N-linked sites for glycosylation, all processed only by signal peptidase, implies that the KP4 toxin was captured by the virus from a cellular transcript, since the *G. zeae* peptide, the *A. oryzae* peptide, and SMK are all encoded by nuclear genes. This evolutionary process is more obvious with the ScV k1 and k2 toxins, whose viral genes preserve the polyA they derived from the 3′ end of cellular messengers as internal portions of the viral plus strands.

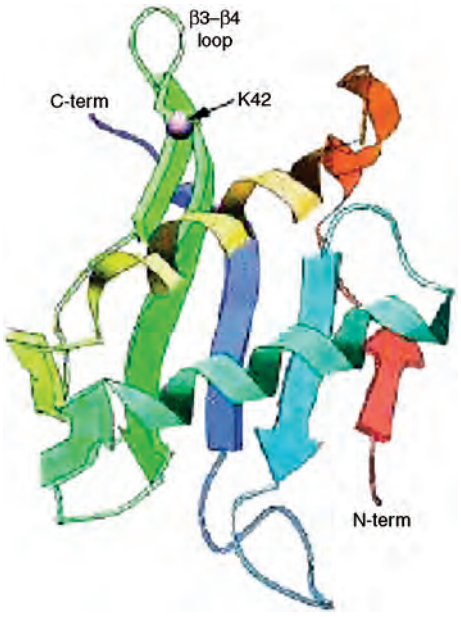

Figure 2 Structure of the KP4 toxin shown as a ribbon rendering. Figure courtesy of Tom Smith.

The KP4 toxin is the only one of the UmV killer toxins about which we have some knowledge of mode of action. The KP4 toxin interferes with the function of calcium channels both in susceptible fungal cells and in mammalian cells. Calcium transport and signaling in fungi are now known to be necessary for many cellular processes and to involve the products of dozens of genes. The fungal calcium channel consists of a typical alpha-subunit (encoded by CCH1 in *S. cerevisiae*) and at least one more polypeptide (encoded by MID1 in *S. cerevisiae*). Presumably, the target for KP4 is located in the cell wall or cell membrane, since its effects are reversible, but it need not be the calcium channel itself. The SMK toxin is known to target a cell membrane ATPase in *S. cerevisiae*, which is susceptible to the SMK toxin but not to KP4. KP4 seems to act by interfering with calcium-regulated signal transduction pathways, thereby preventing cell growth and division. Resistance to KP4, which is encoded by a nuclear gene, might involve an alteration of any component of these signal transduction pathways.

The KP6 toxin is composed of two polypeptides, KP6-alpha and-beta, which are processed from a single precursor protein (a prepropolypeptide) of 219 amino acids encoded on P6M2. The preprotoxin is cleaved by

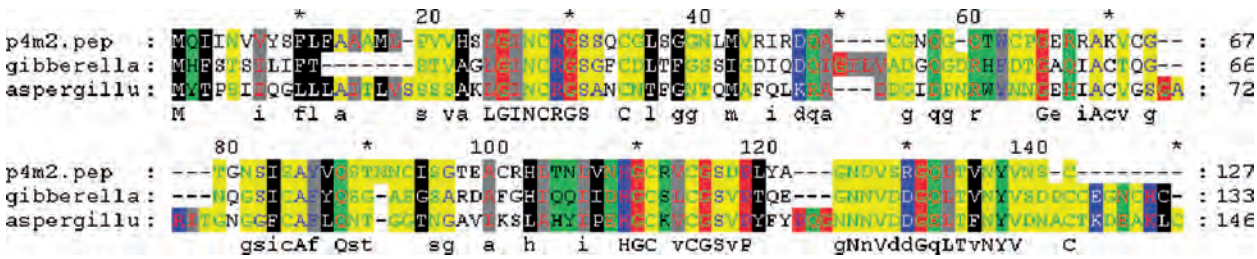

Figure 3 Comparison of KP4 (p4m2.pep) with cellular homologs. This is a Gendoc rendering of a Clustal X alignment showing physical–chemical similarities (color) and similarity (small letters in consensus line) or identity (capital letters in consensus line).

signal peptidase after residue 19; by Kex2p cleavages after residues 27, 108, and 138; and by Kex1p cleavage after residue 137 to yield two polypeptides, alpha of 79 amino acids (8.6 kDa) and beta of 81 amino acids (9.1 kDa). Alpha and beta are not necessarily found as a multimer and can be added separately to susceptible cells to reconstitute killer activity; both are necessary for activity. Unlike the KP4 toxin, KP6 has irreversible effects on susceptible cells, actually killing cells rather than inhibiting growth. The structure of KP6-alpha is known (**Figure 4**). The monomer is a four-stranded antiparallel beta-sheet with two alpha-helices on one side, a small alpha-helix at the N-terminus, and a separate beta-strand, with four disulfide bonds, involving all eight cysteines in the polypeptide. In the crystal, the polypeptide forms trimers held together by salt bridges, and the trimers sit on each other forming an hour-glass shape, suggestive of an ion pore. However, expression of the KP6-beta peptide alone in susceptible cells is lethal, suggesting a mode of action more like that of colicins or diphtheria toxin, in which one of the toxin polypeptides is introduced into the cell by the action of one or more other toxin polypeptides and acts lethally within the cell. KP6-beta also has six cysteines, suggesting a structure with three disulfides. The two monomer nature of the KP6 toxin is reminiscent of the *S. cerevisiae* k1 toxin, which also has two monomers derived from a single prepropolypeptide by signal peptidase, Kex2p, and Kex1p processing. However, in the k1 toxin, the alpha and beta monomers are covalently bound by intermolecular disulfides, which are absent in KP6. The toxin is properly processed and secreted from *S. cerevisiae*, although there are some differences; none of the *Ustilago maydis* killer toxins (or other secreted proteins, apparently) are glycosylated, and processing of mutant precursors is different in yeast and *Ustilago maydis*. The KP6-alpha polypeptide has one possible site for N-linked glycosylation, which is used in yeast but not in *Ustilago maydis*. Unlike the KP4 toxin, the KP6 toxin polypeptides have no significant similarity to any proteins currently in the databases. Resistance to the KP6 toxin maps to the nuclear genome, as with KP4.

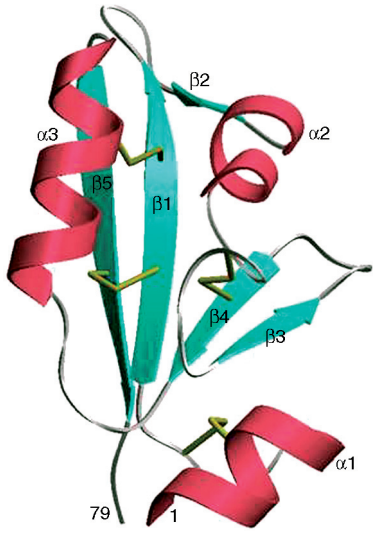

Figure 4 Structure of KP6-alpha shown as a ribbon rendering. Courtesy of the American Society for Biochemistry and Molecular Biology.

The KP1 toxin is encoded by P1M2 and translated as a preprotoxin of 291 amino acids, subsequently cleaved by signal peptidase and Kex2p to produce mature polypeptides alpha (120 amino acids) and beta (117 amino acids). Only beta is required for toxin activity. KP1-beta, like the other *Ustilago maydis* killer polypeptides, has an unusual number of cysteines (six) which, if all were involved in disulfides as in KP6-alpha and in KP4, would indicate three disulfides. P1M2 is different from the toxin encoding dsRNAs in UmVP4 and UmVP6 (P4M2 and P6M1). The 3′ noncoding regions of the plus strands of P4M2 and P6M1 are entirely homologous to the L segments in UmVP4 and UmVP6, respectively, while the L segment in UmVP1 is derived from P4M1. P4M1 does encode a prepropolypeptide, whose processed polypeptides are secreted but have no detectable relation to the KP1 toxin (**Table 1**). Nothing is presently known of the mechanism of action of the KP1 toxin, and none of the UmVP1M1 or UmvP1M2 polypeptides have any homologs in the databases. Resistance to the KP1 toxin may be nuclear or cytoplasmic, hinting that some immunity may result from expression of one or more viral dsRNAs, as with the *S. cerevisiae* k1 toxin.

Replication and Transcription

Like all dsRNA viruses, UmV has a capsid-associated transcriptase that makes the viral plus strands. However, little is known of the nature of the transcripts or the mechanism of transcription. One peculiarity of this system is the presence of dsRNAs (L, 354–355 bp) entirely homologous to the 3′ ends of the plus strands of their cognate dsRNAs (M). Presumably, like all viral dsRNAs, these are the result of replication of plus strands within nascent viral particles. It is not clear if the source of the L plus strands is internal transcription initiation or processing of M plus strands. Normal-sized L plus strands (with exactly the predicted 5′ ends) are produced either by the viral transcriptase or by RNAP II transcription of cDNA clones in *Ustilago maydis* or heterologous systems, implying that a cleavage event must be responsible for production of the L segments.

This cleavage must be either an inherent property of the cognate M plus strand or cleavage by a ubiquitous nuclease activity recognizing a universal feature of the M plus strands. No ribozyme activity can be demonstrated in the cognate M plus strands *in vitro*. However,

all the cognate M plus strands have a peculiar predicted secondary structure, in which the predicted L plus strand includes a very long predicted hairpin stem (23 perfect base pairs in P4M2) immediately following the predicted cleavage site (which is highly conserved). These should make ideal substrates for the recently described cellular machinery (dicer) responsible for siRNA production, which is ubiquitous in eukaryotes.

The function of the L segments is obscure: production of toxin proceeds perfectly well from cDNA constructs lacking the L encoding region, in either homologous or heterologous systems, and the P1M2 segment (encoding the KP1 toxin) has no cognate L segment. The L segments must include a packaging signal, but it is not clear what prevents its inclusion in an M plus strand sequence lacking the 3′ L sequence, a situation that does exist with P1M2. In the closely related virus ScV, a sequence as small as 18 bases serves as the packaging signal.

Transcription in dsRNA viruses may be either semiconservative (resulting in displacement of the parental plus strand) or conservative (*de novo* synthesis of plus strands). Transcription in reovirus and ScV is conservative and in bacteriophage phi6 is semiconservative. An interesting difference in the structure of the viral RdRp may be responsible for this. The phi6 RdRp has an insertion of some 20 amino acids within the N-terminal F motif, an insertion that is absent in the reovirus RdRp (and absent in all the other known RdRp and reverse transcriptase structures). None of the totivirus, chrysovirus, or partitivirus RdRps has a phi6-like insertion; most may therefore be conservative transcriptases. However, UmVP1M2 has been reported to be semiconservatively transcribed.

Viral Structure

Like other fungal viruses, UmV has a small icosohedral capsid of about 41 nm in diameter, with a sedimentation coefficient of 172S and a buoyant density in CsCl of $1.42\,g\,ml^{-1}$. All dsRNA viruses so far characterized in detail (bluetongue virus, or BTV; reovirus, or Reo; and ScV, the *S. cerevisiae* virus) are icosohedral with an inner (or complete) capsid structure of 120 copies of a capsid protein. This is a highly unusual arrangement in viruses, which generally behave according to the Caspar and Klug rules for assembly of icosohedral viruses, which call for the simplest capsids to consist of 60 copies of a single polypeptide ($T = 1$) or 180 copies of a single polypeptide ($T = 3$). However, the dsRNA viruses do not really violate this stricture, since they have 60 copies of a capsid polypeptide in one configuration and 60 copies in another, so that, in effect, they have 60 copies of an asymmetric dimer, in which the two monomers share portions with identical shape and portions with different shape. The *Ustilago maydis* viruses obey this generalization, although, like all the fungal and protozoan viruses, they have a single capsid shell, not two, as in BTV and Reo. One variation of this arrangement exists in the *Penicillium chrysogenum* virus (PcV), in which the two monomers are actually part of a single polypeptide chain, the two halves of which probably share regions of identical structure.

This unique capsid structure must play an important role in properly arranging the viral polymerase within the particle to allow transcription and replication of the genomic dsRNA. In ScV and UmV, this is accomplished by making the polymerase as the carboxy-terminal portion of a fusion protein in which the N-terminal is the capsid polypeptide. In ScV, two copies of this fusion protein are incorporated into each viral particle. Each viral particle has one copy of a single species of viral dsRNA. In UmV and ScV (as well as the other totiviruses), this single species encodes both capsid polypeptide and RdRp. When additional dsRNAs are present (e.g., toxin-encoding species), these are also separately encapsidated, and are considered satellite dsRNAs: they are completely dependent on the capsid/RdRp-encoding dsRNA for their transcription, replication, and packaging. Satellite dsRNAs may be present in more than one copy per virion. This is a considerably simpler strategy than pursued by the reoviruses, orbiviruses, and cystoviruses, all of which package multiple species of dsRNA in each viral particle and as many as 12 copies of the viral RdRp in each.

Genetic Engineering

The production of killer toxins by a plant pathogen (*Ustilago maydis*) has excited some interest in using the toxin to genetically engineer resistance to the fungus in its host crop plants. Since it is possible to produce both KP6 and KP4 toxins in heterologous systems using cDNA expression vectors, transgenic maize (KP6 and KP4) and wheat (KP4) plants have been constructed that express the toxins. These plants do secrete active killer toxins and exhibit some resistance to toxin-sensitive species of *Ustilago*. Since the toxins are harmless to animals when eaten, this may provide a new method of preventing the periodic smut infestations that occasionally decimate susceptible grain crops.

Glossary

Immunogenicity Ability of a substance to stimulate the acquired immune response in a recipient.
Pharming The production of pharmaceutically relevant substances in plants.
Vaccine Substance which elicits an immune reaction which protects against infection by a natural pathogen.

Introduction

The concept of plant-produced vaccines, and in particular viral vaccines for animals and humans, is both recent – the first vaccine-relevant protein was made in plants only in 1989 – and controversial, with dire misgivings still being expressed concerning a number of issues. The central planks of the justification for plant-produced pharmaceuticals in general, and for the production of vaccines in particular, have been that their production in plants is both safe and potentially very cheap. A strong additional argument has been that the use of food plants will allow edible vaccines to be locally produced where they are needed most – in the developing world. Thus, the kind of argument that has developed is that plant production of especially viral vaccines allows the possibility of producing large amounts of high-grade vaccines for very low cost (1) for diseases where there is a high burden of preventable disease, (2) where existing vaccines are expensive, (3) where there are no vaccines for 'orphan diseases', and (4) where therapeutic vaccination could be very effective in treating disease.

The need for low-cost vaccines is borne out by the fact that at least 3 million people die every year of vaccine-preventable diseases, yet it takes many years on average for any new vaccine's price to come down to levels (<US$ 1 per dose) where it can be incorporated into the extended programme of immunization (EPI) bundle.

As with any maturing technology, however, problems have come to light along with proofs of concept, and the current view of the field is very different to the early one. Thus, concerns over genetic 'contamination' of food crops have largely blunted the prospect of edible viral vaccines delivered via unprocessed food plants; regulatory concerns – both for production and registration – have tempered the optimism of early years concerning widespread and rapid adoption of the technology; production via transgenic plants has, on the whole, proved to be less reliable and lower-yielding than was hoped; immunogenicity of model antigens delivered orally has often proved to be disappointingly low; and, most importantly, it has been realised that costs of production are far less important in determining the final price of a vaccine than was generally assumed.

However, there have been notable successes as well: a number of animal model systems have been thoroughly tested, and protection against disease has been obtained; production systems have to some extent been worked out, and the first products have been licenced; transient expression systems are proving to have great potential for even large-scale production; and, most significantly, large pharmaceutical companies are increasingly interested in the prospects of making high-value products in plants.

The increasing exposure of the concept to public view has also brought its share of problems: it was after all the public outcry over 'contamination' of food plants with vaccine protein genes that led to the involvement of regulatory agencies in the issue, and a moratorium on the use of food crops for vaccine production. Moreover, public acceptance of human vaccines made in plants is by no means assured, and the anti-genetically modified (anti-GM) lobby has already made an issue of the means of production. Together with these sobering developments has come the realization that high-value products not meant for use in humans are probably the first best use of the advantages of plant production of biopharmaceuticals.

For example, it is probably a far better idea to use plants to produce proteins and other macromolecules as reagents or components of diagnostic kits than it is to produce far more regulated vaccine components – as well as being a much quicker route to financial gain.

While the initially determinedly rosy picture of very cheap, edible vaccines against orphan diseases and developing country scourges has not been realized, there is now an altogether more realistic consensus view on how to proceed with the application of this still very promising technology to human and animal health. This article covers the historical development of the concept of plant-produced viral vaccines and relevant expression systems, as well as central issues affecting production, purification, and application of such vaccines.

History

The first publication on the production of vaccine-relevant proteins in plants was in 1989, when A Hiatt and colleagues at the Scripps Institute in La Jolla produced mouse-derived monoclonal antibodies (MAbs) in transgenic tobacco (see **Table 1**). This was soon followed in 1992 by the first of a series of papers – in this case involving hepatitis B virus (HBV) surface antigen (HBsAg) – by the group of Charles J. Arntzen and Hugh Mason on the production of human viral vaccine candidate antigens in transgenic plants. While they did not at the time hold out the promise of edible vaccines, they did conclude that plants did produce antigens that were equivalent to those produced in more conventional systems, and they held promise as low-cost vaccine production systems. Concurrent with these advances was a rapid and parallel improvement in the understanding of mucosal immunity and the fact that the mucosa-associated lymphoid tissue (MALT) – and, in particular, the gut-associated lymphoid tissue (GALT) – was probably the premier 'organ' of the entire adaptive immune response. It was perhaps inevitable that these two should come together in the concept of 'edible vaccines', where vaccine antigens would be introduced into people and animals in food, given that most human and animal viruses gain entry to their hosts via mucosal surfaces.

The first proof of concept for edible plant-produced vaccines was performed in the mid-1990s using a bacterial protein – *Escherichia coli* heat-labile enterotoxin (LT-B) – but this was soon followed by work on HBsAg, secretory antibodies, Norwalk virus capsid protein, and a *Vibrio cholerae* enterotoxin subunit vaccine (CTB). These studies laid important ground in terms of demonstrating conclusively that plant-produced vaccine antigens were effectively homologous to those produced by more conventional routes, and that oral dosing or gavage of experimental animals elicited significant immune responses, in the absence of replication of the agent. However, the first demonstration that a plant-produced viral antigen was protective against disease came from an animal model system and the production of the foot-and-mouth disease virus (FMDV) structural protein VP1: mice that were parenterally immunized with a crude extract of transgenic *Arabidopsis thaliana* plants were protected against viral challenge. Another development along these lines in 1999 was the proof that injection of rabbits with rabbit hemorrhagic

disease virus (RHDV) VP60, produced in transgenic plants, could protect them against virus challenge.

Another important development in the mid-1990s was the application of transient plant virus-based expression systems to the expression of vaccines. The first experimental vaccines produced were chimeras of tobacco mosaic virus (TMV) capsid protein fused to malarial peptides; by the late 1990s, a HIV-1 gp41 peptide fused to cowpea mosaic virus capsids had been tested in mice both parenterally and orally. However, it was again an animal model which provided the best proof of concept, and again with FMDV VP1: production of whole VP1 in plants infected with recombinant TMV and parenteral vaccination of mice with leaf extracts allowed successful protection against live challenge with FMDV. This work provided some of the first evidence that full-length foreign proteins could successfully be produced using a plant virus, in amounts that were sufficient to allow immunization using only crude extracts. However, the technology was limited in that the choice of appropriate vectors was limited, as was the choice of host plants, and vectors were often unstable and did not express large proteins very well.

By the late 1990s, it was apparent that many of the early fears voiced by vaccinologists and immunologists about oral delivery of vaccines 'tolerizing' the recipients to the vaccine – and thereby abolishing an immune response to it – were essentially groundless. The basis for a good response to an orally delivered vaccine was that it should be particulate, and that some form of adjuvant may be required. This was borne out by work with human papillomavirus (HPV) virus-like particles produced in a baculovirus expression system, where the number of particles necessary for a strong systemic humoral and mucosal response to orally introduced VLPs in mice could be reduced by an order of magnitude by co-administration with CpG DNA or mutant *Escherichia coli* LT-B (LT R192G). This work, together with reports on oral immunization with respiratory syncytial virus (RSV) F protein and HBsAg, showed that strong Th1-type responses could be elicited by such treatment. The state of the art in mucosal immunity at the time can be summarized as follows: (1) the mucosal immune system consisted of different compartments (such as gut, respiratory, genital mucosa) which intercommunicated, so that, for example, intranasal immunization gave significant immunity at the vaginal mucosa; (2) oral vaccination elicited antigen-specific mucosal secretory IgA as well as systemic immunity, and CD8+ T-cell responses could be elicited. While co-administration of adjuvants such as LT-B, CTB, CpG DNA, and saponins considerably improved mucosal responses and allowed lower dosages, fusion of nonpolymerizing polypeptides to self-assembling adjuvant entities such as LT-B and CTB also allowed significant improvements in immunogenicity.

By 2000, the first human trial results of Norwalk virus capsid protein made in potato had shown that the vaccine was both tolerated and immunogenic, with almost all volunteers developing a significant immune response. Shortly afterward, the Arntzen group showed that a plant material containing HBsAg given orally was an effective prime for a parenteral boost with HBsAg. In 2002, the first successful combination of DNA prime–plant-produced protein boost vaccination in mice with a measles envelope glycoprotein vaccine showed that plant-produced vaccines could be used in very effective combination with DNA vaccines. However, yields of virus vaccine proteins in transgenic plants are low, and oral immunization even with concentrated extracts is not very successful. In contrast, production of antibodies in plants has been more successful and many different kinds of immunoglobulins with various specificities have been produced.

Plant tissues used for production of viral vaccines include leaf and stem tissues of tobaccos of various varieties, *Arabidopsis*, alfalfa, spinach, and potatoes; of aquatic weeds such as *Lemna* spp. (duckweed); seeds of tobaccos, beans, and maize; fruits like tomatoes and strawberries; carrots; single-cell cultures of *Chlorella* and *Chlamydomonas*; suspension cell cultures of tobacco and other plants; hairy root cultures derived from various plants via *Agrobacterium rhizogenes*; and transformed chloroplasts of a variety of plant species. Experience gained from these various systems showed that there was no way of predicting whether or not a given DNA sequence would express protein at a reasonable level, or that the protein would be stable. Although chloroplast expression sometimes gave high yields, this system was not suitable for glycosylated proteins. Single-cell cultures offered few advantages over conventional fermentation/or cell culture techniques, and it seemed that accumulation of proteins in seeds was preferable to expression in green tissue, because of easier purification and higher accumulation levels.

A major setback to the development of plant-produced vaccines occurred in 2002 when soybean and maize harvests in two states in the USA were found to contain maize seeds from 'volunteer' plants engineered to express transmissible gastroenteritis virus (TGEV) capsid protein. The company involved – ProdiGene – had proprietary technology allowing high levels of accumulation of foreign proteins in especially maize seeds, and had potential oral vaccine products including a hepatitis B vaccine, an LT-B vaccine to treat *E. coli* infections in humans, as well as other products under development with large commercial partners. ProdiGene was fined and forced to clean up the seed by the US Department of Agriculture, which has since issued guidelines to prevent a recurrence. The fallout from these incidents has led to an effective moratorium on the development of 'pharmed' products in food crops including vaccine pharming. Another limitation

became obvious in 2005 when the Mason–Arntzen group at Arizona State University released results of a small human trial of a potato-based HBsAg vaccine. In this trial, volunteers previously immunized parenterally with a conventional vaccine ate doses of potato containing ~850 μg of antigen and 63% of them developed increased serum anti-HBsAg titers. However, the immunogenicity was still disappointingly low, despite the ingestion of relatively large doses of antigen.

Growing public unease over the use of transgenic plants for biopharmaceutical production, with the attendant risks of 'contamination' of crop plant gene pools, has prompted the development of other technologies for producing such materials in plants. One such technology is the *Agrobacterium tumefaciens*-based transient expression system: this allows very high levels of expression without the uncertainties inherent in the regeneration and propagation of transgenic plants, and was being used very successfully to produce antibody molecules by 2004. Its main advantage is that the simultaneous expression of a large number of constructs can very rapidly be investigated. Indeed, the Mason group used transient 'agroexpression' very productively in 2004 to explore the conformation and chimeric fusion properties of HBsAg.

By 2005, another major advance in expression technology was announced, which combined the advantages of agroinfection and of viral vectors: this was the 'magnifection' technology of ICON Genetics, which was based on the introduction of recombinant DNA into plants by agroinfection and the subsequent amplification of gene expression by the recombinational reconstitution of a self-replicating TMV-based RNA genome.

Recently, serious reservations have been expressed by researchers and companies about the regulatory acceptance of plant-produced vaccines and other therapeutics, for human and even for animal use. The observed reluctance of large companies to buy into the technology, or to fund it, is probably due to the lack of appropriate regulatory structures and some conservatism in regulatory agencies concerning plant products. However, there is no reason to believe that existing frameworks and regulations could not be adapted to handle plant-produced vaccines: this was demonstrated in 2006 when Dow AgroSciences registered a plant-produced vaccine against Newcastle disease virus (NDV), which affects poultry. This was the first plant-based vaccine registered in the US, and the first to be licenced by the USDA's Animal and Plant Health Inspection Service. The HN envelope glycoprotein of NDV was produced in suspension-cultured tobacco cells, thus avoiding all the production and regulatory problems associated with whole plant production. In the same year, the Centre for Genetic Engineering and Biotechnology (CIGB) in Cuba registered a tobacco-produced MAb for use in purification of their commercially produced HBV vaccine: this development obviates the need for MAb production in ascitic fluid from mice, and considerably reduces the cost of manufacture of a vaccine which is distributed worldwide.

The introduction in mid-2006 of Merck's yeast-produced Gardasil anti-human papillomavirus (HPV) L1 major capsid protein VLP vaccine was hailed as a major development in cancer prevention, and the vaccine is predicted to be a 'blockbuster'. However, at a cost of US$ 360 per course of three doses, it will not make inroads into limiting cervical cancer incidence in developing countries. In 2003, three groups published simultaneous accounts of plant production of HPV L1 proteins. While the antigens were correctly folded and assembled, the yields were low and oral and parenteral immunogenicities were also low: however, these problems were circumvented for HPV-16 L1 in early 2007 by a combination of codon optimization and intracellular targeting, and excellent parenteral immunogenicity was achieved.

Obstacles to Vaccine Pharming

The following obstacles impede the development and potential application of plant-based vaccines, especially in developing countries:

1. increasingly stringent regulatory barriers in developed countries which deter commercial development of new vaccines generally, and vaccines depending on new technology in particular;
2. declining commercial interest in producing vaccines due to negligible return on vaccines needed in developing countries (people who do need vaccines cannot afford them and have to rely on governments and/or aid agencies for making them available);
3. earlier expectations from the technology have not been fulfilled;
4. many developing countries have little or no infrastructure for the approval of experimental drugs and vaccines, or for GM crops;
5. there is widespread and profound suspicion in developing countries of 'GM products', usually fueled by developed country activists;
6. the 'guinea pig' argument: why should developing country populations be used to test products not used in developed countries, where existing but expensive 'best practice' products are already available? and
7. production of vaccine antigens in plants may not significantly decrease the cost of the final vaccines, given that downstream processing and other costs remain the same.

Most of these obstacles could possibly be overcome: countries could pass relevant legislation; regulatory bodies could adopt suitable guidelines; publicity/and information campaigns could change public perceptions, both in the developed as well as in the developing world.

The 'guinea pig' argument could be countered by testing products in developed countries at the same time as in developing countries.

However, a more serious obstacle is that conventional pharma industry is not engaging with plant production technology primarily because it is seen as technology in search of a product, when the technology already available is adequate to the task. Moreover, it is a serious misconception that using plants to produce vaccines would lower prices significantly, as cost of materials and processing is only a minor component of total retail vaccine cost, that is, about 24%. Thus, even a significantly lower cost of vaccine material would not change the cost of the product much, especially as processing costs would remain the same however cheaply one could produce raw vaccine ingredients.

The Way Forward

Vaccine pharming has moved on toward maturity in an encouraging way in recent years, as the dogma of 'cheap oral vaccines' has to some extent shifted to an acceptance that processed and possibly injectable products may be preferred to raw or crudely processed oral vaccines. Indeed, as new needle-free developments in vaccine delivery such as oral and nasal and transdermal delivery are becoming increasingly popular, plant-made vaccines may find a niche, especially in products that need less processing than those intended for parenteral delivery.

It is possible that practitioners will come to accept that success will not be achieved by trying to bring cheap vaccines and therapies for poor people, but by producing generics. For example, it may be a better idea to concentrate on HPV vaccines, which currently are very expensive and have only a few remaining years of patent protection, rather than on HBV vaccines, which are out of patent, are produced conventionally by several high-volume producers, and currently sell for low enough prices to be included in EPI packages.

Another important area to focus on is animal vaccines: these are necessarily very low cost for meat animals such as poultry, sheep, and cattle, and animal model systems have shown very satisfactorily that viral and other plant-produced vaccines could be very useful. The development times are shorter and regulatory hurdles are lower than for similar human vaccines, and edible or minimally processed oral vaccines are probably far more feasible for animals than humans. Major targets could be the already-tested FMDV vaccine for cattle, sheep, pigs, and even wild animals; Newcastle disease and other chicken and poultry viruses; H5N1 and other influenza viruses in domestic and wild fowl; and African horsesickness virus which is currently threatening to emerge into Europe.

It is possible that expression of viral antigens in, for example, maize seed could allow very cheap production of orally dosable vaccines which could be stored for years in a dried form for very little expense, to be pulled out when and if the need for emergency barrier immunization occurred.

It is important for the development of plant-made vaccines that several large companies are interested in the technology, and have done a lot of thorough investigation of its potential. It is especially significant that the first product – Dow's Newcastle disease vaccine – has run the regulatory course and was accepted in 2006.

What is probably needed for the successful future application of pharmed products, especially in developing countries, is a highly effective set of plant-derived products – vaccines and therapeutics – which have been approved by regulatory bodies such as the US Food and Drug Administration (FDA) and European Medicines Agency (EMEA). This will lead to public acceptance and a more welcoming stance by industry, both of which are essential if the technology is to survive.

Glossary

Adjuvant A chemical additive to vaccines that improves the presentation of the antigen to the immune system of the recipient, thereby increasing the effectiveness of the vaccine. The commonest adjuvant is an aluminum salt.
Adventitious agent A contaminating virus or other infectious organism.
Adverse event following immunization Any medical incident that follows immunization and is believed to be caused by the immunization.
Anaphylaxis A hypersensitivity reaction characterized by sudden onset and rapid progression of signs and symptoms in at least two organ systems. It results in release of histamine from mast cells and may follow administration of drugs and vaccines. The severity of the reaction varies from mild symptoms of flushing to severe bronchospasm, collapse, and death. It is treatable with adrenaline.
Auto-disable syringe A form of disposable syringe that automatically locks after one use, preventing its reuse. It is the syringe design of choice for immunization.
Causality assessment A scientific method for assessing the relationship between an adverse event and the receipt of a dose of vaccine.
Clinical trial A research activity that involves the administration of a test regime to humans to evaluate its efficacy and safety. There are classically four phases in clinical trials assessing vaccines.
Guillain–Barré syndrome A polyradiculoneuritis resulting in various degrees of motor and sensory disturbance. The condition frequently follows an acute infection or administration of vaccine.
High-titer measles vaccine A measles vaccine that contains at least one log greater ($>$log 10^4) numbers of live viral particles than a standard vaccine preparation (log 10^3).
Hypotonic hyporesponsive episode (**HHE**) The sudden onset of limpness, reduced responsiveness, and change in skin color in an infant following the administration of a vaccine. Typically (though not exclusively), this may follow administration of pertussis-containing vaccines.
Immunization The process of presenting an antigen to the immune system with the purpose of inducing an immune response. Immunization is synonymous with vaccination.
Injection equipment Any material needed to introduce a vaccine into the body of the recipient. Classically refers to needles and syringes, but new technologies for administering vaccines will widen its usage.
Neurovirulence test One of several tests that is required of live viral vaccines before release to ensure that the vaccine virus does not negatively affect the central nervous system.
Presentation How a vaccine is presented for use (e.g., as a liquid, freeze-dried powder, one-dose vial, 10-dose vial, etc.).
Preservative A chemical (most frequently thiomersal/thimerosal) that is included in a liquid vaccine preparation that inhibits the growth of organisms that inadvertently contaminate the vaccine.
Program error A mistake made by vaccination staff that occurs during administration of a vaccine.
Protective immunity Immunity that protects against actual disease, not simply evoking an immune response.
Regulatory authority An institution/laboratory that takes responsibility for quality control of vaccines used in a country.
Safety box A tough cardboard box into which can be placed used injection equipment. It is generally then transported to an incinerator or can be burnt on the spot, thus safely disposing of medical waste that might otherwise be a hazard.
Stabilizer Proteins or chemicals that are added to a liquid vaccine to maintain it in a stable or unchanging state.
SV40 Simian virus 40 is a virus found in certain monkeys and cell cultures derived from monkey tissues.
Vaccine diluent A liquid (usually sterile water or saline) that is used to reconstitute freeze-dried vaccine.

Vaccine safety The discipline of ensuring that vaccines are manufactured, transported, and administered with minimum risk to the recipient, vaccinator, or general public.

Introduction

Vaccines are arguably the most effective weapon in the modern fight against infectious diseases. They avert millions of deaths and cases of disease every year. But there is no such thing as a 'perfect' vaccine that protects everyone who receives it and is entirely safe for everyone. The scientist attempts to create a vaccine that protects nearly everyone, is extremely effective, and is as safe as humanly possible. That still leaves some vaccine recipients who are not fully protected; and worse, a very small number who suffer negative consequences from the vaccine itself.

There are many aspects that can be considered in the design phase which influence the ultimate safety and public acceptability of a vaccine (**Figure 1**). Vaccine safety can be categorized into aspects related to the manufacture of the vaccine, delivery of the vaccine to the recipient through an immunization programme, and individual and population responses to the vaccine. This article describes the efforts taken to ensure that a vaccine is manufactured, tested, and administered as safely as possible, and identifies how vaccine safety is measured and monitored after a vaccine is licensed for use in the population.

Vaccines are designed to evoke a protective response from the immune system as if it were the actual infectious disease. While a vaccine is designed to maximize the body's reaction and minimize any pathological effects, effective vaccines (i.e., capable of inducing protective immunity) may also produce some undesirable side effects. Clinical trials determine whether side effects are tolerable or not, and detect certain adverse events before the vaccine reaches general distribution. Most adverse reactions are mild and clear up quickly.

Design factors can help minimize programmatic errors in the administration of the vaccine by reducing the chance of human error. The most common types of programmatic errors are unsafe or contaminated injections. It is sobering to realize that up to one-third of injections (not just for vaccination) are not sterile. New technologies have been introduced in the last decade that make injections much safer, including an auto-disable syringe that can only be used once and must be discarded because the plunger mechanism locks after use. This device helps minimize transmission of diseases that result from the reuse of contaminated injection equipment.

Vaccine adverse reactions can be due to the vaccine itself, or to immunological factors in the individual such

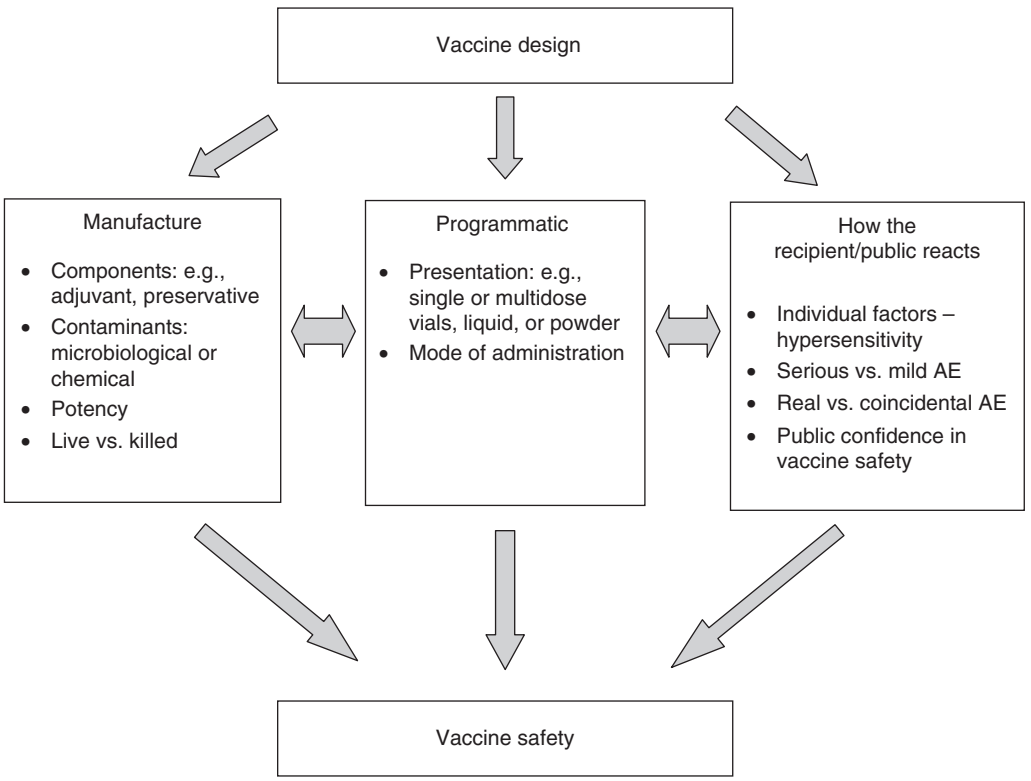

Figure 1 Components of vaccine safety.

as anaphylaxis or hypersensitivity reactions. However, the majority of adverse events thought to be related to the administration of a vaccine are actually not due to the vaccine itself – many are simply coincidental events. For example, many children have a cough around the time of vaccination, but this is independent of the vaccine, not caused by it. An appropriate causality assessment, using internationally consistent methods, is necessary to fully determine whether a particular vaccine causes a specific reaction. Even when scientists have been able to show that a particular event is unrelated to vaccine administration, the public may still perceive there to be a link.

Vaccine Design

Manufacture

A vaccine consists of many parts, only one of which is the antigen by which it is known. Other components may include an adjuvant, a preservative, antibiotics, stabilizers, and certain ingredients that remain from the manufacturing process. There may be components not stated on the information sheet that are classified as proprietary that the manufacturers are not obliged to declare. The safety of the vaccine can be affected by each and all of its components.

How a vaccine is manufactured will also determine its content. For instance, thiomersal may be used in the manufacture of pertussis vaccines to maintain sterility during the manufacturing process. While the bulk of the chemical is removed, the final product will still contain minute amounts of thiomersal. Influenza vaccines are grown on chicken eggs – trace amounts of egg proteins not removed in the purification process can cause severe allergic reactions in susceptible individuals.

Safeguards in vaccine manufacture now make it highly unlikely that currently available vaccines are contaminated with infectious agents that cause disease. Manufacturers supplying the international market are required to submit vaccines to extensive tests to detect known potential pathogens. As well, they must test cell lines used in the production of vaccines for the presence of a variety of infectious agents. Once manufactured, vaccines must undergo rigorous clinical trials for safety and effectiveness before being licensed by regulatory authorities.

Procedures designed to detect and prevent the presence of adventitious agents in vaccines include characterization of the cell substrates used for vaccine production as well as testing the products by specified methods. For example, manufacturers are required to test their cell lines used for the production of poliovirus vaccines (generally monkey kidney cells) for a variety of infectious agents such as tuberculosis, SV40, herpes viruses (including simian cytomegalovirus), Coxsackie virus, and lymphocytic choriomeningitis virus. Cell tissue culture tests must show an absence of cytopathogenic effects. Adult and suckling animals are also used to screen for viable microbial agents. A neurovirulence safety test is conducted for the live oral poliovirus vaccine.

The advent of bovine spongiform encephalitis (BSE) in the 1990s generated concern that the etiological agent might be contaminating vaccines through the use of calf serum during manufacture. Industry has taken steps to ensure that the risk to vaccines from BSE is virtually zero.

New technologies can also give rise to new concerns during manufacture. For instance, some modern vaccines are grown on chick embryo fibroblasts. These vaccines may test positive by a polymerase chain reaction assay for avian leukocytosis virus, a retrovirus not unlike the HIV/AIDS virus. Because the assay is so sensitive, it detects nonreplicating fragments of the virus that have no pathological significance. The cell substrates used for measles/mumps/rubella (MMR) vaccine are derived from flocks free of avian leukosis virus. MMR vaccine is also tested extensively for adventitious viral activity. As technology improves, regulatory authorities are likely to require the application of new methods to screen for infectious agents in vaccines.

Potency

The potency (or viral titer) of a vaccine can influence both its safety and its ability to induce protective immunity. When developing new rotavirus vaccines, the safety and efficacy of low-, medium-, and high-viral-titer formulations of human–bovine reassortant vaccines were assessed in randomized controlled clinical trials of infants. The medium-potency formulation was selected for use in phase III trials as it was found to be more efficacious than the high- and low-titer formulations and had a slightly lower, but not clinically significant, incidence of fever. In another example, a high-titer formulation of measles vaccine was used in some African countries in 1989–92 to protect infants from as early as 6 months of age. Unexpected results showed that the survival of infants who received the high-titer vaccine before 9 months of age was substantially lower than those who received the standard titer vaccine at 9 months of age. The high-titer vaccine was withdrawn from use.

Live or killed vaccine

There are three main types of viral vaccines currently in widespread use: live attenuated virus (e.g., MMR, yellow fever, varicella vaccines), killed virus (e.g., influenza vaccine), and recombinant protein (e.g., hepatitis B vaccine). Safety issues differ to some extent for the three types of vaccine. For all, the risk of an adverse event is highest in the immediate post-vaccination period due to reactions to vaccine components and to programmatic errors. Live-attenuated viral vaccines must undergo viral replication in the recipient to produce sufficient

antigen to generate a protective immune response. The vaccine recipient may experience a mild form of the disease, particularly at the time of peak viral load. Febrile seizure in young children 5–14 days after receiving MMR vaccine is a known adverse event. There is also the potential risk of reversion to virulence if the vaccine strain of virus undergoes genetic mutations either *in vitro* during manufacture or in the vaccinee, that can cause significant illness. Killed vaccines usually contain trace amounts of the inactivating agent (often formaldehyde) that can cause reactions in some individuals. There is also the potential risk of incomplete inactivation with the effect that the vaccine could contain trace amounts of live virus capable of replication in the host to cause disease. An atypical variant of measles infection has been reported in some recipients of killed measles vaccine who were at risk of developing severe delayed hypersensitivity reaction following exposure to wild measles virus. As well as containing no viral genetic material, recombinant protein vaccines have the advantage of presenting fewer antigens to the immune system, thus minimizing the risk of hypersensitivity reaction. However, they are often produced in yeast cells, traces of which may remain after purification and cause allergic reactions in some individuals.

Programmatic Factors, Presentation, and Administration

A 'programmatic error' is caused by an error or errors in the handling or administration of a vaccine. The error is usually the fault of a person rather than the fault of the vaccine or other technology. It can generally be prevented through staff training and an adequate supply of safe injection equipment although vaccine design factors can help minimize the chance of human error.

A programme error may lead to a cluster of events. Improper immunization practice can result in abscesses or other blood-borne infections. Freeze-dried vaccines (such as measles-containing vaccines and yellow fever) are presented as a dry powder in a vial that needs reconstituting with liquid. Errors can occur in reconstituting the powder, such as the use of inappropriate or contaminated liquid. Once a vaccine is reconstituted, it is open to the environment and makes an ideal culture medium for organisms such as *Staphylococcus*. Fatal toxic shock syndrome has been reported following administration of a multidose vial of reconstituted measles vaccine that had become contaminated. In such circumstances, a number of infants immunized from the same vial may die within a short time of injection. To avoid this catastrophe, field staff are required to discard reconstituted vaccine after 6 h, or at the end of the vaccination session, whichever is sooner.

There are options for the way a vaccine is presented that can affect its safety in the field. To reduce cost, vaccines are often presented in multidose vials. It is common in developing countries for diphtheria–tetanus–pertussis (DTP) and measles vaccines to be in 10-dose vials, while BCG is often in 20-dose vials. The downside of multidose vials is that they have the potential for contamination (see above). In contrast, single-dose presentations are unlikely to become contaminated as the vial is discarded once the single dose has been used. Prepackaged mono-dose vials reduce the need for human handling (and hence reduce the risk of contamination) but are more costly per unit. Industrialized countries tend to favor mono-dose presentations because of their increased safety and convenience.

There are a number of different modes of administration of vaccines, and these affect safety in different ways. Aerosol presentations are attractive because they do not need a needle or syringe, thus reducing the risk of contamination. However, administering an inhaled vaccine to a 9-month-old infant is not without its practical problems. Nasal delivery bypasses the intestinal barrier, but recipients with purulent rhinitis (a common situation in developing countries) may interfere with successful seroconversion. Edible vaccines and vaccines presented using skin patches are also attractive for their apparent freedom from these safety concerns.

The injectable vaccine is by far the commonest presentation in the world today. Injections are one of the most common healthcare procedures. Five to ten percent of some 16 billion injections administered worldwide each year are given for immunization. Unsafe injections or unsafe practices in relation to immunization are not only responsible for cases of hepatitis B and C, HIV, and other serious and potentially lethal side effects suffered by vaccine recipients, but may also pose an occupational hazard to health providers and an environmental hazard to communities. Furthermore, unsafe injection practices can seriously impede the progress made by immunization programmes, and have a substantial effect on global immunization coverage. Fortunately, a number of technologies are at hand that help make injections safer.

The reuse of standard single-use disposable syringes and needles becomes unsafe when they are not disposed of after use but are reused multiple times. The auto-disable syringe, which is now widely available at low cost, presents the lowest risk of person-to-person transmission of blood-borne pathogens (such as hepatitis B or HIV) because it cannot be reused. The auto-disable syringe is the equipment of choice for administering vaccines, both in routine immunization and mass campaigns. In 1999, the World Health Organization (WHO) and other United Nations organizations issued a joint statement promoting the use of auto-disable syringes in immunization services. 'Safety boxes', puncture-proof containers – for the collection and disposal of used disposable and auto-disable syringes, needles, and other injection materials – reduce the risk from contaminated needles and syringes. The safe

disposal of used needles and syringes is a critical component of any vaccination program if infection is to be prevented. Poor management of injection-related waste exposes patients, healthcare workers, waste handlers, and, indeed, the wider community, to infections, toxic effects, and injuries.

Program errors may occur when a new vaccine is integrated into an existing immunization programme that has important (and sometimes subtle) differences in its presentation, preparation, or administration. Errors such as the omission of a component, injection of oral vaccines, and the use of incorrect diluent to reconstitute freeze-dried vaccines are examples of this type of errors. While thermostabilty of a vaccine is not strictly an issue of vaccine safety, failure to maintain the cold chain is a significant component of programmatic error. This can lead to vaccine failure and the need to revaccinate populations, thus re-exposing them to the risk, albeit small, of vaccine adverse reactions.

How the Recipient/Public Reacts

While the recipient of a dose of vaccine will hopefully react by developing immunity to the challenging antigen, it is common for there to be various other less desirable reactions following vaccine administration. The WHO describes an adverse vaccine reaction as either 'common' or 'rare'. Common reactions are generally mild, settle without treatment, and have no long-term consequences. More serious reactions are very rare – usually of a fairly predictable (albeit extremely low) frequency.

Rates of common, mild vaccine reactions

The purpose of a vaccine is to induce immunity by causing the recipient's immune system to react to the vaccine. It is not surprising that vaccination commonly results in certain mild side effects (**Table 1**). Local reaction, fever, and systemic symptoms can result as part of the normal immune response. In addition, some vaccine components (e.g., aluminum adjuvant, antibiotics) can lead to reactions. A successful vaccine reduces these reactions to a minimum while inducing maximum immunity.

Rates of rare, more severe vaccine reactions

Most of the rare vaccine reactions (e.g., seizures, thrombocytopenia, hypotonic hyporesponsive episodes, persistent inconsolable screaming) are self-limiting and do not lead to long-term problems (**Table 2**). Anaphylaxis, while potentially fatal, is treatable without leaving any long-term effects.

Public perceptions of vaccine safety

While vaccine manufacture and administration have been getting progressively safer over the last 30 years, the perception of the public has been changing. Certain reports of adverse events following immunization (AEFIs) published in the medical literature over the past few years have resulted in controversy. While generating provocative hypotheses, the studies on which these reports are based have generally not fulfilled the criteria needed to draw conclusions about vaccine safety with any degree of certainty. Yet these reports have had a major influence on public debate and opinion making. Sadly, health professionals have not always handled public announcements about such matters very well and the debate has often spilt over into the political arena and policymaking. At times, mishandling of public information has resulted in a reduced public acceptance of a vaccine. Even when scientific evaluation has been correct, the public has often been swayed by other factors. This again underlines the importance of a correct assessment of causality.

Until very recently, communication with the public by health professionals and vaccine manufacturers has often been on a paternalistic basis: "We know what is best for you." The level of education of the general public has risen, helped by the Internet; freedom-of-information laws in many countries have allowed the public to access what was previously privileged information. As a result, members of the public are often well informed on a given public health issue such as vaccine safety.

Table 1 Summary of common minor viral vaccine reactions

Vaccine	*Local reaction (pain, swelling, redness)*	*Fever*	*Irritability, malaise, and nonspecific symptoms*
Hepatitis B	Adults up to 30% Children up to 5%	1–6%	
Measles/MMR	Up to 10%	Up to 5%	Up to 5%
Oral polio (OPV)	None	Less than 1%	Less than 1%[a]
Influenza	>10%	Up to 10%	Up to 10%

[a]Diarrhoea, headache, and/or muscle pains.

Note: the rates due to the vaccine administration will be lower as these symptoms occur independently as part of normal childhood.

Source: Supplementary information on vaccine safety. Part 2: Background rates of adverse events following immunization. WHO/V&B/00.36. http://www.who.int/vaccines-documents/DocsPDF00/www562.pdf.

Table 2 Summary of rare, serious viral vaccine reactions, onset interval, and rates

Vaccine	*Reaction*	*Onset interval*	*Rate per million doses*
Hepatitis B recombinant vaccine	Anaphylaxis	0–1 h	1–2
	Guillain–Barré syndrome (plasma derived)	1–6 weeks	5
Measles/MMR[a]	Febrile seizures	5–12 days	333
	Thrombocytopenia (low platelets)	15–35 days	33
	Anaphylaxis	0–1 h	1–50
Oral polio (OPV)	Vaccine-associated paralytic poliomyelitis (VAPP)	4–30 days	1.4–3.4[b]
Japanese encephalitis	Serious allergic reaction		10–1000
	Neurological event		1–2.3
Yellow fever	Post-vaccination encephalitis	7–21 days	500–4000 in infants less than 6 months[c]
	Allergic reaction/anaphylaxis	0–1 h	5–20
	Catastrophic system collapse resembling naturally acquired infection	2–7 days	2–32 (higher rates in the elderly or history of thymoma)[d]

[a]Reactions (except anaphylaxis) do not occur if already immune (~90% of those receiving a second dose); children over 6 years unlikely to have febrile seizures.
[b]VAPP risk is higher for first dose (1 per 1.4–3.4 million doses) compared to 1 per 5.9 million for subsequent doses and 1 in 6.7 million doses for contacts.
[c]Isolated cases with no denominator make it difficult to assess the rate in older children and adults, but it is extremely rare (less than four cases per 8 million doses).
[d]Studies have reported >10-fold higher risk of this rare adverse event among elderly vaccine recipients. There is a suggestion that reduced thymus gland activity (through age, immunosuppression, or surgical removal) increases the risk.

Discussions about vaccine safety now must contend with this new era. It is no longer sufficient for professionals to be factually correct – they must present information in ways that are perceived to be correct. A key component of this is representing themselves in ways that generate the confidence and trust of the public. In Jordan, a vaccine scare followed hard on the heels of a scare about water contamination, with major consequences. The public lost confidence in the truthfulness of government spokespersons, even though their claims that the vaccines in question were safe later proved to be correct. A similar situation occurred in the United Kingdom when there was a large decline in MMR immunization rates after publication of a now-disproved hypothesis that MMR vaccine caused autism. One of the factors attributed to this was loss of public confidence in the government and health spokespersons because of the way the BSE situation had been handled some years earlier.

Monitoring and Assessment of Vaccine Safety

The clearest and most reliable way to determine whether an adverse event is causally related to vaccination is by comparing rates of the event in a vaccinated and nonvaccinated group in a randomized clinical trial. Such trials, however, are unlikely to be large enough to assess very rare events, and postmarketing surveillance systems are required to identify events potentially related to vaccination. Postmarketing surveillance capability is improving; more countries now have monitoring systems, and more importance is attached to the reporting of suspected links between vaccination and adverse events. These systems have been successful in bringing to light serious adverse events after vaccines have been approved for use by regulatory authorities. A recent example is intussusception after administration of reassortant rhesus rotavirus vaccine.

Evaluating Adverse Events – Causality Assessment

Clinical events such as anaphylaxis or rash may occur subsequent to vaccination. But are they 'caused' by vaccination? It would be highly likely that collapse within minutes of receiving a dose of vaccine was due to the vaccine. But a rash 3 weeks later may not be – more likely it was coincidental. It is the area between these two scenarios that needs clarification.

Assessment of whether a given vaccine causes a particular adverse reaction varies from the casual observation to the carefully controlled study. The public frequently forms a decision about a vaccine's safety based on the information available to them – often a report based on unscientific observations or analyses that fail to stand the scrutiny of rigorous scientific investigation. Submitting a

study to a scientific process rather than to partially informed opinion is crucial in determining whether a vaccine actually causes a given reaction. If undertaken carelessly or without scientific rigor, the study results will be inconclusive at best, may result in the inappropriate withdrawal of a valuable vaccine from use, or at worst may result in the exposure of a population to a dangerous vaccine.

When the Global Advisory Committee on Vaccine Safety (GACVS) undertakes causality assessment, the criteria it looks for in arriving at conclusions include consistency of observations, strength of the association, specificity, temporal relation, and biological plausibility. Clearly, not all these criteria need to be present, and neither does each carry equal weight for a causal relationship between an adverse event and the vaccine to be determined. Biological plausibility is a less robust criterion than the others described.

An association between vaccine administration and an adverse event is most likely to be considered strong when the evidence is based on well-conducted human studies that demonstrate a clear association in a study specifically designed to test the hypothesis of such association. Such studies may be randomized controlled clinical trials, cohort studies, case-control studies, or controlled case-series analyses. Case reports by themselves, however numerous and complete, do not fulfill the requirements for testing hypotheses.

Surveillance of AEFIs

Vaccines are generally administered to healthy individuals, so any report of vaccine administration causing harm needs to be taken seriously. Although the vaccines in general used in national immunization programmes are extremely safe and effective, adverse events can occur following vaccine administration and no vaccine is perfectly safe. In addition to the vaccines themselves, the process of immunization is a potential source of adverse events. An AEFI is any adverse event that follows immunization that is believed to be caused by the immunization. Using this terminology allows description and analysis of the event without prejudging causality. Immunization will tend to be blamed for any event that happens after immunization. AEFIs can be classified into five categories:

- vaccine reaction: a reaction due to the inherent properties of the vaccine;
- programme error: an error in the immunization process;
- coincidental event: unrelated to the immunization, but has a temporal association;
- anxiety-related: a reaction can arise from the pain of the injection rather than the vaccine; and
- unknown: in some cases the cause of the AEFI remains unknown.

It is important to investigate a report of an AEFI to determine into which of the above categories it fits. The response to an AEFI will vary depending on the cause. However, many countries have ineffective reporting systems or no system at all. Currently, only 35% of 192 countries, and only 25% of 165 nonindustrialized countries, have an adequately functioning system for monitoring adverse events following immunization. The benefits of good surveillance of AEFIs are shown in **Table 3**.

Table 3 Benefits of monitoring AEFIs

Improves vaccine safety by creating awareness among health professionals of the risks of vaccination
Identifies urgent problems that need investigation and action
Improves capacity to respond to AEFI reports
Improves the quality of the vaccination programme by monitoring performance and increasing staff confidence
Stimulates other aspects of programme monitoring, e.g., case reporting
Public perceives that health authorities understand and monitor vaccine safety, building public confidence in immunization
Detects signals for potential follow-up and research
Estimates rates for serious AEFIs
For comparison between products
To determine risks and benefits of immunization
To validate prelicensure data
Identifies programmatic errors and batch problems

Benefits of monitoring AEFIs

As vaccine-preventable infectious diseases continue to decline, people have become increasingly concerned about the risks associated with vaccines. Furthermore, technological advances and continuously increasing knowledge about vaccines have led to investigations focused on the safety of existing vaccines which have sometimes created a climate of concern. Allegations regarding vaccine-related adverse events that are not rapidly and effectively dealt with can undermine confidence in a vaccine and ultimately have dramatic consequences for immunization coverage and disease incidence.

Not only is public awareness of vaccine safety issues rising, there are increasing opportunities for AEFIs to occur due to various factors. For instance, an increasing number of vaccine doses is now given in campaigns than ever before (**Table 4**). Polio virus is targeted for eradication and measles elimination is being implemented in many parts of the world. As a result, vast numbers of doses of vaccine are being given over short time intervals. Thus, even if the AEFI rates stay the same, the actual number of cases is likely to be much higher than would be expected over the same time period, simply because so many doses have been administered.

Classical Safety Events

SV40

Between 1959 and 1963, both inactivated and live attenuated poliovirus vaccines were inadvertently contaminated

Table 4 Possible effect of immunization campaigns on vaccine safety

A real rise in program errors due to pressure on staff
Increased workload on staff can increase human error
Extra or new staff may not be fully trained in administration technique
Because large numbers of doses are administered there may be a rise in the absolute number of AEFIs even though rates may not change
Campaigns can generate popular opposition and rumors about vaccine safety
Rate of AEFIs prior to campaign may be unknown, so that any report of an AEFI appears to be due to the campaign

with simian virus 40 (SV40), a monkey virus known to be oncogenic for newborn hamsters. SV40 was found to be present in monkey kidney tissue used for propagation of the poliovirus during manufacture. From 1961, manufacturers were required by control authorities to test for SV40 using infectivity assays and different cell cultures, and lots positive for SV40 were not released. A few years later, the source of monkeys used for production was changed to species that do not harbor SV40. There is no evidence that polio vaccine administered since the early 1960s has contained SV40, and large epidemiological studies have not identified an elevated cancer risk in persons who received SV40-contaminated vaccines, but fragments of SV40 DNA have recently been identified in certain human tumors.

Swine flu

Influenza vaccine has been the source of a number of issues related to safety over the years. Mass immunization against swine-like influenza was carried out in 1976–77 using the A/New Jersey swine-influenza vaccine. Initially it appeared that this vaccine generated an increased risk of acquiring vaccine-related Guillain–Barré syndrome (GBS). In contrast, the 1978–79 influenza vaccine was not associated with a statistically significant excess risk of GBS. Although the original Centers for Disease Control study of the relation between A/New Jersey/8/76 (swine flu) vaccine and GBS demonstrated a statistical association and suggested a causal relation between the two events, controversy has persisted. At least one recent review of the data seemed to confirm the link. Another review suggested that there was no increased risk of acquiring GBS associated with the influenza vaccines administered during these seasons and that the causative 'trigger agent' in the A/New Jersey (swine) influenza vaccine administered in 1976 has not been present in subsequent influenza vaccine preparations.

There was no increase in the risk of vaccine-associated GBS from 1992–93 to 1993–94. A study by Lasky suggested only slightly more than one additional case of GBS per million persons vaccinated against influenza. More recently, an oculorespiratory syndrome has been described following influenza vaccine.

Recent Safety Events

A number of events in recent years has provoked concern that certain vaccines might be unsafe. Most of these concerns have proved to be unfounded, and some remain unproven or incompletely understood.

Thiomersal

Thiomersal is a mercury-containing preservative used in certain liquid vaccines such as DTP and hepatitis B vaccines. It came into the public gaze in 1999 as the result of a study being undertaken to estimate how much mercury was being administered to children in North America through vaccines. It transpired that the amount exceeded the allowed maximum according to environmental health permitted limits. Scientists assumed that ethyl mercury in thiomersal would have the same toxicology as methyl mercury, a chemical about which a great deal was known. Over the ensuing years, evidence was accumulated that showed it actually had a different metabolic pathway in the human body compared with methyl mercury. Both were metabolized in the liver and excreted in the gut, but methyl mercury was reabsorbed and accumulated in the body. Ethyl mercury, on the other hand, was found to be passed in the stool and lost from the body, thus avoiding a cumulative effect. Overwhelming scientific evidence indicates no clear link between neurodevelopmental disorders or autism and the receipt of vaccines containing thiomersal. One set of authors clearly flies in the face of the weight of scientific evidence, yet support a widely held public belief that thiomersal (in the quantities present in vaccines) is bad for children. Live viral and live bacterial vaccines do not contain thiomersal, largely because the preservative would kill the vaccine organism, rendering the vaccine useless.

Hepatitis B vaccine and multiple sclerosis

Reports of multiple sclerosis developing after hepatitis B vaccination have led to the concern that this vaccine might be a cause of multiple sclerosis in previously healthy subjects. A number of reliable studies have been consistent in showing that there is no association between hepatitis B vaccination and the development of multiple sclerosis.

MMR autism and bowel disease

Reports have proposed a link between the administration of the MMR vaccine and juvenile autism, Crohn's disease, and other forms of inflammatory bowel disease. The weight of scientific evidence strongly favors the conclusion that there is no direct association between measles virus, measles vaccine, autism, or inflammatory bowel disease.

Intranasal influenza vaccine and Bell's palsy

After the introduction of an inactivated intranasal influenza vaccine that was used only in Switzerland, 46 cases of Bell's palsy were reported. The relative risk of Bell's palsy in one study was found to be 19 times the risk in the controls, corresponding to 13 excess cases per 10 000 vaccinees within 1–91 days after vaccination. As a result, this vaccine is no longer in clinical use.

Yellow fever vaccine

Until recently, yellow fever vaccine was considered to be very safe. It has been given to many millions of people over more than 60 years to protect against yellow fever virus infection, which can be fatal in 5% or more of cases. From 1996 onward, a previously unrecognized adverse event of multiorgan failure and death was detected through passive surveillance in the United States, Australia, and other countries. Subsequent studies found that the risk of this rare adverse event was approximately 3 per 1 million doses, and vaccine recipients aged 65 years and older had a 10-fold higher risk than younger vaccinees, particularly following the first dose of the vaccine.

HIV Infection

The era of the HIV epidemic has had an impact on vaccine safety in a number of ways.

- It may be transmitted by injection (not only during vaccination). It could thus be transmitted by incorrect injection practices during routine immunization to a small number of infants attending a clinic at the same time. And it could theoretically be transmitted during mass campaigns where many more children might be at potential risk.
- Staff may be infected because of needle-stick injury or other improper handling of infected body fluids.
- It may alter the immune response of the recipient, either making him/her vulnerable to some negative effect of the vaccine, or diminishing the effect the vaccine has on protecting the infant. Some vaccines are not as effective in more immune-suppressed individuals, and severely immune-depressed infants must avoid vaccines such as BCG as they are at risk of disseminated BCG, which may be lethal.
- The course of the disease might be altered. The activation of CD4+ T lymphocytes following immunization could potentially augment HIV replication and result in accelerated progression to disease. Several, but not all, investigators have described increased HIV RNA plasma levels lasting several days following immunization.

On the positive side, the HIV epidemic has alerted health workers to the potential dangers of contamination during vaccine administration and has resulted in the safer use of syringes and proper disposal of injection equipment.

Conclusions

The design and manufacture of vaccines are of such high standards today that they have become extremely safe. But it will never be possible to say that everything is known about the subject and that vaccines are totally safe. Nor can the unpredictable human element in administration ever be totally excluded from the equation. But new methods of safety testing will emerge as each new threat is discovered. And new technologies will complement existing safety measures. However, communicating to vaccine recipients or their parents that the vaccine they are about to receive is neither totally effective nor totally safe makes health professionals uncomfortable. But the reality is that vaccines are many orders of magnitude safer than contracting the disease. Through constant vigilance, we can anticipate that vaccines will remain extremely safe – as safe as humanly possible. Any lesser alternative is unacceptable.

Introduction

To develop a new viral vaccine, get it licensed, and bring it to market is a lengthy, complex, and very expensive task. It requires a detailed knowledge of all aspects of the virus, especially its structure, epidemiology, pathology, and immunobiology, and demands a close collaboration between fundamental scientists, regulatory authorities, and industrial scientists and engineers. Completely new vaccines against human viruses appear infrequently on the market and the cost and complexity of their development has escalated with time, mainly due to the increased regulatory pressures to have highly defined products and to ensure complete clinical safety and high efficacy. Over the past 20 years or so, six new human virus vaccines have been developed for licensure in major markets; these are hepatitis B, Japanese encephalitis, hepatitis A, varicella (recently with a zoster formulation), and, over the past year, rotavirus, and human papilloma virus (HPV). The introduction of HPV vaccines is a technological triumph that offers to dramatically reduce the incidence of cervical cancer worldwide in the long term. The newest rotavirus vaccines seem, so far, to be free from the complications that led to the withdrawal of the earlier Rotashield vaccine in 1999 and promise to be very effective in reducing the burden of rotavirus diarrhea worldwide. In spite of this impressive progress, however, virus vaccine development has not accelerated over recent decades, and there remains a significant list of human virus diseases of widespread prevalence for which there are no vaccines available. These include human immunodeficiency virus (HIV), hepatitis C, hepatitis E, Eptein–Barr virus, herpes simplex virus (HSV), cytomegalovirus (CMV), respiratory syncytial virus (RSV), and parainfluenza viruses (PIV) (see **Table 1**).

In the veterinary world, the list of successes is significantly more impressive, and both the time cost of developing a new vaccine can be substantially reduced by the ability to reach proof of concept through direct challenge experiments, often with the wild-type virus. In this arena, the requirements are often very different to those for human vaccines, especially for vaccines of production animals where ease of administration and cost per dose are paramount. Recognizing that many approaches and outstanding fundamental challenges are similar for human and veterinary virus vaccines, this article focuses principally on the former with occasional reference to veterinary vaccines where they illustrate particular concepts.

Fueled by the new technologies of genomics, proteomics, and molecular immunology, the past 20 years have seen an impressive increase in our knowledge of all aspects of virology, providing insights to guide new vaccine concepts. The biological properties of viruses influencing choice of strategy include pathogenesis, serotype diversity,

Herpes simplex virus (HSV)	West Nile virus

antigenic variation, immune evasion mechanisms, latency, and route of transmission. New vaccine candidates have been described for a good number of the viruses listed in **Table 1**, and although many of these are in an early, pre-proof-of-concept stage, some are substantially developed and offer realistic prospects of licensure over the next decade. The most promising of these, based on pre-clinical and clinical results obtained so far, are dengue, hepatitis E, and HSV and CMV. Significant challenges remain however, and really promising candidate vaccines against pathogens such as HIV, hepatitis C, and infant RSV remain elusive. This article focuses on the strategies available to develop new viral vaccines and discusses some of the challenges posed by the more difficult targets.

Types of Vaccines

There are multiple possible approaches to the development of a viral vaccine that can be generally described as follows:

1. Killed whole or split virus vaccines. This approach requires that the virus can be grown to high titer in cell culture or other scalable medium such as hens eggs; that the virus can be successfully and completely inactivated using an agent such as formaldehyde or B-propiolactone without destroying immunogenicity; that, from an industrialization perspective, the immunogenic dose is low to modest with respect to virus yield (in the 10 μg range) and that the killed whole or split particle elicits protective immunity. This approach has had excellent successes in the form of vaccines such as inactivated polio vaccine (IPV), hepatitis A (HAV) vaccine, and influenza.
2. Subunits or single proteins prepared by recombinant DNA methods and fermentation processes in cell culture. This approach may work well when a single protein can provide immunity and where the expression system allows appropriate folding and processing of the viral protein.
3. Live-attenuated vaccines. There are several approaches possible.
   a. Use of a closely related animal virus that is not well adapted for efficient and widespread replication in humans and therefore does not cause disease, but nevertheless provokes an immune response that protects against the corresponding human virus. The best known example of this is the use of vaccinia virus to vaccinate against smallpox, but a similar approach has been used for rotaviruses, with genetic reassortment to confer appropriate antigenicity.
   b. Development of an empirically attenuated human virus by multiple passages in tissue culture, typically of nonhuman origin, and/or passage in animals. Attenuation is usually achieved by the accumulation of a number of mutations that affect the efficient functioning at normal body temperature of various genes or gene products, thereby reducing virulence. Replication competence, however, is maintained at a sufficient level to stimulate a protective immune response. Although there are some drawbacks to this approach from a safety perspective (e.g., a risk of reversion), this method has provided a bedrock of vaccinology over many decades and has worked well for viruses such as polio – oral polio vaccine (OPV), mumps, measles, rubella, and yellow fever.
   c. Live-attenuated vaccines prepared by knowledge-based manipulation of the viral genome. There are several examples of candidate vaccines in this category including HSV and influenza.
4. Vectored or chimeric virus approaches. This is where an existing virus vaccine can be modified genetically to carry genes encoding antigens from a foreign virus. The chimeric vaccine should retain the attenuation and growth characteristics of the parent vaccine strain but stimulate immunity against the foreign virus.
5. Naked DNA. This is where a DNA encoding viral antigens plus appropriate expression control sequences is administered directly to the recipient. Expression of the DNA leads to an immune response against the antigens encoded.

Principles of Vaccine Development and Examples

When developing a new vaccine, the choice of approach is made very much on a case-by-case basis, and for a given virus is driven by knowledge of its biology, structure, antigenic diversity, and pathogenesis. High importance should be given to what type of immunity arises as a result of natural infection and whether the pathogen can cause persistent and/or repeated infections in a single host. Experiments in animal models may also allow the dissection of the immune response to identify correlates of protection. The use of primates in particular can be useful if the disease produced is similar to that observed in humans. However, many viruses are highly host specific and may have evolved strategies to evade immune responses that may also be host specific (such as recruitment of downregulators of complement fixation). Care must therefore be taken as results in animal models may not be entirely reproducible in the natural host.

Killed Vaccines

Evidence that circulating antibodies are sufficient to provide immunity may come, for example, from the observation that the disease is modified or exacerbated in

immune deficiencies such as hypo-gammaglobulinaemia and/or that passive immune globulin can protect against infection and disease. The latter observation was made for several viruses prior to vaccine development, including hepatitis A, suggesting that the key to vaccine development in these cases would be the stimulation of a strong humoral immune response. Such responses can often be adequately provided by killed vaccines, and so this was an obvious choice of approach. The strategy will also be influenced by the successes and failures with closely related viruses (either human or animal) that have similarities in epidemiology, pathogenesis, and mode of transmission. Thus, for HAV, the successful paradigm of the inactivated polio virus vaccine from the same virus family (*Picornaviridae*) provided further confidence that a killed whole virus particle approach would be effective. Indeed, inactivated HAV vaccines were developed successfully on this basis by several companies in the early to mid-1990s. Current HAV vaccines are prepared by propagating the virus in an approved cell substrate, human fibroblasts or human diploid cell culture MRC-5, purification, inactivation using formalin, and adjuvanted with aluminum hydroxide. The vaccines are given parenterally, as a two-dose series, 6–18 months apart.

A further example of a killed vaccine is rabies vaccine. Several WHO-recommended inactivated rabies vaccines are available currently. They are all similar in being whole virus, used after inactivation by β-propiolactone, and purification and concentration by ultracentrifugation and/or ultrafiltration. The vaccines are required to have a protective potency defined as >2.5 international units (IU). The potency is determined by the National Institute of Health (NIH) potency test which is based on assays using intra-cerebral challenge of previously immunized mice. The main differences between the rabies vaccines currently available lies in the cell culture used for production. The cell cultures used for the WHO-recommended vaccines are MRC-5 cells for purified human diploid cell vaccine (HDCV), Vero cells for purified Vero cell culture rabies vaccine (PVRV), and primary duck or chicken embryo fibroblasts for purified duck embryo vaccine (PDEV) and purified chick embryo culture vaccine (PCECV), respectively.

When a new virus emerges that poses a severe threat to human health such as the human coronavirus which caused severe acute respiratory syndrome (SARS) in 2002, it is necessary to start working immediately to develop a vaccine. The huge challenge in such a scenario is time. Generally, to develop a vaccine from basic research through animal studies, clinical lot development, analytical test development, clinical trials, industrial scaleup, and licensure takes 8–12 years. These timelines can be compressed in case of extreme urgency, but this compression is not unlimited. Although experience on existing vaccines can be exploited, all processes and procedures need to be evaluated, validated, and implemented. Working with a BMBL Section III Laboratory Biosafety Level 3 (BSL 3) agent, such as human SARS coronavirus, is not exceptional for vaccine manufacturers, but many precautions need to be taken in regards to equipment and laboratory practices, as little was known about the SARS virus in the early stages. The choice of the vaccine approach was indeed influenced by the time factor. If the virus grows well in cell culture, an inactivated viral vaccine is usually the option of choice as it is the fastest to accomplish. Fortunately, in case of the human SARS coronavirus, the virus did grow well on Vero cells, was efficiently inactivated either by formol or β-propiolactone, and appeared to be very immunogenic in several animal models as well as in human beings. After 2003, no more human SARS cases were observed and the development of such vaccines has generally been put on hold for the present.

Recombinant Protein Vaccines

As discussed above, a further simple strategy, particularly when only antibodies are required, is to use recombinant DNA methods to express a single surface structural protein of the virus in a host–vector system such as *Escherichia coli* or one of several yeast species. This approach may be adopted when the virus cannot be propagated efficiently in culture, making a killed vaccine approach impossible, when the inactivation process may diminish immunogenicity, or when a focused immune response against a specific protein is required. This approach has proved very successful for hepatitis B, where the vaccine is composed of particulate complexes of the virus surface glycoprotein HBsAg produced in yeast. These particles mimic virus-like particles produced during natural infection and induce a highly protective and long-lasting immune response. This vaccine has been on the market since 1992 as a three-dose series of injection, each containing 5–20 μg HBsAg. A new version of this vaccine has recently been licensed with a formulation containing 20 μg HBsAg, adjuvanted with monophosphoryl lipid A (MPL) and alum, which reduces the incidence of nonresponders compared to a population vaccinated with the licensed vaccine.

The recently introduced human papilloma virus vaccines have also been developed using the recombinant protein approach (see below). But as with killed vaccine approaches, one size does not fit all, and for many viruses the approach of recombinant protein expression has not proved successful for a variety of reasons. For example, many viruses have a complex structure that cannot easily be reproduced in foreign hosts at high yield, particularly when the final structure is formed from several conformationally interdependent proteins. Incorrectly folded or immature proteins may not elicit functional, protective antibodies. Second, for some viruses, immune responses

to several proteins together may be necessary to provide complete protection against disease. Third, recombinant proteins administered conventionally are generally poor at providing cellular responses of a Th1 profile that may be necessary for protection against viruses such as HIV, hepatitis C virus (HCV), and members of the herpes family. Consequently, for many viruses, live-attenuated approaches or more complex production systems and/or methods of delivery are required as discussed below.

Live-Attenuated Vaccines

Live-attenuated vaccines are used to prevent diseases such as yellow fever, polio, mumps, measles, and rubella. They are based on viral strains that have lost their virulence, but are still capable of replicating sufficiently well to provoke a protective immune response. They cause infection but without inducing the clinical manifestations, eliciting a humoral as well as cellular immune response. Historically, the attenuation was obtained by passage in animals. The first demonstration of attenuation of a virus in cell culture was that of the yellow fever virus by Lloyd and Theiler. The attenuation resulted from a prolonged passage on cultures of chick embryo tissue. Another example is that of the development of the oral polio vaccines by Albert Sabin in the 1950s. Wild-type strains of each of the three serotypes were passaged in monkey testicular tissue both *in vitro* and *in vivo*, while testing in monkeys was performed by intracerebral inoculation at various stages of passage. Eventually, strains were selected that were unable to induce paralysis in animals. The number of passages and cloning steps required to achieve the desired level of attenuation varied between the serotypes. These vaccines are still routinely used in many countries of the world and have been the principal tool with which the WHO has pursued its campaign of global polio eradication.

The advent of genome sequencing and recombinant DNA techniques in the 1980s allowed the key mutations conferring attenuation, empirically introduced by Sabin's passages, to be identified. In addition to temperature sensitivity mutations affecting protein structure, all three attenuated strains had in common, point mutations in the 5′ noncoding regions which affected the stability of RNA secondary structure believed to be important for interaction with host factors and for internal entry of ribosomes.

Rotavirus

As discussed above, live-attenuated vaccines may also be based on a closely related animal virus. The rotavirus vaccine licensed by Merck in 2006 is based on the bovine WC3 rotavirus. The original monovalent bovine strain is naturally attenuated for human beings, but does not induce protective immunity. To improve the effectiveness of the strain for human use, reassortant strains were prepared which contained genes encoding capsid proteins from the most common human serotypes on a background of the bovine strain. The present vaccine contains five single gene reassortants, each containing a gene for a capsid protein from human serotypes G1, G2, G3, G4, and PIA (**Figure 1**). A three-dose regimen with $2.0–2.8 \times 10^6$ infectious units per reassortant, administered orally beginning at age 6–12 weeks with a 4–10 week interval between doses, provides 70% protection against both mild and severe rotavirus diarrhea.

Nowadays, for some viruses, attenuated viral vaccines can be designed on a more rational basis, by specifically targeting virulence factor functions that may not be essential for virus replication, especially in cell culture, but are necessary *in vivo* to counter host innate defense mechanisms. An example here is the NS1 gene of influenza A viruses. This protein is able to downregulate interferon production in the virus-infected cell and some deletion mutants of NS1 lack this function and are therefore much more easily controlled by the host interferon response and are thereby attenuated. The augmented interferon (IFN) response provoked by such viruses may also have the advantage of providing stronger immune stimulation resulting in increased immune responses. So far, such strains have only been tested in animal models but they offer promise as future influenza vaccine strains.

A drawback of many live-attenuated vaccines is that they require a cold chain from point of production to point of use and this may pose logistical difficulty, especially in developing countries. Also, the safety of live-attenuated viral vaccines is under constant scrutiny because of the risk, albeit small, that the mutations conferring attenuation will revert to wild type, allowing the virus to become virulent again. This is the reason why some live-attenuated vaccines are not recommended for immunosuppressed patients.

Viral Vectors

If neither the killed nor the attenuated vaccine approach is appropriate or feasible, one can consider the use of a viral vector. In this case, an attenuated virus is used as a backbone carrying immunogenic proteins of the virus of interest. In general, the viral proteins chosen are the membrane and/or envelope proteins as these proteins are presented on the outside of the virus particle and recognized by the immune system. An example of a viral vector is the yellow virus vaccine strain 17D. This vaccine strain was developed in the 1930s, since which time over 400 million people have been immunized with this vaccine. The strategy here is to use the 17D vaccine as a vector to deliver the two structural proteins, the premembrane PRE-M and envelope proteins from closely related

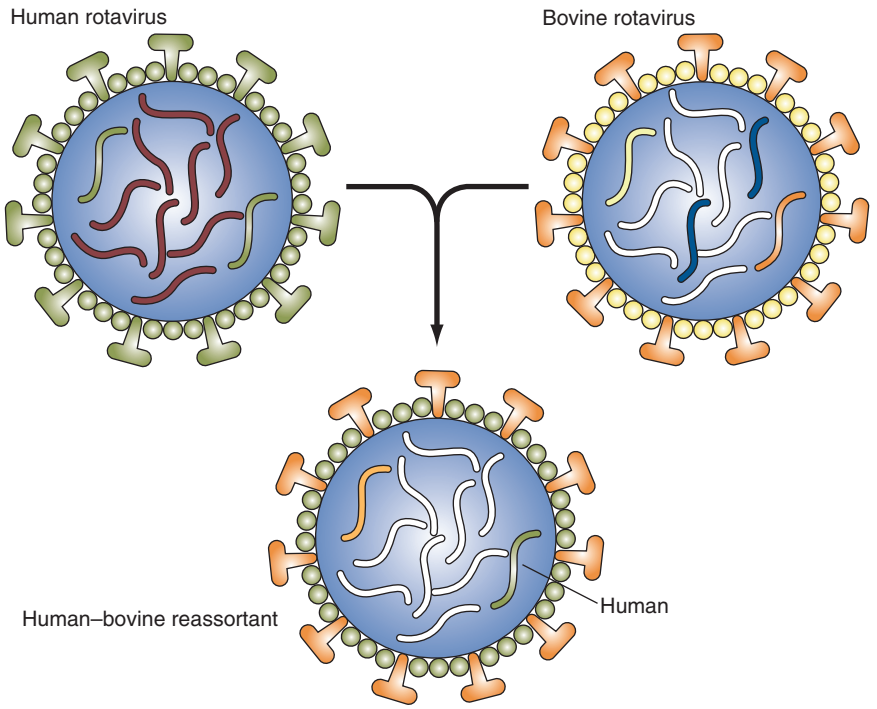

Figure 1 Rotavirus reassortant to generate oral live virus vaccine. RotaTeq is a polyvalent vaccine consisting of five human-bovine reassortants: four G serotypes (G1, G2, G3, G4) representing 80% of the G strains circulating worldwide, and one P serotype representing >75% of the P strains circulating worldwide. flaviviruses. The resulting chimeric virus needs to be viable and to replicate efficiently in an acceptable cell substrate for vaccine production. The chimerivax dengue virus approach (by Acambis in collaboration with sanofi pasteur) has been developed using the PRE-M and envelope genes of wild-type clinical isolates. The technology involved is illustrated in **Figure 2**. The yellow fever virus genome has been cloned as an infectious cDNA. This infectious cDNA is manipulated to remove the PRE-M and E-Genes of yellow fever virus and exchange them for the coat protein genes of each of the dengue virus serotypes. Thus four individual chimerivax cDNAs are constructed. Transcribing these cDNAs to RNA provides infectious RNA with which to transfect cells in culture. Thus, the resulting virus is a heterologous virus containing the immunizing antigens of dengue virus with the replicative engine of the yellow fever 17D vaccine. Chimeric dengue viruses are expected to mimic the biological properties of yellow fever 17D which has the excellent characteristics of providing minimal reactogenicity and lifelong immunity. The candidate vaccines have been characterized in preclinical models, neurovirulence in mice, viremia and immunogenicity in monkeys, and shown to have desirable characteristics. Moreover, when the four constructs are mixed and administered to monkeys, seroconversion against all four dengue serotypes appears to occur simultaneously in most infected animals. Moreover, the antibodies generated seem to be functional in that they neutralize dengue viruses in plaque reduction tests. The chimerivax dengue viruses grow well in culture and are well suited to industrial scaleup. In human volunteers, the chimeric viruses are safe and well tolerated and elicit specific immune responses against the different dengue serotypes. These strains therefore provide excellent candidates for further development.

DNA

Since the early 1990s, there has been considerable interest in the possible use of naked DNA as a vaccine delivery method. Naked DNA has the advantage that it can be taken up by cells and express the viral protein encoded. Depending on the conditions, this expression can be mid- to long term, thereby providing a substantial stimulation of the immune response. DNA vaccinology has apparently worked well in mice, but, so far, results in humans have been mainly disappointing requiring milligram amounts of DNA. Delivery of the DNA on colloidal gold, however, seems to offer a better prospect of success, as reported recently for hepatitis B virus and influenza. Regulatory issues concerning the use of DNA vaccines and its possible insertion integration into chromosomal genes are potential drawbacks to this type of approach, especially for use in prophylactic vaccination in infants. Further work is needed on safety issues before it can be seriously considered as a means to vaccinate populations.

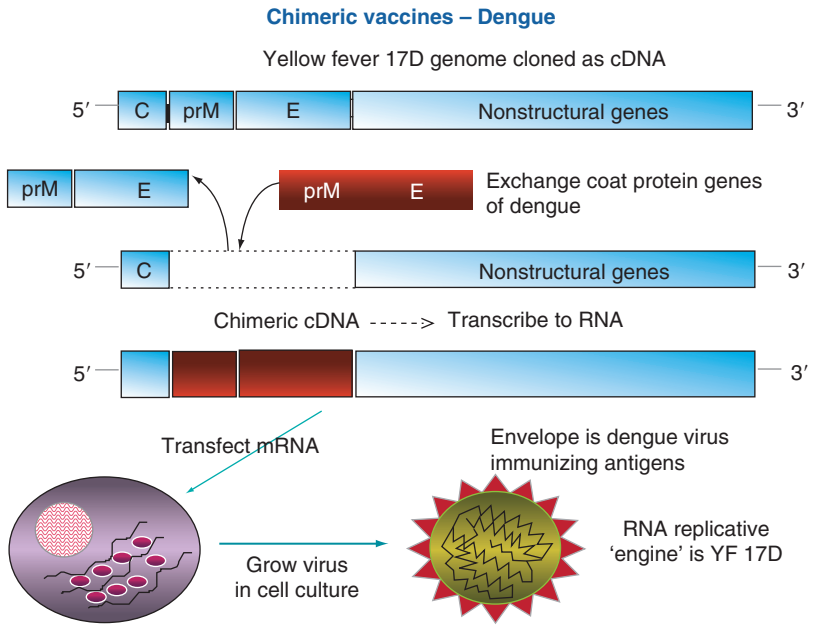

Figure 2 A DNA copy of the genome of yellow fever virus (blue) is manipulated to replace the prM and E genes by those of a related flavivirus such as Dengue (red). Transfection of mRNA transcribed from the resulting cDNA produces a 'chimeric virus' in cell culture.

The Challenge of Antigenic Variation

Antigenic Variation

Antigenic variation is displayed by a number of important pathogenic viruses and poses a particular problem for vaccine developers. The variation may be manifest in different ways depending on the virus' natural biology. Thus, for some viruses such as foot-and-mouth disease virus (FMDV), rhinoviruses, and HPV, multiple antigenic variants or serotypes co-circulate, sometimes with particular geographical patterns or ecological niches. Individual strains may show antigenic drift, presumably generating new serotypes over time. The rate of drift and the generation of new serotypes are not well understood for these viruses but may involve genetic recombination as well as cumulative mutational change. Other viruses may show a different pattern of antigenic variation: for example, influenza A viruses circulate as a limited number of subtypes (currently two in humans, H1 and H3), and each of these accumulate antigenic changes over several seasons (antigenic drift), escaping the most recently generated population-based immunity as they evolve. Occasionally, a new subtype may emerge (antigenic shift) either through genetic reassortment of a human strain with an avian strain, or possibly through direct evolution from an avian strain. Generally new subtypes displace existing subtypes as was the case when H2 emerged to displace H1 in 1957 and when H3 displaced H2 in 1968. For reasons that are not clear, this displacement did not occur when H1 reemerged in 1976 and since then there have been two influenza A subtypes co-circulating in the human population. This type of 'longitudinal' antigenic variation is clearly different from that of the multiple serotype viruses discussed above, and is generally more tractable in terms of vaccine development. Yet a different pattern is observed with HIV and to some extent HCV, where a limited number of genetic clades may contain very many different antigenic variants and where longitudinal variation to escape recently generated immune responses occurs within a single persistently infected individual. This type of natural biology generates a plethora of antigenic variants that can co-circulate. Providing immunological protection against all of these is an immense challenge for vaccine developers.

Multiple Serotype Vaccines

So what are the strategies available to develop vaccines against antigenically variable viruses? Most straightforwardly, one can generate simple killed vaccines against the currently circulating strains as discussed above and use these where the virus is prevalent. This strategy has had some success in the case of FMDV, where the geographical range of the virus may be (at least partially) restricted by regulations on movement of susceptible farm animals, and the vaccines are cheap and quick to prepare. However, even though simple killed vaccines have been shown to work for individual serotypes of rhinoviruses, it is difficult to imagine that this approach would be effective for this virus where, presumably because of widespread human contact and international travel, there seems to be a freer global circulation of multiple and

unpredictable serotypes each winter. Moreover, for most people, rhinovirus infections are relatively trivial and therefore the balance of medical need versus industrial feasibility/commercial attractiveness of preparing vaccines in advance against multiple strains does not favor such a strategy. It would perhaps be a different matter if it were possible to design a simple rhinovirus vaccine that provided cross-protection against all serotypes.

The case of HPV is more manageable because of the small number of serotypes associated with severe disease. Thus, in this case, a significant impact on disease can be made by vaccinating against just a few of the many different genotypes. Both currently available vaccines contain HPV types 16 and 18 to vaccinate against cervical cancer, and the Merck vaccine contains, in addition, HPV types 6 and 11 to vaccinate against genital warts (condylomata accuminata). The absence of efficient cell culture systems for papillomaviruses has required the development of eukaryotic expression systems to produce virus-like particles composed of the L1 capsid protein, which are highly immunogenic. Future, second-generation vaccines will likely incorporate one or more of the additional highly or moderately oncogenic serotypes, such as 31, 33, and 35.

Influenza Annual Vaccination

For influenza, the limited number of circulating subtypes in any particular season makes it possible to adopt a strategy of annual vaccination. Thus, current influenza vaccines are trivalent, containing strains of H1 and H3 of influenza A and an influenza B strain. The strategy of annual vaccination is not without risk and requires a high level of international cooperation on disease surveillance and strain isolation, construction of high-yielding seed viruses, preparation of reagents for formulation, and industrial production. Following strain selection and recommendation by WHO, vaccine production has to occur over a very tight time schedule to ensure that vaccine is ready for the following winter (**Figure 3**). Occasionally problems arise such as a mismatch between the selection of a particular vaccine strain and the virus that eventually circulates during the following winter. This may compromise the effectiveness of that particular component of the vaccine. Other potential problems include less than optimal growth of the high growth reassortant seed at the industrial scale, leading to less vaccine being produced, and the lateness of seeds or reagents impacting on prompt delivery of vaccine for the flu season. The vast majority of influenza vaccine used currently is partially purified, killed whole or split virus prepared in embryonated hen's eggs, formulated to 15 μg of hemagglutinin (HA) of each strain, and provides generally good protection that correlates well with the induction of virus neutralizing or hemagglutination-inhibiting antibodies. However, vaccines prepared using different technologies are arriving on the market or are in advanced stages of development. These include live-attenuated (cold-adapted) strains, licensed by MedImmune in the USA in 2003, influenza-recombinant surface protein (hemagglutinin) produced in a baculovirus expression system from Protein Sciences, and inactivated

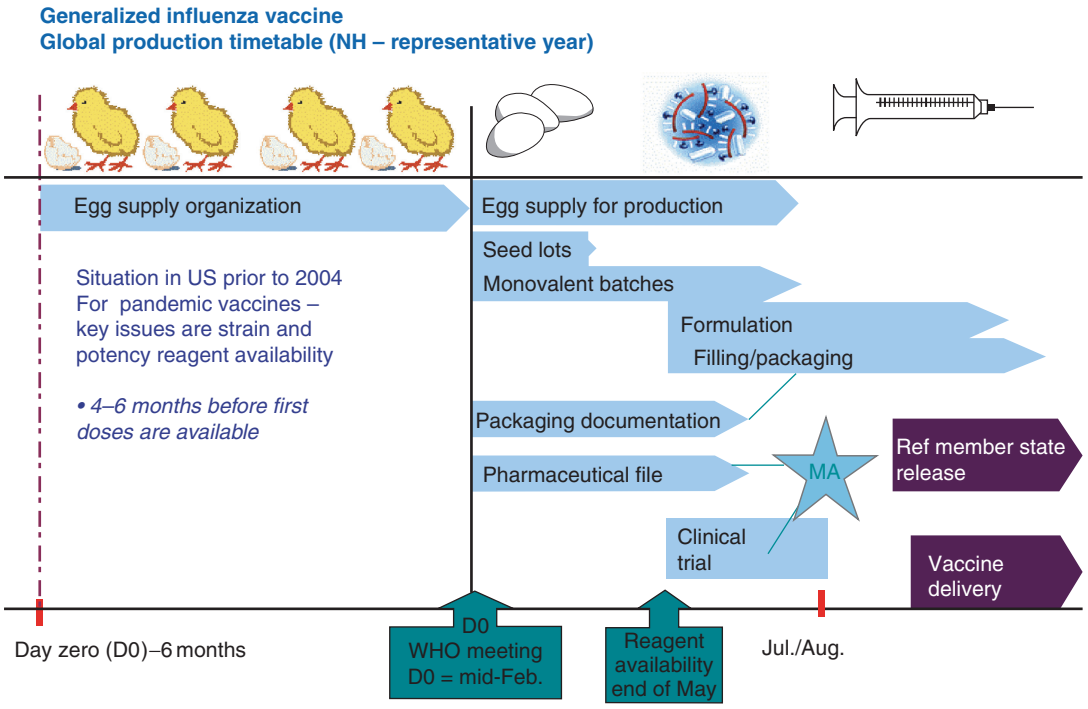

Figure 3 Approximate time schedule for the production of annual influenza vaccine from embryonated hens eggs.

virus vaccines prepared in cell cultures such as Vero, Madin–Darby canine kidney (MDCK), or PerC-6. This exploration of alternative technologies in recent years has been fueled by several criteria, perhaps the most important of which is greater and more flexible scaleup capability. The recent concerns over the possible emergence of an H5 pandemic has focused attention on the present worldwide limits in capacity, most notably in a situation of 'surge' demand, and governments have responded by providing the industry with incentives to increase capacity and diversify methods of production. A further response to this concern has been 'dose sparing' clinical studies on influenza vaccines adjuvanted with alum and other, proprietary adjuvants. These studies, using an H5N1 strain, suggest that it may be possible to reduce the vaccine dose from 2×90 μg HA nonadjuvanted, to 2×30 μg HA adjuvanted with aluminum hydroxide or even as low as 3.75 μg HA adjuvanted with new proprietary adjuvants. Moreover, there have been renewed suggestions that it may be possible to develop vaccines with a broader and perhaps multiseasonal protective effect by stimulating cellular immune responses, particularly against nucleoprotein (NP), a claim currently made for the live-attenuated approach, and even a universal flu vaccine, for example, based on the well-conserved M2 virus surface protein. Animal challenge experiments, especially using multiple arrays of the M2 protein, have been encouraging to date and suggest it may be possible to provoke a much stronger response against M2 than that induced by natural infection. Whether such a response will provide solid protection in humans however remains to be established.

HIV Approaches

The vast array of antigenic variants of HIV and HCV renders the approaches discussed above extremely difficult for these types of viruses. For HIV in particular, many strategies have been tried, so far without significant success. Early on in the AIDS pandemic the focus was on the use of simple recombinant surface glycoproteins, aimed at inducing neutralizing antibodies in the hope that even limited protection against homologous or closely related strains would provide a proof of concept that could be built upon. Unfortunately, this type of approach was not successful and a large phase III clinical trial carried out by Vaxgen using *E. coli*, which produced gp120, was not able to provide convincing evidence of protection even against strains closely related to that present in the vaccine formulation. Subsequently, there has been considerable effort on the induction of cellular responses, especially CD8 cytotoxic T lymphocytes, and more recently on a balanced cellular response to include CD4 effector mechanisms. The objective here is to provide the means for the immune system to launch an immediate attack on the first cells to become infected following exposure to the virus. Ideally, such an attack would prevent the primary viremia by eliminating the virus before it becomes established in the body. However, more realistically, there is evidence from primate studies that strong preexisting T-cell responses can control the primary viremia and reduce the viral set point during the asymptomatic phase. A low viral set point is associated with slow or no progression to AIDS. In addition, the HIV evades immune surveillance by actively downregulating the major histocompatibility complex I (MHCI) molecules on the surface of infected cells by the HIV nef protein. Vaccination strategies to produce cellular responses have mainly used vectors such as the vaccinia virus strains MVA and NYVAC, canarypox, adenoviruses, or naked DNA, either with multiple doses of a single type of construct or in heterologous prime-boost strategies. Antigens delivered have ranged from substantial regions of gag-pol-env of HIV to multiple copies in a 'string of beads' format of defined T-cell epitopes presented by common human leukocyte antigen (HLA) haplotypes. In general, these studies have not delivered T-cell responses of sufficient magnitude to be strongly encouraging, although one such strategy based on canarypox delivery of gag-pol-env antigens, followed by boosting with a recombinant env protein, has progressed to a clinical phase III study. Although many commentators have expressed doubt about whether this approach will show efficacy, it may generate useful information on the role of cellular responses in controlling HIV loads.

Most recently, HIV vaccine efforts have again turned to the induction of neutralizing antibodies, this time aimed specifically at epitopes that have been defined by studying unusual but highly informative broadly neutralizing monoclonal antibodies. The fact that such antibodies exists is highly encouraging from a vaccine perspective. The concepts here are based on the notion that certain conserved but crucial regions of gp120 or gp41 are naturally poorly immunogenic, either because they are relatively hidden in the conformationally folded protein or are shielded by strongly immunogenic noncritical domains or by glycosylation, or because they are only transiently exposed during the structural rearrangements that accompany cell binding and virus penetration. It is argued that because antibodies against these regions are neutralizing they will be protective if they can be generated prophylactically with sufficient avidity and at sufficient titer. This 'cryptic epitope' idea has been discussed for several viruses over many years and is akin to that mentioned above for influenza M2, in that the objective is to generate a far stronger response against a particular antigen or epitope than that resulting from natural infection. Such antibodies, once induced, will need to have the kinetic properties necessary to effectively neutralize the virus *in vivo*. So far there are no examples among virus vaccines that prove this concept. For HIV gp160, the particular

construction, presentation, and formulation of molecules able to raise high-titer antibodies against these conserved regions (many of which are imprecisely defined) are far from obvious. Nevertheless, the induction of prophylactic immune responses of this type is certainly worth detailed investigating in detail, given the magnitude of the HIV problem. The challenge of developing a vaccine against HIV however remains immense.

Conclusions and Perspectives

The easy viral vaccine targets of significant medical importance have been done. The viruses against which we do not have vaccines today are either of regionalized or sporadic importance medically and the incentives to develop them have not been sufficiently large or they are viruses that pose significant challenges in terms of their biological characteristics. Thus, HIV and HCV pose challenges because of their antigenic variation and the fact that natural immune responses are unable to protect and/or eliminate the virus. RSV poses challenges because of the immunopotentiation of pathogenesis that, for infants, must be avoided at all costs.

Nevertheless, there are grounds for optimism. A new generation of adjuvants, making it possible to selectively orientate immune responses toward Th1 or Th2 as necessary, promises the possibility of being able to 'improve on nature' in terms of immune response provoked by the viral antigens. New developments in vectors and virus 'chimeras' offer promise for vaccines such as dengue and perhaps RSV and parainfluenza viruses and targeted modification of immunomodulatory genes may offer prospects of new vaccines against herpes family viruses. Fundamental studies on virus pathogenesis, epidemiology, and immunobiology are greatly aided by new technologies such as genomics and proteomics and it is likely that the improved understanding will increase the technical and scientific feasibility of developing new viral vaccines in the years ahead.

The Origin of Vaccinia Virus

The origin and natural host of vaccinia virus (VACV) remain unknown and have been discussed in detail by Baxby. Although cowpox virus (CPXV) is believed to have been used by Jenner in 1796 for vaccination against smallpox, Downie demonstrated in 1939 that the smallpox vaccine strains in use in the twentieth century were biologically distinct from CPXV. They were called VACV after *vacca*, Latin for cow. Analysis of the genomes of many orthopoxviruses (OPVs) by restriction endonuclease digestion and sequencing confirmed that VACV is a distinct OPV species. Genome sequence analyses showed that VACV was not formed directly from CPXV and variola virus (VARV) by recombination or indirectly from either virus by passage and mutation.

So where did VACV come from? The most probable explanation is that VACV is an OPV that is either no longer endemic or present in a host species in which it is not recognized. Horsepox virus (HSPV) has been proposed, and several anecdotes are consistent with this theory. First, Jenner and other early vaccinators took vaccine from horses when the supply of cowpox (a rare disease) was short. Second, the VACV interferon gamma (IFN-γ)-binding protein binds equine IFN-γ (and IFN-γ from several other species). Third, the sequence of an OPV that caused an epidemic in horses in Mongolia is more closely related to VACV strains than to other OPVs. However, none of these observations proves that VACV has an equine origin. It is possible that VACV in horses is a zoonosis and that its natural host is elsewhere, rather as CPXV and monkeypox virus (MPXV) are

misnomers since their natural reservoirs are different types of rodent.

Currently, VACV-like viruses are circulating among buffaloes in northern India and cattle in South America, but it remains unclear whether these represent infections of animals with the smallpox vaccine that was transferred from man or whether they are natural reservoirs of VACV. VACV can infect many species and has a relatively broad host range, like CPXV and unlike VARV and camelpox virus (CMLV).

If one assumes that Jenner used CPXV for smallpox vaccination in 1796 (and this is uncertain because there is no virus isolate to study), sometime between 1796 and 1939 VACV replaced CPXV as the smallpox vaccine. It is not known when this happened, but anecdotal evidence suggests that it had occurred by the middle of the nineteenth century. First, the smallpox vaccine that was taken from England to the USA in 1856 and that became the New York City Board of Health vaccine is VACV and not CPXV. Second, the histological descriptions of cells infected by the smallpox vaccines in the late nineteenth century mentioned the cytoplasmic B-type inclusion bodies that are characteristic of OPV infections and made by both VACV and CPXV, but failed to report the much more obvious A-type inclusion bodies made by CPXV and not VACV. The failure to report A-type inclusions is consistent with the vaccine used at that time not being CPXV.

VACV: The Smallpox Vaccine

Widespread vaccination with VACV led to the control of smallpox in many countries by the 1970s, its removal from the Indian subcontinent by 1975, and its eradication by 1979. The last naturally occurring case was in Somalia in 1977, but the last person to die of smallpox was in Birmingham, UK, in 1978, following a laboratory escape of the virus. The eradication of smallpox remains the greatest triumph of the World Health Organisation (WHO) and a fine example of the benefit of cooperation among nations. Smallpox and its eradication are described beautifully in a monumental book published by the WHO in 1988.

Although VACV was used to achieve the global eradication of smallpox, it was a vaccine with an imperfect safety record. Several types of complication were noted. Generalized vaccinia was a systemic skin infection that usually resolved without sequelae. Progressive vaccinia was a grave condition that occurred in people with T-cell immunodeficiency. In these cases, the virus spread from the vaccination site without restriction and was often fatal. Eczema vaccinatum was a skin condition associated with infection of eczematous patients and usually resolved safely. There were also unpredictable neurological complications, such as encephalitis and encephalopathy, that were sometimes fatal. Finally, there were cases of myocarditis, and these have been evident again during recent vaccinations in the USA. All types of complication were more frequent in primary vaccinees than in those vaccinated previously. Large-scale studies of the complications of smallpox vaccination in the USA during the late 1960s recorded nine deaths after 14.2 million vaccinations. Without careful screening of vaccinees, it is probable that widespread vaccinations today with the old vaccines would induce a greater number of complications because of more widespread eczema and increased immunodeficiency due to infection with human immunodeficiency virus.

Attenuated VACV Strains

The complications of smallpox vaccination led investigators to develop safer candidate vaccines for smallpox. These were of two types: virus preparations from which infectivity had been removed by chemical or physical means, and virus strains that had diminished virulence. Trials with killed virus preparations failed to induce protection in models of OPV infection because these vaccines were composed largely of intracellular mature virus (IMV) and so lacked the antigens present in the outer envelope of the extracellular enveloped virus (EEV) (see the section titled 'Virion structure'). These antigens are important for the induction of protective immunity against OPV. The attenuated virus vaccines show more promise and several were produced, including modified virus Ankara (MVA) in southern Germany, LC16m8 in Japan, and NYVAC in USA. However, although these viruses are certainly less reactogenic in man, their ability to induce protective immunity is uncertain because they were never used in populations that were exposed to smallpox. They might induce protection against smallpox or they might not. While their utility as smallpox vaccines is uncertain, they do show considerable promise as recombinant vaccines for the delivery of antigens from other pathogens against which protective immunity is needed. In addition, these attenuated virus vaccines might be used for primary smallpox vaccination, followed by vaccination with the traditional vaccines known to protect against smallpox, in order to reduce adverse reactions. Indeed, this strategy was used with the MVA strain in Germany.

Taxonomy

Vaccinia virus is the most intensively studied species in the genus *Orthopoxvirus* of the family *Poxviridae*, and several VACV strains have been sequenced. The first strain sequenced was Copenhagen, which has been a reference for comparison with the sequences of additional VACV strains and other OPVs. Other commonly used, sequenced VACV

strains are Western Reserve (WR), Lister (and derivatives LC16m0 and LC16m8), and MVA. All VACV strains cluster closely together phylogenetically, as do all other OPV species except for CPXV, where two strains (GRI-90 and Brighton Red) are more divergent and might eventually be considered as separate species. HSPV appears to be the OPV most closely related to VACV.

Genome Structure

The VACV genome is a linear, double-stranded DNA (dsDNA) molecule of between 185 and 200 kbp with covalently closed termini that are linked by hairpin loops. There are inverted terminal repeats (ITRs) that vary in length between different VACV strains. These contain blocks of tandem repeats and a few genes that, consequently, are diploid. VACV genes are tightly packed so that there is little noncoding DNA, and mRNAs are not spliced. Overall, the genome may be divided broadly into three regions. The central region (about 100 kbp) encodes proteins that are conserved between VACV strains, other OPVs, and, indeed, all chordopoxviruses. Most (89) of these proteins are essential for some aspect of virus replication. In contrast, the left and right terminal regions encode proteins that are more variable between different VACV strains and other OPVs and are nonessential for virus replication. Instead, these genes affect virus host range, virulence, and interactions with the host immune system. Like other OPVs, the VACV genome is rich (67%) in adenine and thymine (A + T) residues.

Virion Structure

The structure of the VACV particle has been studied extensively and different models have been presented. There is agreement that there are two morphologically distinct forms of virus produced from each infected cell, and these have been called IMV and EEV. The terms mature virus (MV) and extracellular virus (EV) have been used by some authors recently. Each virion is brick-shaped, has dimensions of 250 nm × 350 nm, and is surrounded by one or more lipid membranes. The formation of IMV and EEV is considered later (see the section titled 'Assembly'). Studies in the early 1960s proposed that the IMV particle is surrounded by a single membrane, which is synthesized *de novo* in the cytoplasm and is not linked to cellular membranes. Subsequently, this view was challenged and it was proposed that the IMV form was surrounded by a double layer of membrane derived from and continuous with preexisting cellular membranes between the endoplasmic reticulum and the Golgi stack. Current evidence favors a single membrane covered by a proteinaceous layer. Inside this, there is a dumbbell-shaped virus core with lateral bodies in the concavities of the core. The core contains pores in its outer layer and is surrounded by a palisade of protein spikes. Within the core, the virus genome is packaged with structural proteins and enzymes that are needed to transcribe virus genes upon infection.

The EEV form comprises an IMV that is surrounded by an additional lipid membrane derived from the *trans*-Golgi network or early endosomes. The extra lipid envelope is fragile and contains antigens that are absent from the IMV particle.

Replication Cycle

Entry

The entry of VACV starts with the binding of either an IMV or EEV to the cell surface. The cell receptors for these virions have not been identified, but are different. The entry of IMV is considered first. IMV particles can bind glycosaminoglycans (GAGs) or laminins on the cell surface. Although several virus proteins (H3, D8, and A27) were reported to bind GAGs, these interactions seem nonessential because virions lacking these proteins individually retain infectivity. After binding to the cell, the IMV particle enters either by fusion at the cell surface in a pH-independent manner (**Figure 1**) or by endocytosis followed by fusion with the vesicle membrane. Unlike other enveloped viruses, which usually have a single protein mediating fusion of the virus and cellular membranes, the VACV fusion machine consists of a complex of at least nine proteins that are all essential for entry.

The entry of EEV is more complicated, owing to the need to remove both lipid envelopes before the core can be released into the cytoplasm. This is achieved by shedding the EEV outer envelope via a nonfusogenic mechanism that is triggered by interaction of EEV surface proteins with GAGs on the cell surface (**Figure 2**). This enables the IMV particle within the EEV envelope to bind to the cell surface and enter in the same way as a free IMV particle. Once a virus core is released into the cell, it is transported on microtubules deeper into the cell, and virus factories develop near the nucleus.

Transcription

Within minutes of infection, VACV mRNAs are synthesized by the virus DNA-dependent RNA polymerase, which is packaged in virions together with associated transcription factors and enzymes to cap and polyadenylate the mRNAs. Virus mRNAs are extruded from the core, presumably through the pores in the core wall. Early proteins include enzymes for synthesis of nucleoside triphosphate precursors and for DNA replication, and factors that block the innate immune response to infection. After early proteins have been expressed, the virus core is

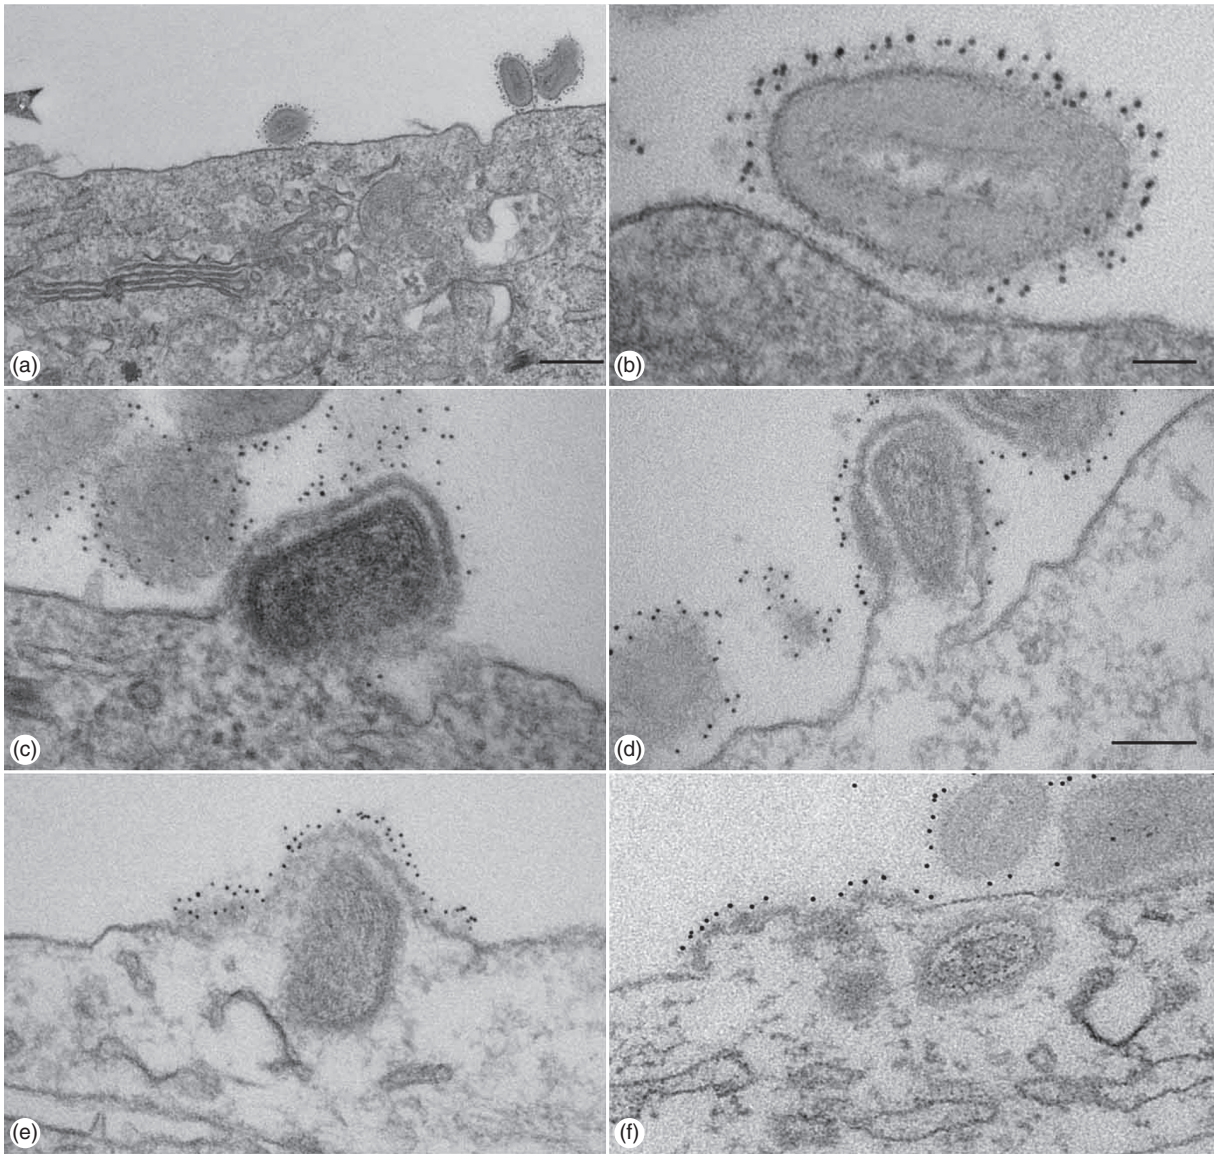

Figure 1 Electron micrographs showing the entry of VACV IMV by fusion at the cell surface. Purified VACV strain Western Reserve (WR) IMV (325 p.f.u./cell) was spinoculated onto PtK_2 cells to study the binding and entry of IMV, and samples were either retained on ice or incubated at 37 °C for 10 min. The IMV surface antigen D8 was labeled with D8-specific monoclonal antibody (mAb) for immunoelectron microscopy. Images show IMV particles bound to cells at 4 °C (a) and 37 °C (b), the IMV membrane fusing with the plasma membrane (c and d), the core entering into the cytosol (e), and the core leaving the site of entry (f). Scale = 200 nm (a), 50 nm (b), and 100 nm (d). Panels (c)–(f) are all shown at the same magnification. Reproduced from Carter GC, Law M, Hollinshead M, and Smith GL (2005) Entry of the vaccinia virus intracellular mature virion and its interactions with glycosaminoglycans. *Journal of General Virology* 86: 1279–1290, with permission from the Society for General Microbiology.

uncoated further and the genome is released for DNA replication. Once virus DNA replication has commenced, the pattern of transcription changes and intermediate genes are transcribed. Several intermediate genes encode late transcription factors needed for expression of late genes. Late genes encode the structural proteins that make up new virus particles, enzymes that may be packaged into these virions, and additional factors that influence the host response to infection. Host protein synthesis is shut off shortly after VACV infection, and this is mediated by the D10 protein, which removes the methylated cap structure of mRNAs. Virus and host mRNAs are both cleaved, and, since the former are more abundant, virus protein synthesis predominates.

DNA Replication

Virus DNA replication takes place in cytoplasmic factories from which most cellular organelles are excluded. The virus genome encodes many of the factors and

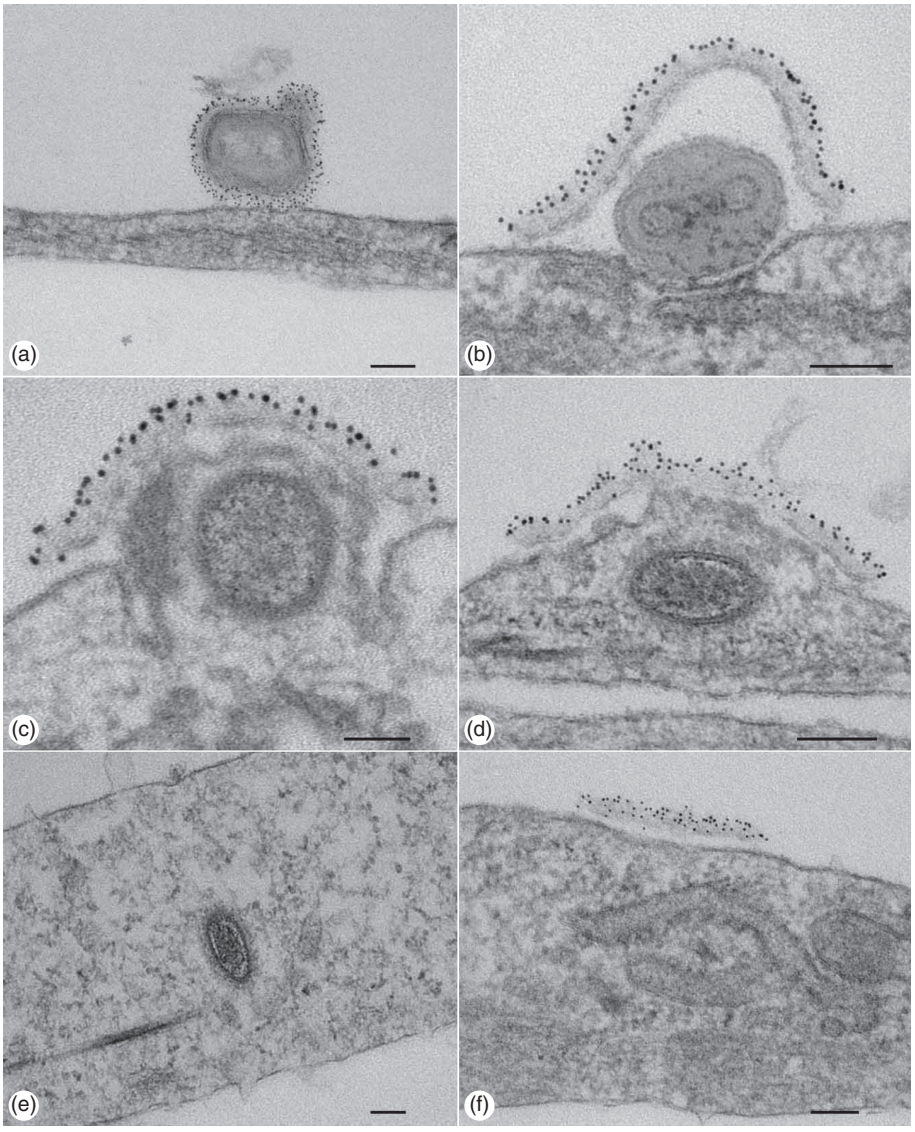

Figure 2 Electron micrographs showing the entry of EEV into cells by ligand-induced nonfusogenic dissolution of the EEV outer envelope followed by fusion of the IMV with the plasma membrane as in **Figure 1**. Fresh EEV of VACV strain WR was spinoculated onto PtK2 cells at 4 °C (a) and then incubated at 37 °C for 10 min (b–f). The EEV surface was labeled by rat anti-B5 monoclonal antibody (mAb) 19C2 (10), then by rabbit anti-rat IgG followed by 6 nm protein A–gold conjugate, and the samples were processed for electron microscopy. Scale = 100 nm (for all panels). Reproduced from Law M, Carter GC, Roberts KL, Hollinshead M, and Smith GL (2006) Ligand-induced and nonfusogenic dissolution of a viral membrane. *Proceedings of the National Academy of Sciences, USA* 103: 5989–5994, with permission from the National Academy of Sciences, USA.

enzymes needed for DNA replication, such as a DNA polymerase, nucleoside phosphohydrolase, a single-stranded DNA-binding protein, a processivity factor, and a protein kinase. In addition, the virus encodes a topoisomerase and DNA ligase, although the latter is (surprisingly) not essential for virus replication. DNA replication starts by the introduction of a nick into one DNA strand near the terminal hairpin loop. This enables the loop to unfold and serve as a template for DNA synthesis. After elongation to the end of the unfolded hairpin, the nascent and parent DNA strands separate, refold to create the hairpin, and thereby enable DNA replication to continue down the dsDNA genome by strand displacement. On reaching the distal end of the genome, the polymerase elongates round the hairpin and along the opposite DNA strand to produce concatemeric DNA molecules of greater than unit length. These are resolved into unit-length monomers by introduction of specific nicks near the terminal hairpins followed by re-ligation. Up to 10 000 copies of the virus genome may be produced from each infected cell, but only a fraction of these may be packaged into new virus particles.

Assembly

Virus assembly occurs in cytoplasmic factories in which the first visible structures are crescent shaped and are composed of virus protein and host lipid (**Figure 3**). The available evidence favors a model in which these structures contain a single lipid bilayer covered by a protein layer. The surface layer contains the D13 protein, which is essential for morphogenesis. Viruses lacking the D13 protein, or treated with the drug rifampicin, fail to form crescents. The D13 protein forms trimers that assemble into a lattice, or sheet, which appears to stabilize the formation of a nascent membrane. The crescents then grow into complete ovals or spheres into which the virus genome is packaged before the immature virion is sealed. Proteolytic cleavage of some of the capsid proteins and condensation of the virus core lead to the formation of an infectious IMV.

Most IMV particles remain within the cell until it lyses, but some are transported on microtubules to near the microtubule organizing center where they are wrapped by a double membrane (derived from either the *trans*-Golgi network or endosomes) that has been modified by the inclusion of several virus proteins (mostly glycosylated). The wrapping process produces a virion with three membranes that is called intracellular enveloped virus (IEV) (or wrapped virus (WV), using the nomenclature adopted recently by some authors), which is transported on microtubules to the cell surface. Upon reaching the cell periphery, the virus outer membrane fuses with the plasma membrane to externalize the virion by exocytosis. This surface virion is called cell-associated enveloped virus (CEV) and is surrounded by two membranes. CEV induces the formation of actin tails from beneath the plasma membrane where the CEV sits, and growth of these tails propels the virion away from the cell and into surrounding cells. VACV mutants unable to synthesize actin tails form small plaques, indicating the importance of this mechanism for cell-to-cell spread of virus. Alternatively, virions exposed on the cell surface may be released as EEV.

EEV are important for long-range spread of virus infection in cell culture and *in vivo*. The ability to spread in this way is conveniently studied by the comet assay, in which virus plaques are allowed to form on cell monolayers in liquid culture medium. Under these conditions, EEV particles spread from the original plaque in a unidirectional manner (caused by convection currents), giving rise to a comet-shaped plaque in which the primary plaque represents the head and secondary plaques form the tail. Antibodies directed against the EEV surface, but not IMV, inhibit comet formation. EEV particles not only are important for virus spread *in vivo* but are also important targets for antibodies that protect against OPV-induced disease.

The release of EEV from the cell surface or the retention of CEV is influenced by not only the cell type and virus proteins, primarily the A34 protein, but also the B5 and A33 EEV-specific envelope glycoproteins.

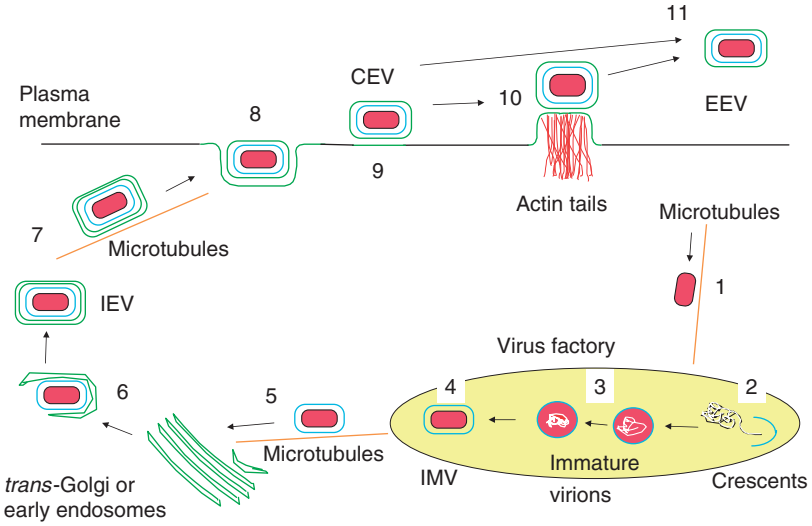

Figure 3 Schematic presentation of VACV morphogenesis. 1. After VACV entry, the virus core is transported on microtubules to a site near the nucleus where a virus factory develops. 2. A virus crescent forms and becomes associated with virus DNA associated with core proteins. 3. The virus membrane is sealed to form immature virions, which undergo condensation associated with proteolytic cleavage of several capsid proteins to form IMV (4). 5. IMV is transported on microtubules. 6. IMV is wrapped by modified membranes derived from the *trans*-Golgi network or endosomes to form intracellular enveloped virus (IEV). 7. IEV is transported on microtubules to the cell periphery. 8. IEV fuses with the plasma membrane to expose a cell-associated enveloped virus (CEV) on the cell surface by exocytosis. 9. CEV on the cell surface may induce the formation of actin tails (10) or dissociate from the cell to form EEV. 11. EEV may be formed by release of CEV from the cell surface before or after formation of actin tails. Virulence

VACV virulence and the mechanisms by which infection leads to disease (pathogenesis) have been studied in several animal models. The validity of any single model is uncertain because the natural host of VACV is unknown, but mice have been used most often and have been infected by dermal scarification or intranasal, intradermal, intraperitoneal, intracranial, or intravenous routes. The intranasal or intradermal routes are considered more physiologically relevant and have been used widely. Following intradermal infection, the virus causes a localized mild disease characterized by the formation of a lesion that heals in about 2 weeks. Virus does not spread from the site of infection and animals remain healthy. The intranasal model causes a more systemic illness in which the animals lose weight and the virus may spread to other tissues. The outcome of infection is influenced by the dose and strain of virus administered.

Many VACV proteins have been reported to affect the outcome of infection in one model or another. These proteins may be grouped into three types. The first group comprises enzymes (such as thymidine kinase, thymidylate kinase, and ribonucleotide reductase) that synthesize nucleoside precursors, or enzymes involved in DNA metabolism (e.g., DNA ligase). The second group comprises proteins that affect virus transport, release, and cell-to-cell spread. These include intracellular proteins F12 and A36, and the EEV proteins F13, A33, A34, and B5. The third and largest group comprises proteins that interfere with the host response to infection, which have been called immunomodulators.

VACV immunomodulators are numerous and target many aspects of the host immune system. They may be subdivided into those proteins that act within the infected cell and those that are secreted and act extracellularly. Intracellular proteins inhibit signaling pathways, such as those leading from Toll-like receptors (TLRs) or receptors for interleukins (ILs), tumor necrosis factor (TNF), or IFNs to the production of pro-inflammatory cytokines or IFNs. Such proteins include A46, A52, K1, M2, and N1. Other intracellular proteins (B13, F1, and N1) may block apoptosis, and yet others (K3 and E3) block the action of IFN-induced antiviral proteins. One intracellular protein contributes to virulence by synthesizing steroid hormones (A44). Extracellular proteins bind to complement factors (VCP), type I and type II IFNs (B8 and B18), cytokines IL-1β, IL-18, and TNF-α (B15, C12, and CrmC), and CC chemokines (vCKBP, B7, and A41). These VACV proteins function either by preventing soluble factors binding to their natural receptors on cells, or by preventing the establishment of chemokine concentration gradients, thereby diminishing the host response to infection. Collectively, these immunomodulatory proteins provide a substantial defense against the innate immune system. The contribution of individual proteins to virus virulence has been studied by using mutants lacking specific genes in several mouse models of infection. Loss of specific genes can either diminish, enhance, or have no effect on virulence, and the outcome can vary depending on the model of infection used.

The degree of virus attenuation derived from loss of proteins involved in virus transport and spread is in general much greater than that derived from removal of immunomodulators or enzymes synthesizing nucleoside triphosphate precursors.

Host Range

VACV infects a very broad range of cultured cells and only a few cell types, such as Chinese hamster ovary (CHO) cells, are nonpermissive. VACV also infects a broad range of host species, rather like CPXV and unlike the narrow host range of VARV and CMLV.

VACV Expression Vectors

VACV was developed as an expression vector in 1982. Since that time, this expression system has been refined to synthesize proteins in significant quantities in mammalian cells, and is employed widely as a laboratory tool by immunologists, virologists, and cell and molecular biologists. Recombinant VACV strains have been proposed as live vaccines for infectious diseases and cancer, and as oncolytic tools to target human cancers. The widespread use of VACV-based therapies has been hampered by their imperfect safety record. Therefore, attenuated strains are being utilized and engineered to improve immunogenicity by removal or modification of immunomodulatory proteins.

Antiviral Drugs

During the last 5 years, there has been a concerted effort to develop drugs against OPVs due to concerns about the possible use of VARV in bioterrorism. Given the highly conserved nature of OPV replication, the targets for these drugs are mostly conserved between OPVs and work against both VARV and VACV. Two particularly encouraging drugs are cidofovir (and acylated derivatives thereof) and ST-246. The former is a licensed drug for treating human cytomegalovirus infection and the latter is a new compound that targets morphogenesis by blocking formation of IEV particles by inhibiting wrapping of IMVs.

Immune Response to Vaccination

VACV infection in man and animals induces a robust antibody and T-cell response. It is clear that both are important in protection against VACV-induced disease,

and a T-cell response is essential for recovery from infection. The latter was evident historically from the life-threatening infections caused by vaccination of children suffering from T-cell immunodeficiency. The exact correlates of protection against smallpox are unknown, not least because smallpox was eradicated before much of modern immunology was developed. However, recent vaccination programs to defend against the perceived threat of bioterrorism with VARV have prompted detailed studies of the immune responses induced by VACV strains that protected against smallpox. These studies showed that both antibody and T-cell responses are very long-lived in humans (many decades) and that antibody responses were induced against a wide range of antigens. Several proteins on the surface of IMV are targets for neutralizing antibodies (including A27, D8, and H3), whereas the only antigen on the EEV surface that is a target for neutralizing antibody, in the absence of complement, is B5. B5 is therefore an important component of vaccines against OPV diseases, including smallpox. It is notable that one of the attenuated vaccines proposed as a safer vaccine against smallpox (LC16m8) lacks the B5 antigen.

Future Perspectives

VACV remains the only vaccine to have eradicated a human disease, smallpox. Despite the eradication of this disease 30 years ago, there remain many good reasons to continue to study VACV today. The ongoing development of this virus as a vaccine for infectious disease and cancer remains central, and its wide range of immunomodulatory proteins for interference with the innate immune system make it an excellent model for studying interactions between viruses and their host.

Varicella-Zoster Virus: General Features

J I Cohen, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Glossary

Acantholysis Breakdown of a cell layer in the epidermis by separation of individual epidermal keratinocytes from their neighbors.
Dysesthesia Distortion of any sense, especially touch.

History

Descriptions of vesicular rashes characteristic of chickenpox (varicella) date back to the ninth century. In 1875, Steiner showed that chickenpox was an infectious agent by transmitting the disease from chickenpox vesicle fluid to previously uninfected people. Shingles (zoster) has

been recognized since ancient times. In 1909, Von Bokay suggested that chickenpox and shingles were related infections, an idea that was confirmed experimentally in the 1920s and 1930s when children inoculated with fluid from zoster vesicles were shown to contract chickenpox. In 1943, Garland suggested that zoster was due to reactivation of varicella virus that remains latent in sensory nerve ganglia, and, in 1954, Hope–Simpson reaffirmed this hypothesis.

The viral agents of varicella and zoster were first cultivated by Weller in 1952 and shown on morphologic, cytopathic, and serologic criteria to be identical. In 1984, Straus and colleagues showed that viruses isolated during sequential episodes of chickenpox and zoster from the same patient had identical restriction endonuclease patterns, proving the concept of prolonged latent carriage of the virus. In 1983, Gilden showed that varicella-zoster virus (VZV) DNA is latent in human sensory ganglia and, Hyman and colleagues showed that VZV RNA is present in human trigeminal ganglia. In 1974, Takahashi developed a live attenuated VZV vaccine for prevention of varicella, and, in 2005, Oxman and colleagues showed that a high potency formulation of this vaccine is effective in reducing rates of zoster and postherpetic neuralgia.

Taxonomy and Classification

VZV (species *Human herpesvirus 3*) is a member of genus *Varicellovirus* in subfamuly *Alphaherpesvirus* of the family *Herpesviridae*. Other alphaherpesviruses that infect humans include herpes simplex viruses 1 and 2 (HSV-1 and HSV-2), and, rarely, B virus (a macaque herpesvirus). All of these agents exhibit relatively short replicative cycles, destroy the infected cell, and establish latent infection in sensory ganglia.

Simian varicella virus (SVV) is the most closely related, well-characterized virus to VZV. Natural infection with SVV can cause a varicella-like illness in Old World monkeys; the virus establishes latency in trigeminal ganglia, and can spontaneously reactivate to cause a rash that can transmit the virus to naive animals. The complete sequence of SVV has been determined and the virus shares nearly an identical set of genes with VZV. SVV is not known to infect humans.

Geographic and Seasonal Distribution

Varicella and zoster infections occur worldwide. Over 90% of varicella occurs during childhood in industrialized countries located in the temperate zone, but infection is commonly delayed until adulthood in tropical regions. Zoster may occur less frequently in tropical areas, because of later acquisition of primary infection. Varicella infection is epidemic each winter and spring, while zoster occurs throughout the year, without a seasonal preference.

Host Range and Virus Propagation

The reservoir for VZV is limited to humans. The virus inherently grows poorly in nonhuman animals or cell lines. Myers and colleagues, however, developed a guinea pig animal model of VZV infection by adapting the virus for growth in guinea pig embryo cells *in vitro*. Inoculation of animals results in a self-limited viremic infection and the emergence of both humoral and cellular immunity. Latent VZV DNA has been demonstrated in dorsal root and trigeminal ganglia. Rats, cotton rats, and mice inoculated with VZV develop latent infection of dorsal root ganglia. Inoculation of VZV into fetal thymus–liver implants in severe combined immune deficiency (SCID) mice results in virus replication in T cells; inoculation of virus into subcutaneous fetal skin implants reproduces many of the histopathologic features of varicella. Intravenous inoculation of SCID mice with VZV-infected human T cells results in virus infection of human skin xenografts.

An alternative, but less ideal, animal model involves the common marmoset (*Callithrix jacchus*). VZV replicates in the lungs with a mild pneumonia and a subsequent humoral immune response. Inoculation of chimpanzees with VZV results in a transient rash containing viral DNA and evokes a modest humoral immune response. None of these animal models have, as yet, reproduced the disease pattern seen in humans, namely a vesicular rash and spontaneous reactivation from latency.

VZV is usually cultured in human fetal diploid lung cells in clinical laboratories. The virus has been cultivated in numerous other human cells including melanoma cells, primary human thyroid cells, astrocytes, Schwann cells, and neurons, and can be grown in some simian cells including primary African green monkey kidney cells and Vero cells, and in guinea pig embryo fibroblasts.

VZV is extremely cell associated. The titer of virus released into the cell culture supernatant is very low, and preparation of cell-free virus, by sonication or freeze–thawing cells, usually results in a marked drop in viral titer. Therefore, virus propagation is usually performed by passage of infected cells onto uninfected cell monolayers. VZV is detected by its cytopathic effect with refractile rounded cells that gradually detach from the monolayer, or by staining with fluorescein-labeled antibody.

Genetics

Several markers can be used to distinguish different strains of the virus. These include temperature sensitivity, plaque size, antiviral sensitivity, and restriction

endonuclease cleavage patterns. The molecular basis for most of these strain differences is unknown, but viruses that are resistant to acyclovir usually have mutations in their thymidine kinase gene; other resistant strains have mutations in the DNA polymerase gene.

The genome of the prototypical laboratory strain VZV Dumas consists of 124 884 bp. The identification of many viral genes was made by analogy to HSV-1 genes with similar sequences and by genetic-complementation studies in which cell lines expressing selected VZV proteins were used to support the growth of HSV-1 mutants. Cosmids and bacterial artificial chromosomes (BACs) derived from VZV have been developed to allow targeted deletion, insertion, or site-directed point mutations in individual viral gene products. Using these systems, 22 viral genes have been shown to be dispensable, and 5 genes have been shown to be required, for virus replication *in vitro*. Recombinant VZV containing Epstein–Barr virus (EBV), hepatitis B virus, HIV, or HSV genes have been constructed.

Evolution

Comparison of the nucleotide and predicted amino acid sequences of VZV with HSV-1 and HSV-2 indicates that these viruses originated from a common ancestor. They share similar gene arrangements and only five genes of VZV do not appear to have HSV counterparts.

VZV is more distantly related to all other human herpesviruses, but many of the nonstructural proteins involved in viral replication have conserved elements and activities. Comparison of VZV, for example, with EBV shows that the majority of VZV genes are homologous with EBV. Three large blocks of genes are conserved, although rearranged within the two genomes.

VZV isolates have been classified into three different clades, corresponding to Japanese, European, and mosaic genotypes (combination of European and Japanese). Other investigators have proposed two clades: a Singapore/Japanese and a North American/European genotype.

Serologic Relationships and Variability

There is only one serotype of VZV. Antibodies detected by the complement-fixation test and virus-specific immunoglobulin M (IgM) antibodies decline rapidly after convalescence from varicella. Other, more sensitive serologic tests, including immune adherence hemagglutination (IAHA), fluorescence antibody to membrane antigen (FAMA), and enzyme-linked immunosorbent assay (ELISA), recognize antibodies that persist for life. VZV-specific antibodies are boosted by both recrudescent infection (zoster) and exposure to others with varicella.

Variability of VZV strains has been shown primarily by differences in restriction endonuclease patterns. Passage of individual strains *in vitro* eventually results in minor changes in restriction endonuclease patterns, predominantly through deletion or reiteration of small repeated elements scattered throughout the genome. Other than these sites, the genome sequence is remarkably stable. For example, the sequence of the thymidine kinase gene has been determined for several epidemiologically unrelated wild-type and acyclovir-resistant strains and found to possess >99% nucleotide and amino acid sequence identity.

Epidemiology

Varicella may occur after exposure of susceptible persons to chickenpox or herpes zoster. Over 95% of primary infections result in symptomatic chickenpox. Over 90% of individuals in temperate countries are infected with VZV before age 15.

Zoster is due to reactivation of VZV in patients who have had prior chickenpox; some of these patients may not recall the primary infection. Zoster is not clearly related to exposure to chickenpox or to other cases of zoster. About 10–20% of individuals ultimately develop herpes zoster – the risk of which rises steadily with age (**Figure 1**). Severely immunocompromised patients, such as those with the acquired immunodeficiency syndrome (AIDS), have a particularly high incidence of zoster. Recurrent zoster is uncommon; less than 4% of patients experience a second episode. Asymptomatic viremia has been detected in bone marrow transplant recipients and has been followed by recovery of cell-mediated immunity.

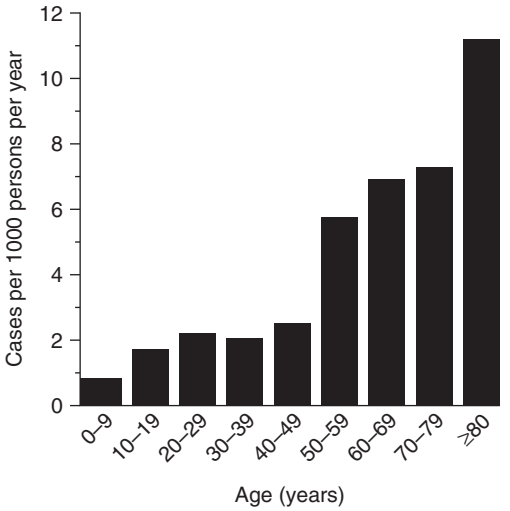

Figure 1 Incidence of herpes zoster. Reproduced from Kost RG and Straus SE (1996) Postherpetic neuralgia – pathogenesis, treatment, and prevention. *New England Journal of Medicine* 335: 32–42, with permission from Massachusetts Medical Society.

Transmission and Tissue Tropism

VZV is transmitted by the respiratory route. VZV has been detected by polymerase chain reaction (PCR) in room air from patients with varicella or zoster. Intimate, rather than casual, contact is important for transmission. Chickenpox is highly contagious; about 60–90% of susceptible household contacts become infected. Herpes zoster is less contagious than chickenpox. Only 20–30% of susceptible contacts develop varicella. Patients with varicella are infectious from two days before the onset of the rash until all the lesions have crusted.

Primary infection with VZV results in viral replication in the upper respiratory tract and oropharynx with lesions present on the respiratory mucosa. T cells subsequently becomes infected and transmit virus to the skin. Virus has been detected by PCR in the oropharynx and virus has been cultured from the blood early during varicella. Virus infection of epidermal cells in the skin is thought to be initially limited by interferon; later T cells trafficking in the skin may become infected and disseminate the virus to various organs throughout the body including the nervous system. During latency, VZV DNA can be detected in ganglia of the cranial nerves (e.g., trigeminal ganglia), dorsal roots (e.g., thoracic and trigeminal ganglia), and autonomic nervous system (e.g., celiac and vagus nerve) by PCR. Using *in situ* hybridization, VZV has been detected predominantly, if not exclusively, in neurons. During latency, only 6 of the 70 known viral genes are expressed.

Zoster is due to reactivation of virus in the sensory ganglia. The factors leading to its reactivation are not known, but are associated with neural injury and cellular immune impairment. Reactivated virus spreads down the sensory nerve to the skin, where the resulting vesicles are typically confined to a single dermatome. Viremia and subsequent cutaneous or visceral dissemination of lesions may occur in zoster, especially in immunocompromised patients.

Pathogenicity

Passage of wild-type VZV in cell culture by Takahashi in 1974 led to attenuation of the virus and changes in its temperature sensitivity and infectivity for certain cell lines. The resulting Oka vaccine strain has nucleotide polymorphisms at 31 sites. Comparison of the complete nucleotide sequence of the Oka vaccine strain with its parental virus shows 42 nucleotide and 20 amino acid differences. Multiple nucleotide changes in several genes are responsible for attenuation of the vaccine for growth in skin. The Oka vaccine strain can be distinguished from wild-type strains by differences in restriction endonuclease patterns.

Clinical Features of Infection

The incubation period for chickenpox is 2 weeks, with a range of 10–21 days. The disease begins with fever and malaise, followed by a generalized vesicular rash (**Figure 2(b)**). Lesions tend to appear first on the head and trunk and then spread to the extremities. New lesions usually follow viremic waves for 3–5 days and, in the normal host, most lesions are crusted and healed by 2 weeks. Lesions in different stages coexist in an individual. The disease is usually self-limited in the normal host.

Complications of varicella are more common in neonates, children with malnutrition, immunocompromised patients (e.g., malignancy or immunosuppressive therapy), pregnant women, and older adults. These complications include bacterial superinfection of the skin, pneumonia, hepatitis, encephalitis, thrombocytopenia, and purpura fulminans. Reye syndrome occurs in rare children who take aspirin to treat varicella fevers. Prior to the widespread use of the varicella vaccine in the USA, there were about 3–4 million cases of varicella each year with about 100 deaths; however, the number of cases has dropped sharply and death from varicella in the USA is very rare.

Zoster usually presents with pain and dysesthesias 1–4 days before the onset of the vesicular rash. The rash is usually painful and confined to a single dermatome (**Figure 2(c)**), but may involve several adjacent dermatomes. Fever and malaise often accompany the rash. Vesicles often are pustular by day 4 and become crusted by day 10 in the normal host.

Postherpetic neuralgia (PHN), manifested by pain lasting for weeks to several years in the area of the initial rash, is the most common and disconcerting complication of zoster in the normal host. Less common complications include encephalitis, myelitis, the Ramsay–Hunt syndrome (lesions in the ear canal, with auditory and facial nerve involvement), ophthalmoplegia, facial weakness, and pneumonitis. Immunocompromised patients with zoster are more likely to develop disseminated disease (**Figure 2(d)**) with neurologic, ocular, or visceral involvement. Patients with AIDS have a high frequency of zoster and may develop recurrent or chronic disease with verrucous, hyperkeratotic skin lesions.

Pathology and Histology

Varicella lesions are readily recognized in the skin and mucous membranes. However, similar lesions also occur in the mucosa of the respiratory and gastrointestinal tracts, liver, spleen, and any tissue, and remain unrecognized except in severe cases. With severe disease, there is inflammatory infiltration of the small vessels of most organs. Zoster causes inflammation and necrosis of the

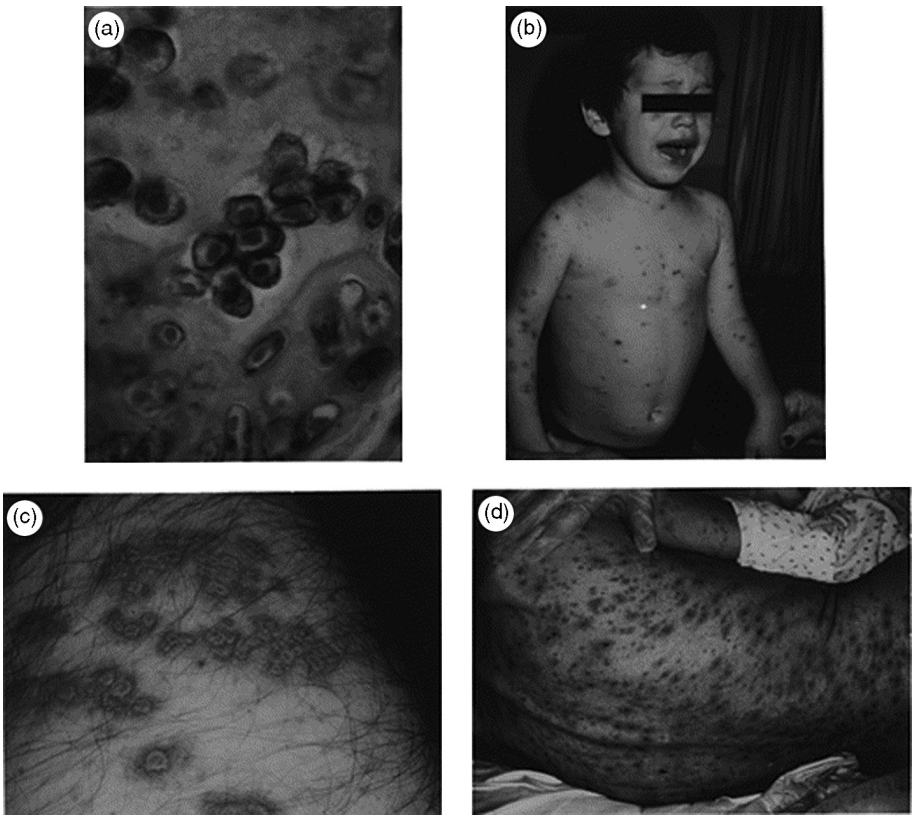

Figure 2 Histopathology and clinical findings of varicella-zoster virus infections. sensory ganglia and its nerves, and skin lesions that are histopathologically identical to those seen with varicella.

Cutaneous lesions due to VZV begin with infection of capillary endothelial cells followed by direct spread to epidermal epithelial cells. The epidermis becomes edematous with acantholysis and vesicle formation. Mononuclear cells infiltrate the small vessels of the dermis. Initially, vesicles contain clear fluid with cell-free virus, but later the vesicles become cloudy and contain neutrophils, macrophages, interferon, and other cellular and humoral components of the inflammatory response pathways. Subsequently, the vesicles dry leaving a crust that heals usually without scarring.

Cells infected with VZV show eosinophilic intranuclear inclusions with multinucleate giant cell formation (**Figure 2(a)**). These changes are not specific for VZV, as they are seen with HSV and cytomegalovirus infections.

Immune Response

Infection with VZV elicits both a humoral and cellular immune response. The ability of VZV immune globulin (VZIG) to attenuate or prevent infection in exposed children (see the next section) indicates that virus-specific antibody is important in protection from primary infection. The presence of VZV-specific immunoglobulin G (IgG) does not correlate, however, with protection from zoster. Antibody to VZV is often present by the time the rash of varicella first appears. Virus-specific IgM, IgG, and IgA are present within 5 days of symptomatic disease; however, only IgG persists for life. Antibodies to viral glycoproteins gE, gB, gH, and the immediate-early 62 protein (IE62) have been detected during acute infection, and the titers of antibodies to these proteins are boosted during recurrent infection. The mere presence of antibody to VZV glycoproteins in children with leukemia who had received live varicella vaccine is not adequate to prevent breakthrough varicella or zoster.

Cellular immune responses to VZV are more important in recovery from acute varicella infection and for prevention of, and recovery from, zoster. The level of cellular immunity correlates with disease severity during acute varicella. Cytotoxic T cells that lyse virus-infected cells are present by 2–3 days after the onset of the rash of varicella. Cell-mediated immunity, as measured by

lymphocyte proliferative response, is directed against cells expressing glycoproteins gE, gB, gH, gI, and gC, the IE4, IE62, and IE63 proteins, and other viral proteins. Interferon is present in VZV vesicles.

Most varicella infections result in lifelong immunity to reinfection. Second episodes of varicella are rare; these individuals tend to have reduced humoral and cellular immunity to VZV at the time of the second infection. Zoster is associated with a reduction in cellular immunity to VZV that, in the normal host, is partially restored in response to this recurrent infection. Recurrent zoster is uncommon, except in severely immune-deficient patients, such as those with AIDS.

Prevention and Control

Prevention of varicella can be achieved by restricting exposure or by resorting to either immunoglobulin prophylaxis or vaccination with live, attenuated virus. If given within 4 days of exposure to the virus, VZIG prevents or attenuates varicella in seronegative persons. The preparation has no effect in modifying zoster. VZIG is recommended for individuals (1) with recent, close contact to patients with varicella or zoster, (2) who are susceptible to varicella, and (3) who fall in a high-risk category. The latter include premature or certain newborn infants, pregnant women, and patients with congenital or acquired cellular immunodeficiencies. Supplies of VZIG are currently very limited in the USA and VariZIG, prepared from high-titer human immune serum, has replaced VZIG.

The live, attenuated varicella vaccine (Oka strain) was licensed in the USA in 1995 and is recommended for vaccination of healthy children and adults. Most children develop adequate humoral and cellular immunity to varicella after a single dose of vaccine; an additional dose enhances the degree of immunity and is recommended for susceptible children and adults. A rash may follow vaccination. It is usually mild, but can be severe if the vaccine is given to patients experiencing periods of profound cellular immune impairment. The live vaccine virus establishes neural latency and can reactivate. Thus, zoster has been reported in vaccinees, especially those who are immunocompromised, but the rate appears to be no higher than that following natural infection. Vaccination may be used for postexposure prophylaxis.

A high-titer formulation of the Oka vaccine virus was licensed in the USA in 2006. It reduced the frequency of zoster and PHN by 51% and 67%, respectively, in healthy persons $\geq$60 years old. The most common side effects were mild injection-site reactions; no significant severe adverse reactions were attributed to the vaccine.

Patients with varicella or zoster should be isolated from susceptible persons until all lesions have crusted. This is particularly important for hospital workers and immune-deficient patients.

Acyclovir and leukocyte interferon have been used in the treatment of varicella and zoster in immunocompromised patients. Interferon proved to be an inadequate and impractical therapy. Acyclovir is the current treatment of choice for selected infections. It results in a shorter duration of symptoms and decreased visceral dissemination of varicella or zoster in the immunocompromised host. Acyclovir also prevents spread of trigeminal zoster to the eye and modestly shortens the duration of varicella and zoster symptoms in the normal host. Analogs of acyclovir, such as famciclovir and valaciclovir, result in higher levels of antiviral activity than oral acyclovir and have been licensed for oral therapy of zoster in the USA. Acyclovir-resistant strains of VZV have been reported in patients with AIDS; these infections are best treated with foscarnet. Corticosteroids, when used early during zoster, reduce acute pain. Herpes zoster, particularly in elderly patients, may lead to prolonged and severe PHN. Treatment of PHN is difficult and often unsatisfactory, but many patients experience improvement with gabapentin, pregabalin, or tricyclic antidepressant drugs like amitriptyline.

Future Perspectives

Widespread vaccination of children with the attenuated, live varicella vaccine has reduced the incidence and severity of varicella. Use of a high-titer live varicella vaccine was shown to lower the incidence of zoster and postherpetic neuralgia in the elderly. Further research is needed into the mechanisms of VZV latency and reactivation as well as identification of which viral proteins are critical for protection from varicella and zoster. Since the live varicella vaccine can reactivate to cause zoster and since breakthrough cases of varicella continue to occur in vaccinated persons, further knowledge of VZV latency and immunity should lead to safer and more effective vaccines against varicella and herpes zoster.

Virion and Genome Structure

The Virion

The virion of varicella-zoster virus (VZV), like those of all herpesviruses, is enveloped and approximately spherical, with a diameter of 100–300 nm. A minimum of 30 proteins ranging in size from ~250 to 17 kDa have been identified as components of the virion. The viral double-stranded DNA genome is contained in an icosahedral nucleocapsid 100 nm in diameter that has 5:3:2 axial symmetry and is embedded within a structure known as the tegument. The tegument is composed of virus-encoded proteins, several of which are involved in expression of the viral genome (see below). The thickness of the tegument can vary, even within a single virion. The lipid envelope of the virus, which is derived from cellular membranes, surrounds the tegument and contains a minimum of eight viral glycoproteins.

The Genome

The VZV genome is a linear, double-stranded DNA molecule of *c.* 125 kbp with a G + C content of 46%. The genome consists of two covalently joined segments, the unique long (U_L) and unique short (U_S) regions, each bounded by a terminal and internal inverted repeat (TR_L/IR_L (88 bp) and TR_S/IR_S (7.3 kbp) respectively). The repeats allow structural rearrangements of the unique regions to occur during viral DNA replication and, as a result, encapsidated genomes exist as a mixture of four isomers. Two isomers are found predominantly in viral particles and are termed P (prototype) and I_S (inverted U_S). Two other isomers, which contain U_L inverted with respect to U_S in the P and I_S configurations, are designated I_L and I_{SL}. These represent 2–5% of the virion DNA. A small amount of full-length closed circular DNA (representing 0.1–5% of the total) has also been isolated from virions. The function of these molecules in relation to the viral life cycle remains unknown.

Analysis of the complete sequence of the VZV Dumas strain revealed the protein-coding potential of a total of 71 open reading frames (ORFs) that were named sequentially according to location in the genome (ORF1–ORF71, with ORF33.5 overlapping ORF33 and ORF62–ORF64 in IR_S duplicated as ORF69–ORF71 in TR_S). Two other genes (ORFS/L and ORF9A) were added subsequently. The genome map thus contains 71 unique genes, the first of which (ORFS/L) is located at the left end of the genome and the last (ORF68) at the right end of U_S, with ORF62–ORF64 in IR_S duplicated as ORF69–ORF71 in TR_S. The VZV ORFs encode proteins involved in regulation of viral gene expression, viral DNA replication, and regulation of nucleotide pools, and structural proteins including those required for DNA packaging and capsid assembly, as well as the viral glycoproteins (**Table 1**).

Understanding of the roles of the VZV gene products was long hampered owing to the highly cell-associated nature of the virus, which precluded plaque purification, and to the lack of a good animal model of VZV infection. The development of a cosmid transfection system and, more recently, a VZV bacterial artificial chromosome (BAC), coupled with a severe combined immunodeficiency (SCID) mouse/human (hu) xenograft model of pathogenesis, has resulted in considerable progress in the delineation of VZV gene function.

Productive Infection

Productive VZV infection begins with fusion of the virus envelope with the membrane of a susceptible cell. This occurs via interactions between one or more VZV

The predicted molecular weights are based on the sequence of the Dumas strain of VZV.

glycoproteins and as yet unidentified receptors on the cell surface. Upon entry and uncoating, the capsid is translocated to the nuclear membrane and the viral genome enters the nucleus, presumably through a nuclear pore. Viral tegument proteins also enter the nucleus, including several that regulate viral gene expression. Transcription and viral DNA replication are then believed to occur in a regulated temporal cascade, as is typical of all herpesviruses. Both viral and cellular proteins are involved in these processes. Progeny viral DNA molecules in the form of concatamers are presumably generated via a rolling-circle mechanism, and then cleaved and packaged into preassembled capsids. Tegument assembly is believed to occur at least in part in the nucleus. The infectious virion is believed to be formed following the de-envelopment/re-envelopment model currently extant for herpesvirus morphogenesis (see below). The virus grows slowly in tissue culture and is highly cell associated, and purified virions exhibit low levels of infectivity. The cell-associated nature of the virus has also led to speculation that, during infection of specific cell types, infectious spread occurs primarily via cell-to-cell fusion, whereas for other cell types intact cell-released virions are required.

Genome Replication

Replication of the VZV genome has not been subject to extensive biochemical analysis, primarily due to the difficulty in obtaining sufficient numbers of synchronously infected cells. Consideration of the relative proportions of the isomeric genome forms and the frequency of novel junctions in DNA isolated from virions and from infected cells have led to the following model. Upon entry into the nucleus, the viral genome circularizes and undergoes a limited number of rounds of bidirectional replication. This initiates at one or both copies of the origin of DNA replication (ori_S), which is located in TR_S and IR_S. The minimal ori_S sequence consists of a series of 16 AT repeats and an upstream consensus binding sequence (5′-CGTTCGCACTT-3′) for the origin-binding protein encoded by ORF51. During this phase, inversion of U_L and U_S is believed to occur via intramolecular recombination mediated by the inverted repeats. Replication then shifts to a rolling-circle mechanism, generating head-to-tail concatamers, and this phase accounts for the bulk of viral DNA synthesis. Finally, the newly synthesized DNA is cleaved into unit-length molecules and packaged into preassembled capsids in the nucleus. The unequal proportions of isomeric genome forms within particles are postulated to result from preferential cleavage of concatemers at the novel junction between TR_L and TR_S generated by the initial circularization event, rather than at the normal junction between IR_L and IR_S.

The full complement of viral and cellular proteins required for complete replication of the VZV genome has not yet been enumerated. However, orthologs of the seven genes required for origin-dependent replication of herpes simplex virus (HSV-1) DNA have been identified. These include the proteins encoded by ORF6, ORF16, ORF28, ORF29, ORF51, ORF52, and ORF55. ORF6, ORF55, and ORF52 encode the primase, helicase, and an accessory factor, respectively, which are believed to form a heterotrimeric complex by analogy with HSV-1. ORF28 encodes the catalytic subunit of the viral DNA polymerase and is the target of the antiviral drugs acyclovir and valacyclovir. ORF16 encodes the polymerase processivity factor that interacts directly with the catalytic subunit. The ORF29 protein is the major single-strand DNA-binding protein (SSB) and, as indicated above, the ORF51 protein binds to ori_S in a site-specific manner and also contains a helicase activity. Of these seven factors, only the DNA polymerase, the origin-binding protein, and SSB have been characterized at a biochemical level.

Overview of Gene Expression

Upon entry into the cell nucleus, the VZV genome is transcribed by the host cell's general transcription apparatus, including RNA polymerase II (RNA Pol II). By analogy with other alphaherpesviruses, the ORFs are believed to be expressed in three distinct kinetic classes: immediate early (IE), early (E), and late (L). However, clear evidence for this temporal cascade has been difficult to obtain owing to the low titers and cell-associated nature of VZV grown in tissue culture. Only three proteins have been shown to be expressed under IE conditions. These are IE4 (encoded by ORF4), IE62 (ORF62 and its counterpart in TRs, ORF71), and IE63 (ORF63 and its counterpart, ORF70) the latter two of which are expressed from ORF62 and ORF63 in IR_S (and their duplicates in TR_S, ORF70 and ORF71).

VZV promoters have been shown in general to be essentially quiescent in the absence of virus-encoded transcriptional activators. Several VZV-encoded proteins have been shown in transient transfection assays to be capable of transactivating or transrepressing specific viral promoters, promoters from heterologous virus families, and cellular promoters. These include the IE62, IE4, IE63, ORF10, and ORF61 proteins. However, IE62 is considered to be the primary viral transactivator during the lytic phase of VZV replication. It is known to activate expression of genes from all three putative kinetic classes of VZV genes and can act independently of all other viral factors. Efficient activation of VZV promoters by IE62 usually occurs via synergistic interactions between this viral protein and ubiquitous cellular transcription factors whose consensus binding sites are found within VZV promoters. Predominant among these factors are specificity factor-1 (Sp1) and upstream factor (USF), which are predicted to be involved in regulating the expression of over half of the viral genome. When other viral factors are present, they have been shown to be capable of modulating the level of IE62 activation, even in some cases where the promoter in question appeared responsive only to IE62.

Promoter Structure

Results from analysis of a small number of VZV promoters, and predictions of the positions of putative promoters, indicate they appear to be relatively typical RNA Pol II promoters with TATA-like elements and binding sites for ubiquitous cellular transcription factors upstream of the TATA elements. Due to the compact nature of the VZV genome, many promoters are predicted to lie completely or partially within the coding sequences of genes immediately upstream. VZV promoters are also characterized by the fact that the TATA elements required or predicted to be positioned correctly for expression are frequently atypical and therefore less likely to be bound with high affinity by the TATA-binding protein (TBP). Thus far, no TATA-less VZV promoters have been identified and no promoters showing dependence on the presence of an initiator element (INR) at or just downstream of the start site of transcription are known. This most likely reflects the fact that only a few promoters have been analyzed in detail at the functional level, rather than any specific absence of these alternatives.

Potential VZV promoters can be separated into three general categories: A, B, and C type. This classification is preliminary as it is based on a meager amount of functional data. A-type promoters contain only a TATA element. B-type promoters contain a TATA element and one or more functional upstream binding sites for ubiquitous cellular transcription factors with which IE62 can interact physically or functionally. Examples of such promoters are that for ORF67 (encoding a glycoprotein, gI) and the regulatory element controlling divergent expression of ORF28 (DNA polymerase) and ORF29 (SSB). C-type promoters contain a TATA element, binding sites for factors with which IE62 can interact, and binding sites for factors that function to activate the promoter independently of IE62. The only known example of this type of promoter is that driving expression of the gene (ORF62) that encodes IE62 itself. A fourth class of promoter, at this time hypothetical, is one that is activated in the absence of IE62 by cellular or other viral proteins.

IE Gene Expression

Examination of the putative promoter regions of the three IE genes reveals, as noted above, that only the promoter for ORF62 (and its duplicate, ORF71), which encode IE62, contains binding sites for the cellular factor Oct-1. The presence of the Oct-1 recognition sequence and the existence of ORF10, the ortholog of HSV-1 VP16, indicate that IE62 can be expressed via the same mechanism as the HSV-1 IE genes, whereas IE4 and IE63 might be expressed via mechanisms possibly novel to VZV. By analogy with the HSV-1 IE expression mechanism, ORF10 would interact with Oct-1 bound to the promoter and the cellular transcription factor host cell factor-1 (HCF-1) to activate IE62 expression (**Figure 1**). This does appear to be one mechanism by which IE62 is expressed, since the existence of Oct-1/ORF10/HCF-1 complexes interacting with the IE62 promoter has been demonstrated, and depletion of HCF-1 by small interfering RNA (SiRNA) significantly reduces ORF10-mediated transactivation of the IE62 core promoter.

IE62 has also been shown to regulate expression of its own promoter and, unlike HSV-1 ICP4, is capable of positive as well as negative regulation. An alternative pathway for initial expression of the three IE genes involves the direct action of IE62 that enters the infected

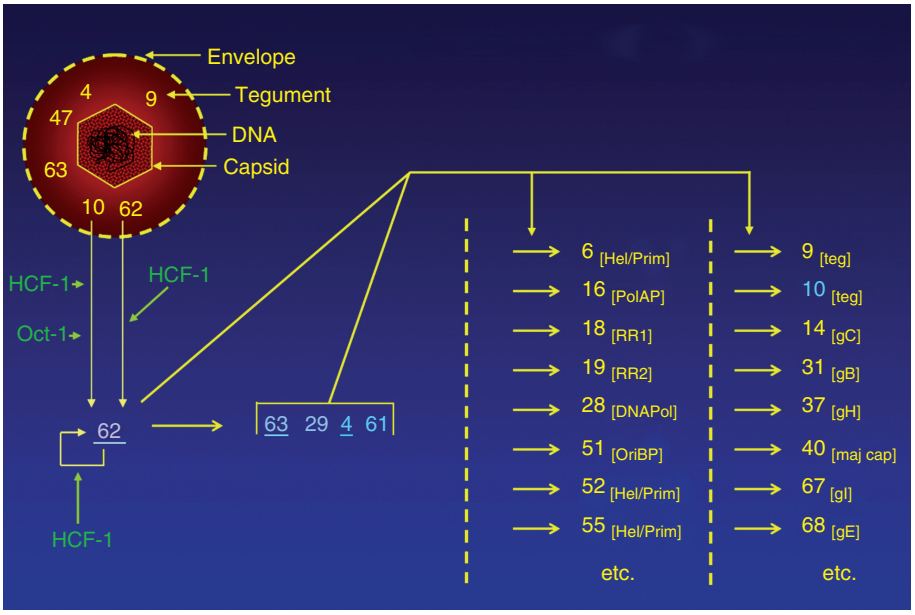

Figure 1 Schematic of the VZV virion and data on lytic phase gene expression. Numbers refer to the ORFs within the VZV genome. The IE genes are underlined. VZV genes whose protein products are known to be directly involved in viral gene expression are shown in blue. Cellular factors involved in IE gene expression are shown in green. Cellular factors such as Sp1 and USF known to be involved in non-IE gene expression are not shown. The vertical dashed lines delineate ORFs whose gene products are primarily involved in DNA replication and nucleotide metabolism or in the structure of the virion.

cell as part of the virion tegument. This pathway involves the cellular factor HCF-1, which has been shown to interact functionally with IE62. IE62 and HCF-1 cooperate in activating the IE62 promoter, resulting in a positive feedback loop allowing for efficient IE62 expression and IE62-mediated activation of the IE4 and IE63 promoters. This mechanism appears to be unique among the alphaherpesviruses to VZV.

Non-IE Gene Expression

Expression of the majority of VZV genes homologous to HSV-1 E and L genes is believed to be mediated primarily through the action of IE62 in conjunction with other viral proteins (the IE4, IE63, ORF61, and ORF29 proteins) and cellular factors. Information regarding expression of these genes is limited owing to the small number of promoters that have been analyzed. It is currently believed that IE62 is capable of transactivating the great majority of VZV promoters in the absence of other viral gene products. However, this rule is not hard and fast since the responsiveness to IE62 of promoters expressing structural proteins such as gI appears to be much less than that observed with IE promoters and the promoters controlling expression of DNA polymerase and SSB. Based on their ability to interact directly with IE62 and the frequent presence of their binding sites in VZV promoters, the ubiquitous cellular factors USF and Sp1 appear to play a significant role in IE62-mediated expression of VZV genes. They are believed to stabilize TBP binding, and both have been shown to interact directly with IE62. The roles of these transcription factors in IE62-mediated activation of specific VZV promoters have been validated in the SCID/hu mouse model of VZV pathogenesis.

These results represent only the beginnings of our understanding of the full spectrum of VZV gene regulation. As indicated above, IE4 and the ORF61 protein can also activate some non-IE promoters in the absence of IE62. Moreover, in the case of low levels of IE62 in the infected cell, expression of the ORF47 kinase and IE4 remains at essentially wild-type levels, in contrast to other known IE62-responsive genes, thus suggesting that there may be alternative non-IE62-mediated mechanisms for expression of some VZV genes. Other cellular transcription factors are also likely to be involved in VZV gene expression, including those in the CREB family (AP-1 and ATF-2). Finally, it is not known whether HCF-1 is required for activation of all IE62-responsive promoters, or whether this factor is important only for IE gene expression.

Protein Translation

Little is known about the details of translation in VZV-infected cells. It is assumed that mRNAs are translated in a fashion similar to that in HSV-1- and other alphaherpesvirus-infected cells, and that translation occurs on both free and membrane-bound polysomes.

Following translation, viral proteins are efficiently transported to specific cellular organelles (e.g., the nucleus and *trans*-Golgi network), where they perform their roles in viral replication and particle assembly. It has been shown recently that IE63 increases expression of the cellular factor EF-1α, which is involved in the initiation of translation. Thus, VZV infection may increase the efficiency of translation.

Post-Translational Processing

The most extensively studied post-translational processes involving VZV proteins are glycosylation and phosphorylation. Glycosylation is mediated by cellular genes, whereas phosphorylation involves the kinases encoded by ORF47 and ORF66, as well as cellular kinases. The VZV glycoproteins are all N-linked glycosylated and the majority show additional modifications such as O-linked glycosylation, sulfation, and phosphorylation. For example, gE contains both O-linked and N-linked glycans and is heavily sulfated and phosphorylated, with phosphorylation occurring at the level of both the polypeptide chain and glycosyl residues. The phosphorylated amino acids are serine and threonine but not tyrosine, and the enzymes involved are probably cellular casein kinases I and II. The enzyme responsible for phosphorylation of the complex oligosaccharides has not been identified, and roles for the specific phosphorylated or sulfated residues are unknown.

Viral proteins that are modified primarily by phosphorylation include the IE62, ORF61, and IE63 proteins. Phosphorylation of IE62 is known to involve the ORF66 and ORF47 kinases, as well as cellular kinases such as casein kinases I and II and protein kinase C. The function of the majority of these phosphorylation events is unknown, but phosphorylation by the ORF66 kinase plays a role in intracellular localization of IE62. Specifically, upon phosphorylation by the ORF66 kinase, IE62 is excluded from the infected cell nucleus, resulting in a diminution of viral gene expression and incorporation of IE62 into the virion particle. The ORF47 and ORF66 kinases also play roles in viral cell tropism and pathogenesis, since viruses lacking these functions are deficient for growth in human T cells and primary skin cells.

Assembly, Release, and Cytopathology

Models for assembly and release of VZV virions are derived from extensive electron microscopic studies and from analysis of the synthesis and trafficking of VZV glycoproteins in infected cells. However, no consensus model exists. Fully assembled capsids containing unit-length genomes representative of all four possible isomeric forms appear to be released from the nucleus, having acquired a portion of the tegument and a lipid coat from the nuclear lamella. These particles are then deenveloped and bud into the Golgi apparatus, where additional tegument proteins are acquired. The mature viral envelope derived from Golgi membranes and containing the fully processed viral glycoproteins is then added. The particles are either released from the cell by fusion of virus-containing vesicles with the plasma membrane or of vesicles containing enveloped particles with lysosomes, in which case complete or partial degradation of the virions may take place. The involvement of lysosomes is proposed to rest on their mannose-6-phosphate receptors, which are capable of binding this sugar present on the surface of VZV particles. This process does not occur in the skin of the human host since the cells in the superficial layers of the skin lack lysosomal vesicles. This may explain why virus isolated from vesicle fluid is more infectious than that obtained in tissue culture and why it exhibits a higher and more stable titer.

In tissue culture, cells infected with VZV initially show increased refractility followed by rounding and swelling. Multinucleated cells are observed late in infection, although the extent of syncytium formation is cell type dependent and usually is less than that seen with syncytial HSV-1 strains. The infected cells eventually detach from the support surface. The nuclei of infected cells are larger than those of uninfected cells, with marginally located chromatin and peripherally located nucleoli.

Gene Expression during Latency

There is evidence that, during VZV latency, a small number of lytic genes are expressed at both the RNA and protein levels. These include ORF4, ORF21, ORF29, ORF62, and ORF66. These proteins play unknown roles during latency, and are made even more intriguing in that they are localized primarily in the cytoplasm rather than the nucleus. The relative frequencies of detection of expression of these genes varies considerably, with the two most frequently detected being the products of ORF63 (IE63) and ORF29 (SSB). Therefore, the promoters regulating expression of these two genes appear to be the best candidates in which to find clues relating to the mechanisms of latent gene expression.

The putative IE63 promoter borders on ori_S, which is present in TR_S and IR_S. Little work has been published concerning the promoter-regulating expression of IE63. A putative TATA element has been identified by computer analysis 28 nt upstream from the transcriptional start site, as have several potential binding sites for Sp1 and CAAT. None of these elements has yet been authenticated by site-specific mutation.

More information is available concerning expression of ORF29. The promoter lies within an intergenic region situated between the divergently oriented ORF28 and ORF29 protein-coding regions, and shares a required USF site with the ORF28 promoter. ORF28 and ORF29 can be expressed either coordinately or independently, and the observed expression of only ORF29 during latency may involve neuron-specific cellular factors that recognize sequences within the ORF29 promoter and lead to its activation.

An alternative regulatory mechanism could involve variations in the chromatin structures of the promoter regions of the latently expressed genes. Like the HSV-1 genome, the VZV genome is episomal during latency and is likely to be bound by histones. This raises the possibility that, during latency, the promoters and coding regions of the putative latency-associated genes, particularly ORF63 and ORF29, could be histone-free (euchromatic) and non-repressed. How and why these specific regulatory elements could be singled out remains to be established.

HCF-1 may also play a role in reactivation of VZV from latency. In contrast to the situation in other tissues, HCF-1 is not detected in the nuclei of sensory ganglia but rather in the cytoplasm. However, experimental conditions that induce reactivation of HSV-1 result in rapid nuclear localization of HCF-1. Thus, redistribution of HCF-1 may trigger expression of IE62, ultimately resulting in the production of infectious virus.

Subjects for Future Investigation

Molecular Mechanism of Vaccine Attenuation

The live-attenuated vaccine for prevention of varicella has been in use in Japan for over two decades and was approved for use in the USA in 1995, where coverage is now approaching 95% of the susceptible pediatric population. This vaccine has also recently been shown to be efficacious for the prevention of zoster and for mitigation of postherpetic neuralgia. This being said, the vaccine represents a mixture of strains and retains the capacity to establish a latent infection and reactivate. Moreover, the molecular mechanism of attenuation remains unknown. A large number of mutations are present in vaccine virus IE62, but it is clear that the cause of attenuation extends beyond IE62 and is multifactorial. An important area of future study would involve definition of the mechanism of attenuation and production of a better characterized, and therefore safer, second-generation vaccine.

Molecular Basis of Post-Herpetic Neuralgia

One of the problems facing the current aging population in the USA and the rest of the world is the morbidity associated with post-herpetic neuralgia resulting from episodes of zoster. Nothing is known about the roles that viral genes play in this process. Investigation of the effects of specific VZV proteins on the expression or elaboration of neuropeptides and neuronal processes will be important in elucidating the molecular mechanisms responsible for post-herpetic neuralgia. This may aid the development of drugs specific for amelioration of this syndrome. Particular focus would be appropriate on the IE63 and ORF29 proteins, which have been detected in human ganglia.

VZV and Cellular Processes

There is now a considerable and continuously expanding body of information concerning the interaction of various VZV gene products with host cell components. Furthermore, recently reported gene array analyses indicate that the expression of numerous cellular genes is affected during infection. However, little information is available on the specific VZV factors involved in these changes and in what ways these changes are important for infection and pathogenesis. VZV-induced alteration of host cell function is known to differ to some extent from that observed with HSV-1, since VZV infection, unlike HSV-1 infection, inhibits the cellular nuclear factor kappa B (NFκB) pathway. Examination of these questions at the molecular level in the context of the various cell types infected by VZV will reveal important information, which will not only provide insights into VZV infection but also into fundamental cellular processes.

Glossary

Big-vein disease of lettuce A lettuce disease that is characterized by abnormal dilation or enlargement of a vein or artery in a lettuce leaf, decreasing market value and reducing the proportion of marketable lettuce plants. The name 'big-vein disease' refers to the appearance of the major symptoms.
L protein A main subunit of the polymerase complex, responsible for most of the functions required for transcription and replication: RNA-dependent RNA polymerase, mRNA 5′ capping, 3′ poly(A) synthesis, and protein kinase activities.
Olpidium brassicae An obligate parasitic root-infecting fungus and a member of the *Chytridiomycetes* that seldom appears to be deleterious to the host plants but acts as vector of plant viruses.
Stop-and-start model A model for RNA synthesis of nonsegmented negative-sense RNA viruses that the viral polymerase complex transcribes a gene, polyadenylates and releases mRNA, and reinitiates transcription of the next gene under the direction of the gene-junction sequence.

History

Big-vein disease of lettuce (*Lactuca sativa* L.) was first reported in 1934. The causal agent was postulated to be a root-infecting virus, but the virus particles remained unidentified for more than half a century. In 1983, a rod-shaped virus was found in field-grown lettuce showing big-vein symptoms. Because the rod-shaped virus is always associated with big-vein-affected lettuce, it was regarded as the agent that induced big-vein disease, although this virus alone had not been shown to actually induce big-vein symptoms in lettuce. The rod-shaped virus was named *Lettuce big-vein virus* and was classified as the type species of the genus *Varicosavirus*, which had been established by the International Committee on the Taxonomy of Viruses (ICTV) in 2000.

Since 2000, however, a second virus assigned to the genus *Ophiovirus* and named mirafiori lettuce virus (MiLV; also referred to as mirafiori lettuce big-vein virus), has been consistently isolated by various researchers from field-grown lettuce showing big-vein symptoms. Mechanical inoculation of partially purified MiLV preparations and transmission experiments using MiLV- or lettuce big-vein associated virus (LBVaV)-carrying fungal vectors independently (and conclusively) showed that MiLV, but not LBVaV, is the causal agent of big-vein disease. Therefore, lettuce big-vein virus was renamed lettuce big-vein associated virus by ICTV in 2005. However, the etiology of big-vein disease is still not fully understood, because big-vein affected plants serologically negative for MiLV but positive for LBVaV were reported in a field experiment in Italy. A transgenic line carrying the coat protein (CP) gene of LBVaV in antisense orientation showed resistance both to LBVaV infection and to MiLV infection, and was thus resistant to big-vein disease.

Stunt disease of tobacco (*Nicotiana tabacum* L.) reported only from Japan was first recorded in 1931 as a seed-bed disorder. Stunt disease seriously damaged tobacco leaf production in Japan until the 1960s, when the disease was found to be transmitted by an obligate parasitic soil-borne fungus, and tobacco growers paid more attention to tobacco

seed-bed sanitation. Because tobacco with stunt symptoms invariably has a varicosavirus and inoculation of tobacco seedlings with partially purified virion preparation produces typical tobacco stunting, the virus is regarded as the causal agent of tobacco stunt disease. Because of marked differences in the host reaction between the varicosavirus and LBVaV, the virus was initially considered to be a distinct species, rather than a strain of LBVaV, and named tobacco stunt virus (TStV). LBVaV and TStV are serologically indistinguishable and a recent comparison of nucleotide and amino acid sequences for LBVaV and TStV confirmed that TStV is a strain, a tobacco strain, of LBVaV.

In 2000, ICTV listed camellia yellow mottle virus and freesia leaf necrosis virus as tentative varicosaviruses. However, in 2005 ICTV dropped the two viruses from the genus *Varicosavirus* due to the lack of reliable information on their biological and virion properties. LBVaV is thus the only confirmed virus species of the genus *Varicosavirus*.

LBVaV was initially believed to have a divided genome consisting of two components of double-stranded (ds) RNA, approximately 7.0 and 6.5 kbp in size. Once LBVaV purification was established and the complete nucleotide sequence of LBVaV determined, a precise reinvestigation of LBVaV genome components showed that LBVaV is not a dsRNA virus but a single-stranded RNA virus with a bipartite genome. Negative-sense and positive-sense RNAs are separately encapsidated in the virions, with the negative-sense RNA being predominant.

Taxonomy and Classification

LBVaV particles are fragile, nonenveloped rods about 18 nm in diameter with a dominant particle length of 360 nm. Virus particles have a central canal about 3 nm in diameter and an obvious helix with a pitch of about 5 nm, resembling the inner striated nucleocapsid core of the rhabdovirus. Virus particles are very unstable *in vitro*; so the helix of particles, especially those in purified preparations, tends to loosen and come partially uncoiled, even if fixed with glutaraldehyde.

Criteria for membership in the genus are nonenveloped rod-shaped particles, a two-segmented negative-sense RNA genome, and transmission through moist soil by motile zoospores of an obligate parasitic soil-borne fungus. The fungal vector is reported to be *Olpidium brassicae*, but the taxonomy and nomenclature of the fungus needs to be reevaluated.

Genetics and Evolution

Nucleotide sequence and genome-mapping studies of LBVaV showed that the LBVaV genome consists of 12 878 nucleotides (nt) and is divided into two segments (**Figure 1**). The larger LBVaV genome segment (LBVaV RNA1) contains antisense information for a small gene and a large gene that encodes a large protein (L protein)

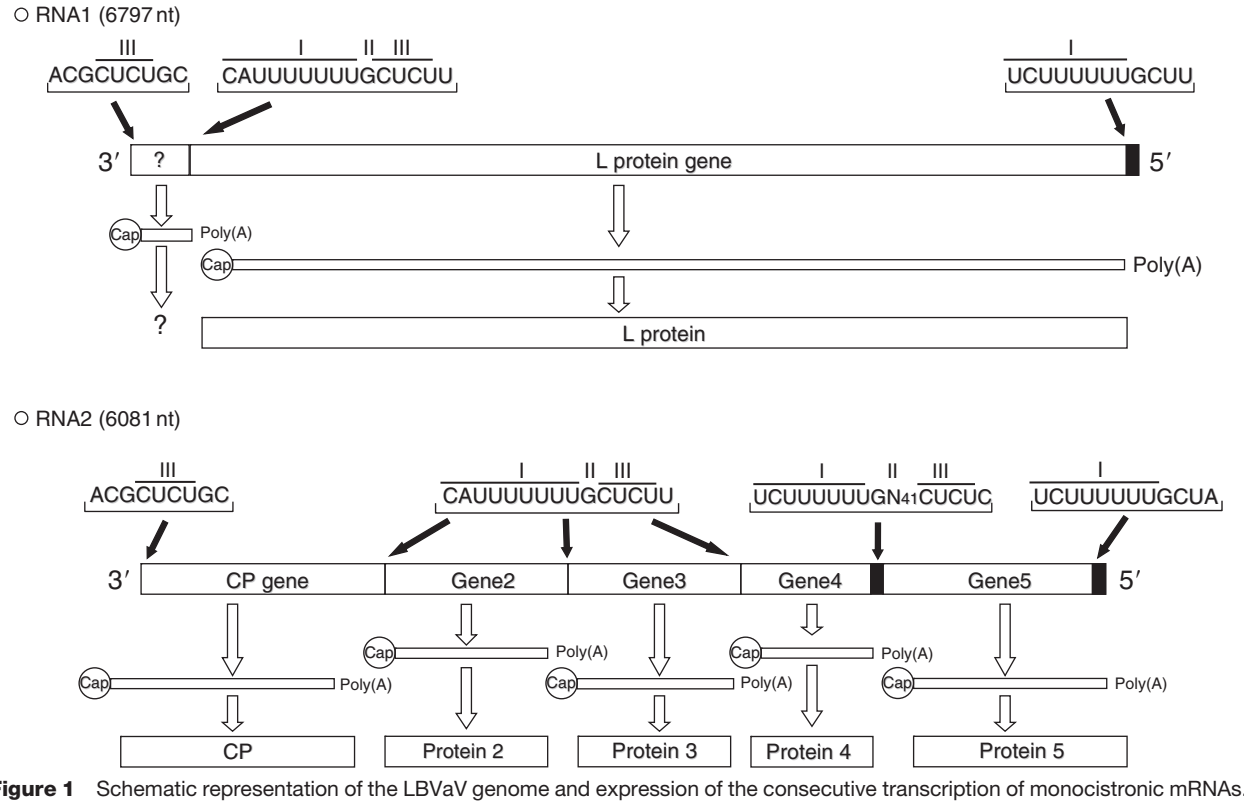

Figure 1 Schematic representation of the LBVaV genome and expression of the consecutive transcription of monocistronic mRNAs. Gene-junction regions, including a gene-end sequence (I), an intergenic sequence (II), and a gene-start sequence (III), are shown above negative-sense genomic RNAs.

of 2040 amino acids. The smaller LBVaV genome segment (LBVaV RNA2) contains antisense information for five major genes, which have coding capacities of 397, 333, 290, 164, and 368 amino acids, with the gene at the 3′ end of the LBVaV RNA2 encoding the CP. FASTA and BLAST analyses of the LBVaV CP and L protein revealed the amino acid sequence similarities to the nucleocapsid (N) proteins and the L proteins of rhabdoviruses, respectively. However, the translated sequences from the other four LBVaV genes showed no striking similarity to other known viral sequences.

Even though LBVaV is a two-segmented negative-sense RNA virus with a fragile nonenveloped rod shape, LBVaV shares several features with a rhabdovirus, which has a linear nonsegmented negative-sense RNA genome and large enveloped particles with a prominent fringe of peplomers.

L Protein Encoded on RNA1

As with other negative-sense RNA viruses, the L protein of LBVaV is positively charged and contains polymerase and RNA binding domains. Alignment of the LBVaV L protein sequence with those of several other negative-sense RNA viruses shows the conservation of functional motifs of an RNA-dependent RNA polymerase (**Figure 2**). The L protein of LBVaV contains a conserved premotif A, which presumably plays an important role in RNA template binding and positioning, and four motifs that correspond to motifs A, B, C, and D, thought to comprise the palm and finger regions of the polymerase active site in negative-sense RNA viruses. A putative ATP binding motif, $Kx_{17}GxGxG$, proposed to be involved in ATP binding associated with polyadenylation or protein kinase activity, is present at position 1643–1665, and LBVaV actually transcribes 3′ polyadenylated mRNAs.

The L protein is the only region sufficiently conserved to establish evolutionary relationships among negative-sense RNA viruses. Even though the LBVaV genome is segmented, most of the conserved motifs previously identified in the L proteins of nonsegmented negative-sense RNA viruses are conserved in the L protein of LBVaV (**Figure 2**), particularly the conserved sequence GDN in motif C, which likely constitutes the evolutionary and functional equivalent of the sequence GDD in polymerases of positive-sense RNA viruses. This is in striking contrast to the segmented genome of negative-sense RNA viruses whose polymerase has the conserved sequence SDD. Amino acids G at position 662 and W at position 671 in motif B, specific to the nonsegmented viruses, are also conserved in the L protein of LBVaV. Tetrapeptide E(F/Y)xS, located downstream from motif D, which is specifically conserved in polymerases of segmented negative-sense RNA viruses, is not found in the L protein of LBVaV.

Phylogenetic data and pair-wise amino acid sequence comparisons of the partial LBVaV L protein with those of nonsegmented negative-sense RNA viruses also prove that LBVaV is more closely related to viruses of the family

Figure 2 Comparison of L protein motifs conserved among LBVaV, eight rhabdoviruses (lettuce necrotic yellows virus (LNYV), northern cereal mosaic virus (NCMV), sonchus yellow net virus (SYNV), rice yellow stunt virus (RYSV), vesicular stomatitis Indiana virus (VSIV), rabies virus (RABV), bovine ephemeral fever virus (BEFV), and infectious hematopoietic necrosis virus (IHNV)), and tomato spotted wilt virus (TSWV) and rice stripe virus (RSV), two segmented negative-sense RNA viruses of plants. Numbers at the beginning of lines indicate the position of the first displayed amino acid. Numbers within brackets indicate the numbers of amino acids not represented in the figure. Conserved residues recognized previously for L proteins of negative-sense RNA viruses are shown in bold letters and residues characteristic of the division between nonsegmented and segmented negative-sense RNA viruses are underlined.

Rhabdoviridae than to those of the family *Bornaviridae*, *Filoviridae*, and *Paramyxoviridae*. Phylogenetic analysis of the partial L proteins between LBVaV and rhabdoviruses shows that the L protein of LBVaV clusters with viruses of the family *Rhabdoviridae*, and that the L protein of LBVaV is more distantly related to those of plant rhabdoviruses (genera *Cytorhabdovirus* and *Nucleorhabdovirus*) than they are to each other. On the other hand, the L protein of LBVaV is more closely related to those of plant rhabdoviruses than those of other rhabdoviruses (**Figure 3**).

Proteins Encoded on RNA2

The first gene at the 3′ end of genomic RNA encodes the CP which shows low but significant similarity to the N protein of rhabdoviruses. The other genes encode proteins of unknown functions, while the second and fifth encoded proteins (proteins 2 and 5) have features slightly similar to corresponding proteins of rhabdoviruses.

Gene Bank Database Homology searches using the amino acid sequence of the LBVaV CP consistently retrieve N proteins of rhabdoviruses. Phylogenetic analysis of the LBVaV CP and N proteins of rhabdoviruses shows that the LBVaV clusters with viruses of the family *Rhabdoviridae*, and that LBVaV CP is most closely related to the N protein of infectious hematopoietic necrosis virus (IHNV) a fish rhabdovirus (genus *Novirhabdovirus*), and to a lesser extent with plant rhabdoviruses. In a

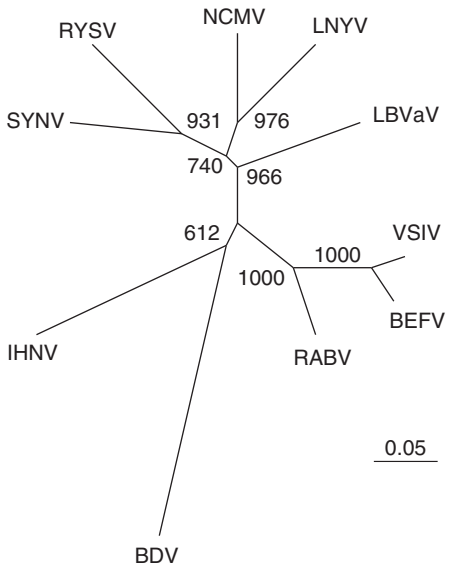

Figure 3 Computer-generated tree illustrating phylogenetic relationships between LBVaV and selected rhabdoviruses on the basis of aligned amino acid sequences of the partial L protein between premotif A and motif D. The tree is constructed using neighbor joining, and numbers at nodes are confidence values for 1000 bootstrap replicates; bootstrap values below 500 are not shown. Borna disease virus (BDV) is used as an out-group. See **Figure 2** for abbreviations of virus names.

PSI-BLAST search against the ProDom protein domain database, the carboxy-terminal part of the LBVaV CP shows similarity to two domains; one is the homologous domain among N proteins of plant rhabdoviruses and another is the homologous domain among those of fish rhabdoviruses.

The LBVaV protein 2 is encoded by the second gene that corresponds in position to a gene coding for the phosphoprotein (P protein) of rhabdoviruses, which interacts with the N protein and the L protein and constitutes the active polymerase complex. However, the 333 amino acid protein encoded by the second gene of RNA2 has no significant amino acid sequence relatedness to P proteins of rhabdoviruses. The overall structure of the LBVaV protein 2 and P proteins, assessed by amino acid composition and by relative hydropathicity distribution, is similar. Coiled-coil regions of P proteins of rhabdoviruses have been used to predict the regions for their oligomerization and interaction. Analysis using the COILS2 program predicts that the LBVaV protein 2 contains three possible coiled-coil regions at the amino-terminal (aa 29–48), central (aa 122–135), and carboxy-terminal (aa 239–253) domains that are similar in position, to those in the P protein of sonchus yellow net virus (SYNV). In site-directed mutagenesis experiments using the bacterially expressed P protein of vesicular stomatitis Indiana virus (VSIV), detailed analysis of phosphorylation sites for cellular casein kinase II in the P protein confirmed that five of ten potential phosphorylation sites of the P protein, which may regulate transcription and replication, are required to form the active polymerase complex. The LBVaV protein 2 also has ten potential phosphorylation sites, and the five essential phosphorylation sites for the P protein of VSIV are conserved in positions similar to those of the LBVaV protein 2. A predominantly basic 20-amino acid-long region near the carboxy terminus of the P protein of VSIV, which may act as a site for binding to the L protein, appears to be highly conserved in the carboxy-terminal region of the LBVaV protein 2.

The LBVaV protein 5, which corresponds in position to a gene coding for the glycoprotein (G protein) of rhabdoviruses, also has little direct relatedness to the envelope-associated glycoproteins of rhabdoviruses. The LBVaV protein 5 does not contain any canonical sites for N-linked glycosylation, and does not contain the N terminal signal peptide or carboxy-terminal hydrophobic transmembrane anchor domains, which are common among G proteins of rhabdoviruses. Conservation of cysteine residues is another common feature of G proteins of rhabdoviruses. Alignment using the Clustal W program for G proteins with plant rhabdoviruses shows that 11 cysteine residues are situated at conserved positions. In the case of LBVaV, six of ten cysteine residues are located at similar conserved positions in G proteins of plant rhabdoviruses. The LBVaV protein 5 may thus result from the degeneration of G proteins of plant

rhabdoviruses. The six cysteine residues in the LBVaV protein 5 that may play an important role in activities, such as forming the secondary structure of G proteins of plant rhabdoviruses appear to have been stringently conserved among the LBVaV protein 5 and G proteins of plant rhabdoviruses. The other five cysteine residues, however, appear to have evolved extensively to accommodate diverse host requirements and vector adaptations.

Transcription Termination/Initiation Strategy

From the LBVaV genome, capped and polyadenylated monocistronic mRNAs are transcribed. In the gene-junction regions of LBVaV, transcription termination/polyadenylation and initiation signal sequences comparable to those of rhabdoviruses especially cytorhabdoviruses are recognized (**Figure 4**) suggesting that LBVaV and rhabdoviruses may use a similar mechanism of transcription, a stop-and-start model, to differentially express individual genes from a contiguous virus genome.

Gene-junction regions of LBVaV, and likewise rhabdoviruses, are grouped into three elements: a gene-end sequence (element I) at the 3′ end of each gene on the genomic template, which is required for transcription termination/polyadenylation; a short nontranscribed intergenic sequence (element II), which is not represented in mRNAs and separates each gene; and a gene-start sequence (element III) located at the beginning of each subsequent gene, which plays an important role in transcription initiation. Gene-end sequences of rhabdoviruses consist of an AU-rich region, a cytidylate, and a poly(U) tract and the poly(U) tract is thought to be a template for the poly(A) tail of mRNA due to reiterative transcription or slippage. The gene-end sequences of LBVaV are either 3′-UAUNCAUUUUUUU-5′ (type A) or 3′-AUAAUCUUUUUU-5′ (type B), reminiscent of those observed in rhabdoviruses. When the gene-end sequence of LBVaV is type A, transcription of the next gene is initiated immediately after a single nucleotide G, while for type B, the two genes (genes 5 and L) were located at the 5′ most ends of each RNA (negative-sense) or transcription is reinitiated after a long 42 nt intergenic sequence located between genes 4 and 5, suggesting that the two variations of the gene-end sequences may influence signaling initiation of downstream mRNA synthesis as reported for VSIV in which the gene-end sequence plays an important role both in transcription termination/polyadenylation and in reinitiating transcription of downstream genes.

Figure 4 Comparison of gene-junction regions between LBVaV and selected rhabdoviruses. Gene-junction regions are separated into three elements: element I is a gene-end sequence that constitutes the poly(U) tract at the 3′ end of each gene on negative-sense genomic RNAs and plays the role of a transcription termination/polyadenylation signal; element II is a short intergenic sequence that is not transcribed during mRNA synthesis; and element III is a gene-start sequence that constitutes the initiation site for transcription of each mRNA. Bold type in viral sequences indicates consensus nucleotides, R and W indicate A/G and A/U, and (N)*x* corresponds to a variable number of nucleotides. See **Figure 2** for abbreviations of virus names.

The short nontranscribed intergenic sequence in most rhabdoviruses generally consists of a few nucleotides. Although intergenic sequences of rhabdoviruses are highly conserved in sequence and length in the genera *Vesiculovirus* and *Nucleorhabdovirus* but not in the genera *Lyssavirus*, *Ephemerovirus*, and *Cytorhabdovirus*, the first residue of the intergenic sequence is G. Site-directed mutagenesis experiments in the intergenic sequence using the infectious cDNA of VSIV indicated that the G residue is required for efficient termination of the upstream transcript. In the case of LBVaV, the intergenic sequence, except between genes 4 and 5, is highly conserved, consisting of a single nucleotide, G. Intergenic sequences of fish rhabdoviruses in the genus *Novirhabdovirus* also consist of a single nucleotide, G or A.

In contrast to most rhabdoviruses, including nucleorhabdoviruses whose gene-start sequence in gene-junction regions is 3′-UUGU-5′, the conserved gene-start sequence of LBVaV is 3′-CUCU-5′. Sequence 3′-CUCU-5′ is also conserved in gene-junction regions of lettuce necrotic yellows virus (LNYV) and northern cereal mosaic virus (NCMV) in the genus *Cytorhabdovirus*, suggesting that sequence 3′-CUCU-5′ may be important in acting as a transcription initiation signal for both LBVaV and cytorhabdoviruses, which replicate in the cytoplasm of plant cells.

Host Range and Geographic Distribution

LBVaV is extremely unstable *in vitro* making a mechanical transmission difficult, time-consuming, and inefficient. Since LBVaV inocula are frequently contaminated with MiLV and specific detection of LBVaV and MiLV has become feasible only very recently, available information on the symptomatology and experimental host range of LBVaV needs to be verified. We recently confirmed through fungal vector transmission experiment, however, that LBVaV systemically infected seven species in four families, and the infected plants including lettuce did not show any symptoms. In contrast, the experimental host range of the tobacco strain of LBVaV encompasses 41 species in nine dicotyledonous families

following mechanical inoculation and 35 plant species in 13 families after fungal vector transmission. The tobacco strain does not infect lettuce, but induces vein clearing, vein necrosis, mottling, and stunting in many *Nicotiana* species.

LBVaV is widespread in cool to temperate regions and several parts of subtropical regions in Europe, Asia, and North and South America, but the tobacco strain probably occurs only in Japan.

Transmission and Vectors

In nature, LBVaV is transmitted through motile zoospores of an obligate parasitic soil-inhabiting fungus. LBVaV is very stable in soil within long-lived, resting spores of the fungus for 20 years or more. It remains unclear whether the virus replicates inside fungal spores.

The natural vector for LBVaV is reported to be *Olpidium brassicae* (Wor.) Dang. *O. brassicae* was first found in a cabbage (*Brassica oleracea*) root in 1878 and the species name of the fungus is derived from the genus name of cabbage. Many strains of *O. brassicae* differing significantly in host specificity, morphology, and vector capacity have been recognized. In particular, a crucifer strain, which readily multiplies in the roots of crucifer plants such as cabbage and mustard, is differentiated from a noncrucifer strain that can not multiply in the roots of crucifer plants. The crucifer strain is host-specific and the noncrucifer strain highly plurivorous. Morphologically, zoosporangia and exit tubes of the crucifer strain differ slightly from those of the noncrucifer strain. The noncrucifer strain is generally a vector of MiLV and tobacco necrosis virus but the noncrucifer strain fails to transmit these viruses. Furthermore, the crucifer strain shows sexual reproductivity, although the noncrucifer strain does not reproduce sexually. Zoospores from a single-sporangium isolate of the crucifer strain do not develop a resting spore, but after mating between different mating (sexual) types, a resting spore forms. In contrast, zoospores from the noncrucifer strain develop a resting spore without mating. Based on these differences, the crucifer and noncrucifer strains have been divided into two distinct species, but this proposal has long been ignored. Recent rDNA-ITS analysis of *O. brassicae* strongly supported the notion that crucifer and noncrucifer strains are separate species rather than strains of the same *Olpidium* species, and a new species name, *O. virulentus*, has been proposed for the noncrucifer strain. The noncrucifer strain was confirmed to be a vector of LBVaV, whereas there is no reliable evidence that the crucifer strain (*O. brassicae*) is capable of transmitting LBVaV.

Glossary

Anthroponosis Virus transmitted among human hosts.
Arbovirus Virus transmitted by blood-feeding arthropods among vertebrates.
Diapause Arthropod hibernation.
Gonotrophic cycle Cycle of blood feeding and egg deposition.
Transmission Distribution of virus usually by the bite of an infectious vector.

Vector Animal (usually an arthropod) that distributes viruses among hosts.
Vector competence Ability of vector to become infected with and transmit a virus.
Vectorial capacity Mathematical measure of case distribution or the force of transmission.
Viremia The presence of viruses within the vertebrate host peripheral circulatory system.
Zoonosis Virus transmitted mainly among animal hosts with incidental transmission to humans.

Vector Transmission

This article describes how vectors (usually arthropods and especially insects) distribute or transmit viruses among vertebrate hosts. Although occasional instances of mechanical transmission by contaminated mouthparts of the feeding arthropod have been documented and nonviremic transmission among blood-feeding vectors has been demonstrated in the laboratory and occurs in nature, virus transmission generally is biological and propagative (**Figure 1**). This type of transmission demonstrates that the virus infects and multiplies within the tissues of both arthropod and vertebrate hosts before transmission can occur. Viruses transmitted by arthropods have been lumped into a loose assemblage termed 'arboviruses' that includes viruses within the families *Bunyaviridae*, *Flaviviridae*, *Rhabdoviridae*, and *Togaviridae*. Transmission rates and therefore the numbers of cases typically remain at low levels, unless there is a disruption in system balance such as a climate anomaly, virus mutation to a virulent form, or an ecological disturbance, or large-scale host movement that enables virus amplification to epidemic levels.

Horizontal Transmission

Arthropod vectors, such as mosquitoes, feed on vertebrates to obtain blood which is used as a dietary supplement to stimulate and support egg development. If the vertebrate host is circulating a sufficient quantity of virus within its peripheral blood (i.e., is viremic) and if the arthropod is susceptible to infection, then the arthropod may become infected soon after blood feeding. After the blood meal is digested and the eggs are laid, completing the gonotrophic cycle, the surviving arthropods will then seek a subsequent blood meal to initiate the maturation of the next batch of eggs. The duration of the gonotrophic cycle essentially delineates the frequency of vector–host contact and therefore the number of opportunities for transmission by an arthropod during its lifetime. Horizontal arbovirus transmission occurs after the arthropod becomes infectious and is capable of expectorating virus when it feeds to obtain the next and subsequent blood meals. All arthropods expectorate salivary secretions while blood feeding, and this provides a mechanism to deliver the virus to the host thus completing horizontal transmission. After becoming infectious, most arthropods continue transmitting virus throughout the remainder of their lifetime. West Nile virus (WNV) is an example of a virus maintained by horizontal transmission from bird to mosquito to bird.

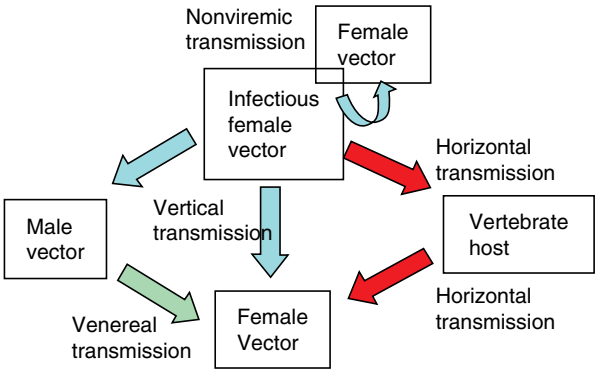

Figure 1 Types of arbovirus transmission within arthropod vectors and between arthropod vectors and vertebrate hosts. Vertical transmission can be trans-stadial, as in ticks, or transgenerational, as in mosquitoes.

Vertical Transmission

Some arboviruses acquired by the arthropod host are transmitted vertically to the next blood-feeding life stage. In ticks that feed once per life stage, transmission is trans-stadial (across life stages) from the larvae or nymphs that acquire the virus, molt, and then pass the virus to nymphs and/or adults that transmit their acquired infection to vertebrate hosts during the next blood meal. Tick-borne encephalitis virus (TBEV) is an example of a virus that is vertically maintained and transmitted within populations of the tick vectors, *Ixodes persulcatus* or *Ixodes ricinus*. In Diptera, acquisition of virus by the host-seeking female may be followed by passage of virus through the egg, larval, and pupal stages to adults in the next generation when transmission to vertebrate hosts is facilitated by infectious females. LaCrosse virus (LACV) is an example of a virus that is maintained vertically by efficient vertical transmission by its primary mosquito host, *Aedes triseriatus*, but is also transmitted horizontally to chipmunk reservoir hosts and occasionally to humans. In contrast, vertical passage of WNV occurs occasionally, but still may be important in virus amplification and persistence. In most arthropods vertical transmission is not 100% efficient, and therefore for a virus to be maintained, amplification by horizontal transmission is necessary to increase the number of infected individuals within the vector population.

Venereal Transmission

Although male mosquitoes and other arthropods may become infected vertically, they usually do not blood-feed and therefore generally are 'dead end' hosts for the viruses that infect them. However, in some instances infected males are able to transmit virus venereally to uninfected females during mating. These females may become infective and then transmit virus horizontally as well as vertically. LACV is also an example of a virus that may be transmitted venereally and then horizontally and vertically by infected females. In contrast, all male tick life stages require a blood meal for molting and therefore can become infected orally. In some instances these males, orally infected as immatures, can transmit virus venereally.

Nonviremic Transmission

When multiple vectors feed in close proximity, virus may be transmitted from infectious to uninfected arthropods without the host developing a viremia. This method of transmission initially was described for TBEV among *Ixodes* ticks that often attach near to one another on the host and require 4–5 days to blood-feed. Recently, however, nonviremic transmission has also been demonstrated for *Culicoides* flies as well as mosquitoes in laboratory experiments.

Types of Transmission Cycles

Epidemiologists have classified virus transmission cycles by the types of vertebrate hosts, with zoonoses maintained by transmission among animal hosts with occasional tangential involvement of humans, and anthroponoses maintained by direct transmission among humans (**Figure 2**).

Zoonoses

Many arboviruses are zoonoses that are maintained and amplified in transmission cycles involving one or more vectors and a variety of animal hosts. When amplification progresses to elevated levels, transmission may spill over to tangentially include domestic animals and/or humans. St. Louis encephalitis virus is an example of a zoonosis that is maintained and amplified by horizontal transmission by mosquitoes among birds, but spills over to tangentially infect humans (**Figure 2**). In this instance, birds serve as maintenance reservoir and/or amplification hosts, because they are susceptible and capable of producing viremias of sufficient titer to infect blood-feeding mosquitoes. Humans are 'dead end' hosts, because they do not produce sufficient viremias to infect additional mosquitoes. Vectors that participate in the basic zoonotic cycle are termed maintenance vectors, whereas those that carry the virus from the enzootic cycle (among animals) to domestic animals or humans are termed 'bridge' vectors. Bridge vectors may not be able to maintain transmission in the absence of more susceptible and effective maintenance vectors. Although in many zoonoses humans are 'dead end hosts', humans still become infected and may develop serious disease.

Anthroponoses

In some circumstances, humans produce a viremia sufficiently elevated to infect vectors and maintain a vector–human transmission cycle independent of animal hosts. Dengue viruses (DENVs) are examples of anthroponotic viruses maintained by human–mosquito–human transmission (**Figure 2**). Although there have been reports of horizontal enzootic and vertical transmission of DENV, these events rarely have been associated with or have led
